This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

+ *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.

+ *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.

+ *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.

+ *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at `http://books.google.com/`

EDITOR'S PREFACE TO THE SIXTH EDITION

One criticism upon most of the current text-books of human anatomy is that they are too extensive for the beginner. Much precious time is wasted by him in floundering through a mass of details which obscure the fundamental facts. And yet it is important to have these details conveniently accessible for both present and future reference. To meet this difficulty, the attempt is made in this edition to discriminate systematically in the use of sizes of type. The larger type is used for the more fundamental facts, which should be mastered first, and the smaller type for details. While it has been found difficult to apply this principle uniformly through the various sections, it is hoped that the plan, even though but imperfectly realized, will prove useful to the beginner.

In the illustrations of the bones, as heretofore, the origins of muscles are indicated by red lines, the insertions by blue lines, and the attachments of ligaments by dotted black lines.

Each of the various sections has been throughly revised, and some of them entirely rewritten. The previous section on Morphogenesis is now entitled Developmental Anatomy. It has been rewritten by Prof. R. E. Scammon, and its scope extended so as to include both prenatal and postnatal changes, thus bridging the gap between embryology and adult gross anatomy. The section on Skin and Mammary Gland has been separated from the Glands of Internal Secretion, the former being rewritten by Prof. Charles R. Stockard and the latter by Prof. J. F. Gudernatsch. The spleen, formerly included with the ductless glands, was also revised for the present edition by Dr. Gudernatsch, but has been transferred to its more appropriate position under the Lymphatic System.

Each author is alone responsible for the subject-matter of the article following his name. Care has been exercised on the part of the editor, however, to make the whole uniform, complete and systematic.

As to nomenclature, the Anglicised form of the BNA has been continued, excepting those cases where the Latin form is adopted into English (e.g., most of the muscles), and rare cases where the BNA term seems undesirable. As a rule, the Anglicised form where first used is followed by the BNA Latin term *in brackets*, except where the two are practically identical. For convenience of reference, some of the commoner synonyms of the old nomenclature are also added in parenthesis.

The fourth edition of Morris's Anatomy was the first general text-book of anatomy in English to adopt the BNA. During the past few years the merit of this system of nomenclature has become so widely recognized that it is now very generally accepted among the English-speaking nations. Lack of space forbids the enumeration of the many advantages of this system, not the least of which is the reduction of some 30,000 anatomical terms (including synonyms) to 5000. The comparatively few defects of the BNA will doubtless be remedied by revision.

In addition to the bibliographical references scattered throughout the text, a brief list is given at the close of each section. These brief lists of carefully selected references are intended merely as a guide to put the student 'on track' of the original literature.

Due credit has been given throughout the book wherever illustrations have been taken, or modified, from other works. Special acknowledgement should be made of our indebtedness to the works of Toldt, Rauber-Kopsch, Poirier and Charpy, Henle and Spalteholz.

In the present edition many new figures have been added, and in addition a large number of the older figures have been improved or replaced. For the generosity of the publishers in this connection, and for the hearty coöperation of the contributors in the revision of the various sections, the editor desires to express his deep indebtedness.

C. M. JACKSON.

INTRODUCTION

By C. M. JACKSON, M.S., M.D.

PROFESSOR OF ANATOMY, UNIVERSITY OF MINNESOTA

ANATOMY, as the term is usually employed, denotes the study of the structure of the human body. Properly, however, it has a much wider significance, including within its scope not man alone, but all animal forms, and, indeed, plant forms as well; so that, when its application is limited to man, it should be termed human anatomy. *Human anatomy*, then, is the study of the structure of the human body, and stands in contrast to, or rather in correlation with, *human physiology*, which treats of the functions of the human body, the two sciences, anatomy and physiology, including the complete study of man's organization and functional activities.

In the early history of the sciences these terms sufficed for all practical needs, but as knowledge grew, specialization of necessity resulted and new terms were from time to time introduced to designate special lines of anatomical inquiry. With the improvement of the microscope a new field of anatomy was opened up and the science of *histology* came into existence, including the portion of anatomy which deals with the minuter details of structure. So, too, the study of the development of the body gradually assumed the dignity of a more or less independent study known as *embryology*, and the study of the structural changes due to disease was included in the science of *pathology;* so that the term anatomy is sometimes limited to the study of the macroscopic structure of normal adult organisms.

It is clear, however, that the lines of separation between anatomy, histology, embryology, and pathology are largely arbitrary. Microscopic anatomy necessarily grades off into macroscopic anatomy; the development of an organism is a progressive process and the later embryonic or fetal stages shade gradually into the adult; and structural anomalies lead insensibly from the normal to the pathological domains. Furthermore it is found that in its individual development the organism passes through stages corresponding to those of its ancestry in evolution; in other words, ontogeny repeats phylogeny. A comprehensive study of anatomy must therefore include more or less of the other sciences. Since an appreciation of the significance of structural details can be obtained only by combining the studies of anatomy (including histology) and embryology, and since, further, much light may be thrown on the significance of embryological stages by comparative studies, anatomy, embryology, and comparative anatomy form a combination of sciences by which the structure of an organism, the significance of that structure, and the laws which determine it are elucidated. For this combination it is convenient to have a single term, *morphology*, a word meaning literally the science of form.

In morphological comparisons the term *homology* denotes similarity of structure, due to a common origin in the evolution of organs or parts; while *analogy* denotes merely physiological correspondence in function. Thus the arm of man and the wing of a bird are homologous, but not analogous, structures; on the other hand, the wing of a bird and the wing of an insect are analogous, but not homologous. *Serial homology* refers to corresponding parts in successive segments of the body.

Nomenclature.—Formerly there was much confusion in the anatomical nomenclature, due to the multiplicity of names and the lack of uniformity in using them. Various names were applied to the same organs and great diversity of usage prevailed, not only between various countries, but also even among authors of the same country. Recently, however, a great improvement has been made by the general adoption of an international system of anatomical nomenclature. This system was first adopted by the German Anatomical Society at a meeting in Basel, in 1895, and is hence called the Basel Nomina Anatomica, or briefly, the BNA. The BNA provides each term in Latin form, which is especially desirable for international usage. Each nation, however, is expected to translate the terms into its own language, wherever it is deemed preferable for

everyday usage. Thus in the present work the Anglicised form of the BNA is generally used. Where not identical, however, the Latin form is added once for each term in a place convenient for reference, and is designated by enclosure in brackets [ ]. Where necessary the older terms have also been added as synonyms.

The Commission by whom the BNA was prepared included eminent anatomists representing various European nations. The work of the Commission was very thorough and careful, and extended through a period of six years. Among the guiding principles in the difficult task of selecting the most suitable terms were the following: (1) Each part should have one name only. (2) The names should be as short and simple as possible. (3) Related structures should have similar names. (4) Adjectives should be in opposing pairs. A few exceptions were found necessary, however.

On account of its obvious merits, the BNA system has been generally adopted throughout the civilized world, and the results are very satisfactory. Comparatively few new terms have been thereby introduced, over 4000 of the 4500 names in the BNA corresponding almost exactly to older terms already in use by the English-speaking nations. Certain minor defects have been criticized; but these are outweighed by the advantages of this uniform system.

Abbreviations.—Certain frequently used words in the BNA are abbreviated as follows: a., arteria (plural, aa., arteriæ); b., bursa; g., ganglion; gl., glandula; lig., ligamentum (plural, ligg., ligamenta); m., musculus (plural, mm., musculi); n., nervus (plural, nn., nervi); oss., ossis (or ossium); proc., processus; r., ramus (plural, rr., rami); v., vena (plural, vv., venæ).

Terms of position and direction.—The exact meaning of certain fundamental terms used in anatomical description must be clearly understood and kept in mind. In defining these terms, it is supposed that the human body is in an upright position, with arms at the sides and palms to the front.

The three **fundamental planes** of the body are the sagittal, the transverse and the frontal. The vertical plane through the longitudinal axis of the trunk, dividing the body into right and left halves, is the *median* or *midsagittal* plane; and any plane parallel to this is a *sagittal* plane. Any vertical plane at right angles to a sagittal plane, and dividing the body into front and rear portions is a *frontal* (or coronal) plane. A plane across the body at right angles to sagittal and coronal planes is a *transverse* or *horizontal* plane.

Terms pertaining to the front of the body are *anterior* or *ventral;* to the rear, *posterior* or *dorsal;* upper is designated as *superior* or *cranial;* and lower as *inferior* or *caudal.*

The term *medial* means nearer the midsagittal plane, and *lateral*, further from that plane. These terms should be carefully distinguished from internal (inner) and external (outer), which were formerly synonymous with them. *Internal*, as now used (BNA), means deeper, i. e., nearer the central axis of the body or part; while *external* refers to structures more superficial in position. *Proximal*, in describing a limb, refers to position nearer the trunk; while *distal* refers to a more peripheral position.

Adverbial forms are also employed, e. g., anteriorly or ventrally (forward, before); posteriorly or dorsally (backward, behind); superiorly or cranially (upward, above); and inferiorly or caudally (downward, below).

It should also be noted that the terms ventral, dorsal, cranial and caudal are independent of the body posture, and therefore apply equally well to corresponding surfaces of vertebrates in general with horizontal body axis. On this account these terms are preferable, and will doubtless ultimately supplant the terms anterior, posterior, superior and inferior.

The discrimination in the use of several similar terms of the BNA should also receive attention. Thus *medianus* (median) refers to the median plane. *Medialis* (medial) means nearer the median plane and is opposed to lateral, as above stated. *Medius* (middle) is used to designate a position between anterior and posterior, or between internal and external. Between medialis and lateralis, however, the term *intermedius* is used. Finally, *transversalis* means transverse to the body axis; *transversus*, transverse to an organ or part; and *transversarius*, pertaining to some other structure which is transverse.

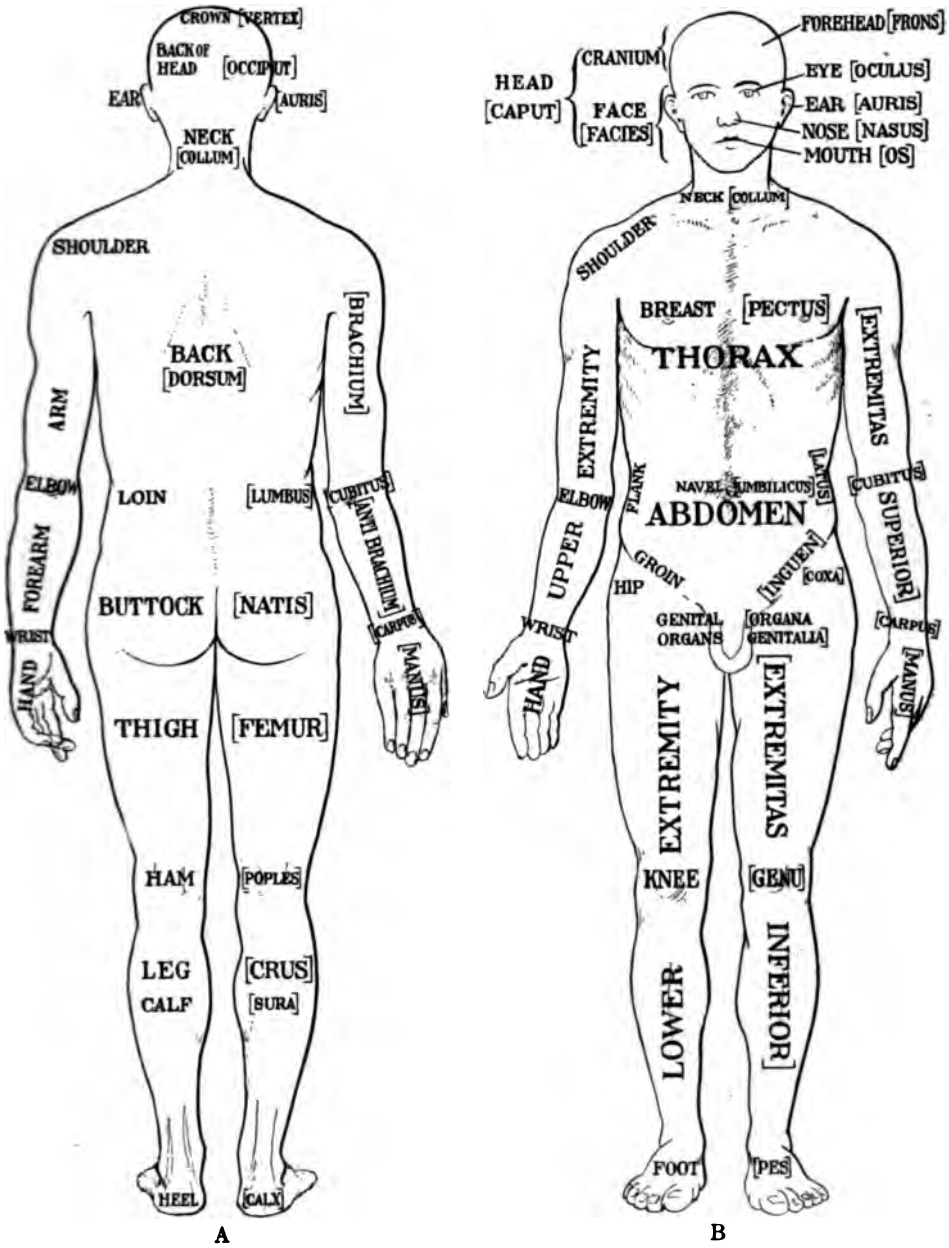
Parts of the body.—The primary divisions of the human body (fig. 1) are the head, neck, trunk and extremities. The *head* [caput] includes *cranium* and *face* [facies]. The *neck* [collum] connects head and trunk. The *trunk* [truncus] includes *thorax, abdomen*, and *pelvis*. The *upper extremity* [extremitas superior] includes *arm* [brachium], *forearm* [antibrachium], and *hand* [manus]. The *lower extremity* [extremitas inferior] includes *thigh* [femur], *leg* [crus], and *foot* [pes].

Each of the parts mentioned has further subdivisions, as indicated in fig. 1. The cranium includes: *crown* [vertex]; *back* of the head [occiput]; *frontal* region [sinciput], including *forehead* [frons]; *temples* [tempora]; *ears* [aures], including *auricles* [auriculæ].

The face includes the regions of the *eye* [oculus], *nose* [nasus], and *mouth* [os], the subdivisions of which will be given later under the appropriate sections.

The thorax includes: *breast* [pectus]; *mammary gland* [mamma]; and *thoracic cavity* [cavum thoracis]. The *back* [dorsum] includes the vertebral column [columna vertebralis]. The abdomen includes: *navel* [umbilicus]; *flank* [latus]; *groin* [inguen]; *loin* [lumbus]; and the *abdominal cavity* [cavum abdominis]. The

FIG. 1.—PARTS OF THE HUMAN BODY. A, Posterior view. B, Anterior view.



pelvis includes: *pelvic cavity* [cavum pelvis]; *genital organs* [organa genitalia], *buttocks* [nates], separated by a cleft [crena ani] at the *anus*. The *hip* [coxa] connects the pelvis with lower extremity.

In the lower extremity, the thigh is joined to the leg by the *knee* [genu]. The foot includes: *heel* [calx]; *sole* [planta]; *instep* [tarsus]; *metatarsus*; and five *toes* [digiti I–V], including the *great toe* [hallux] and *little toe* [digitus minimus].

The upper extremity is joined to the thorax by the *shoulder*. The arm is joined to the forearm at the *elbow* [cubitus]. The hand includes: *wrist* [carpus]; *metacarpus*, with *palm* [vola or palma] and *back* [dorsum manus]. The five *fingers* [digiti I–V] include: *thumb* [pollex], *index* finger [index]; *middle* finger [digitus medius] *ring* finger [digitus annularis] and *little* finger [digitus minimus].

Organ-systems.—Each of the various parts of the body above outlined is composed of various *organs*, and the groups of related organs make up *organ-systems*.

The various organ-systems are treated as special branches of descriptive anatomy. The study of the *bones* is called *osteology;* of the *ligaments* and *joints*, *syndesmology* (or arthrology); of the *vessels*, *angiology;* of the *muscles*, *myology;* of the *nervous system*, *neurology;* and of the *viscera*, *splanchnology*. Further subdivisions are also made. The viscera, for example, include the *digestive* tract, *respiratory* tract, *urogenital* tract, etc.

Tissues and cells.—The body, as above stated, has various parts, each of which may be subdivided into its component systems and organs. A further analysis reveals a continued series of structural units of gradually decreasing complexity. Thus each organ is found to consist of a number of *tissues* (epithelial, connective, muscular or nervous). Finally, each tissue is composed of a group of similar units called *cells* which are the ultimate structural units of the body. The body may therefore be regarded as composed of myriads of cell units, organized into units of gradually increasing complexity, very much as a social community is composed of individuals organized into trades, municipalities, etc.

Most of the individual tissues can be recognized by their gross appearance. In fact, the principal tissues were first demonstrated by Bichat through skilful dissection, maceration, etc., and without the aid of the microscope. The cellular structure of the tissues was later discovered by Schwann in 1839.

Each cell is composed of a material called *protoplasm*, a viscid substance variable in appearance and exceedingly complex in chemical composition. It readily breaks down into simpler chemical compounds, whereby energy (chiefly in the form of heat and mechanical energy) is liberated. It has also the power of absorbing nutritive material to build up and replace what was lost. Its decomposition results from stimuli of various kinds, and hence it is said to be irritable. The mechanical energy which it liberates is manifested by its contractility, especially in the muscle cells. It excretes the waste products produced by its decomposition. Each cell has the power, under favorable conditions, of reproducing itself by division. Protoplasm presents, in short, all the forms of activity manifested by the body as a whole; and indeed, the activities of the body are the sum of the activities of its constituent cells.

In the protoplasm of each cell is a specially differentiated portion, the *nucleus*. The nucleus plays an important part in regulating the activities of the *cytoplasm*, the general protoplasm of the cell body. The nucleus differs from the cytoplasm both structurally and chemically, and contains a very important substance, *chromatin*, which during cell division is aggregated into a definite number of masses called *chromosomes*. Further details concerning the cells and tissues may be found in the text-books of cytology and histology.

In earlier days human anatomy was almost entirely a descriptive science, but little attention being paid to the significance of structure, except in so far as it could be correlated with physiological phenomena as they were at the time understood. In recent years attention has been largely paid to the morphology of the human body and much valuable information as to the meaning of the structure and relations of the various organs has resulted. Since the form and structure of the body are the final result of a series of complicated developmental changes, the science of embryology has greatly contributed to our present knowledge of human morphology, and, accordingly, an account of some of the more important phases of morphogenesis and developmental anatomy will form a fitting introduction to the study of the adult.

References.—*General:* For looking up the literature upon any anatomical topic, the best guide in general is the Jahresbericht über die Fortschritte der Anatomie und Entwicklungsgeschichte, which contains classified titles and brief abstracts of the more important papers in gross anatomy, histology and embryology. Other useful aids are the Index Medicus and the catalogue of the Surgeon General's Library of the War Dep't. (Washington, D. C.). The latter two contain titles only, but cover the whole field of medicine. The Concilium Bibliographicum also provides a convenient card-index system of references for the biological sciences, including Anatomy. For *nomenclature:* His, Archiv f. Anat., 1895 (BNA system); Barker, Anatomical Nomenclature; Eycleshymer, Anatomical Names. *Cells and tissues:* Wilson, The Cell; Hertwig, Zelle und Gewebe (also English transl.); Schaefer, Microscopic Anatomy (in Quain's Anatomy, 11th ed.); Heidenhain, Plasma und Zelle; Kölliker, Gewebelehre; Prenant, Bouin et Maillard, Traité d'Histologie.

SECTION I

DEVELOPMENTAL ANATOMY

REWRITTEN FOR THE SIXTH EDITION

BY RICHARD E. SCAMMON, PH.D.

PROFESSOR OF ANATOMY, UNIVERSITY OF MINNESOTA

THE life history of man, in common with most higher organisms, is characterized by continuous change and presents a cycle in which may be recognized the succeeding phases of growth and differentiation, maturity, and old age or senescence. In man nearly one-third of the traditional span of life is required for the body to reach its full size and differentiation. This portion of the human life cycle may be called the developmental period, and the study of the structure of the body and its changes in this time may be termed developmental anatomy.

Divisions of the developmental period.—The developmental period is divided by the incident of birth into prenatal and postnatal epochs and in these a number of more or less arbitrarily defined subdivisions may be recognized. The divisions of the developmental period are shown on the following table. In this scheme puberty is regarded only as a transition point between later childhood and adolescence. The length of the developmental period and of its several subdivisions varies greatly with sex, race, environment, and physical constitution. A distinction is often drawn between the anatomic or physiologic age of the individual, as indicated by the degree of physical development of the body, and the calendar or chronologic age. As females pass through most of the transitions of the developmental period a little earlier than do males the physiologic age of girls is usually somewhat greater than that of boys of the same calendar age.

DIVISIONS OF THE DEVELOPMENTAL PERIOD IN MAN

Prenatal life

Period of the ovum.
From fertilization to the close of the second week of prenatal life.

Period of the embryo.
From the close of the second week to the close of the second (lunar) month.

Period of the fetus.
From the close of the second (lunar) month to birth at 10 lunar months.

Birth

Postnatal life

Period of the newborn (Neonatal period).
From birth to the close of the second (postnatal) week.

Infancy.
From 2 weeks to the close of the first year or until the habitual assumption of the erect posture (usually in the thirteenth or fourteenth month).

Childhood

Early childhood (Milk-tooth period).
From 1 to 6 years.

Middle childhood.
From 6 to 9 or 10 years.

Later childhood (Prepuberal period.
From 9 or 10 years to 12–15 years in females and 13–16 years in males.

Puberty
Fourteenth year in females. Sixteenth year in males. (According to American data.)

Adolescence.
From puberty to the last years of the second decade in females and to the first years of the third decade in males.

Growth and differentiation.—The changes which characterize the developmental period do not take place at the same time or at equal rates in all regions of the body, for each organ and part has its own peculiar life cycle. In a few

organs, such as the mesonephros of the embryo, this cycle is very short. Other organs persist during childhood and then decline, while the great majority continue, with varying degrees of change, throughout postnatal life.

The characteristic life cycle of the various organs depends upon the changes in the structural units which compose them and, in the last analysis, upon the growth and differentiation of their constituent cells. Each cell has a definite life cycle, an early period of rapid and vigorous changes, later periods of differentiation and maturity, followed by stages of degeneration and death. This cycle of cell changes is termed *cytomorphosis*. The length of life cycle of the various types of cells in the body differs greatly, some of the blood cells living probably a month or less while certain brain cells may survive throughout postnatal life. The growth of cells may take place either by the enlargement (hypertrophy) of individual cells or by the multiplication (hyperplasia) of cells by mitosis. Cell division is necessary for continued cell growth for otherwise the cell would soon reach a size where its surface would be inadequate (for nutritive, respiratory and excretory purposes) to its mass. In general, however, cell division is most active in the early embryonic periods, during which the cells remain small. Later, cell division diminishes or ceases, and growth is due chiefly to the enlargement of cells already present. The growth of the structural units of organs also follows this general rule, the production of new units being confined mainly to fetal and early postnatal life.

While the functional and structural differentiation of cells and structural units may take place during the period of their rapid multiplication these processes are usually partially disassociated and the phase of active differentiation comes some time after the period of most active growth.

THE EARLY DEVELOPMENT OF THE EMBRYO

The germ-cells and fertilization.—The period of development in man, as in the great majority of multicellular animals, is inaugurated by the process of fertilization which consists of the union of the male germ-cell or spermatozoon with the female germ-cell or ovum.

The ovum and spermatozoon are differentiated, by the process of maturation, from certain more primitive germ-cells set aside from the general body or somatic cells at an early period in development. In maturation both the ovum and spermatozoon undergo profound nuclear changes and each becomes highly specialized in form and structure for its part in the fertilization process.

The ripe spermatozoon or sperm is a slender lance-like structure 0.05 or 0.06 mm. long (fig. 3).

The ripe human ovum or egg-cell is a spheroidal body whose greatest diameter is approximately 0.1 mm. (fig. 2). It contains a nucleus about 0.02 mm. in diameter which is generally slightly eccentric in position. Suspended in the protoplasm of the cell-body are numerous droplets and granules which are presumably reserve food substances. The ovum is bounded by a delicate vitelline membrane.

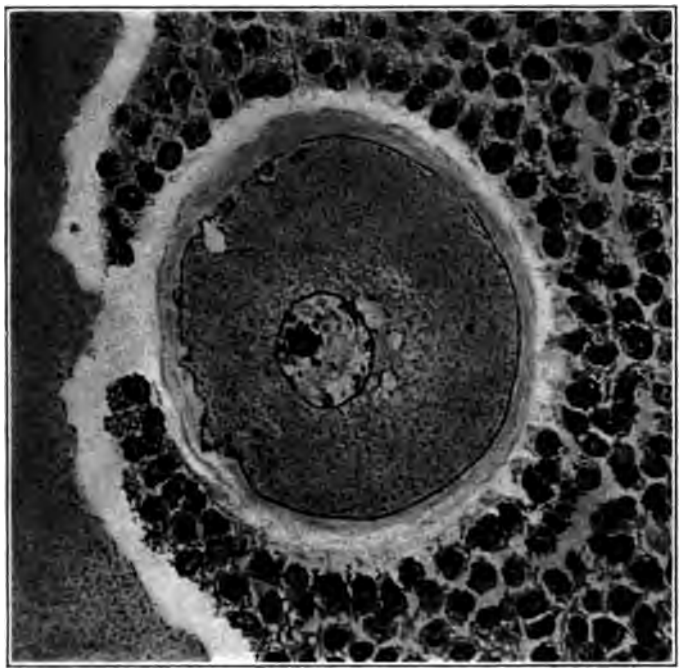
Fertilization has not been observed in man but it has been studied in detail in several mammals and it is most probable that the process is essentially the same in all higher forms. After escaping from the ovary through the rupture of the Graafian follicle the ovum enters the ostium of the uterine tube and passes down the lumen. The union of the ovum with the spermatozoon probably takes place in most cases during this process.

Segmentation of the ovum.—The fertilized ovum is converted into a solid ball of much smaller cells by a series of cell-divisions. This process is known as segmentation and the mass of cells resulting from it is called the *morula*. Like fertilization, segmentation has not been observed in man and our concepts of the process in the human species are based upon observations on the ova of lower animals. It is probable that the first segmentation divisions are equal but that the later ones are quite irregular. The morula which results from them is a solid body at first but an eccentrically placed cavity soon appears within it and the structure is differentiated into an outer shell, the *trophoblast*, and a cluster of cells termed the *inner cell-mass*. The inner cell-mass is broadly attached to the inner surface of the trophoblast and the cavity between the two is filled with fluid and bridged by delicate cellular strands, the *magma reticulare*.

It is probable that after fertilization approximately ten days are required for the ovum to reach this stage of development. During this period the ovum has left the uterine tube and has come to rest on the inner surface of the uterus. The uterine epithelium in contact with the ovum is destroyed, presumably

through the activity of the cells of the trophoblast, and the ovum sinks into the uterine mucosa and is inclosed by it. Until this implantation takes place the ovum is an independent organism dependent upon its own scanty reserve food supply for nourishment. Consequently it grows little if any during this period. With implantation, however, the ovum becomes, in a fashion, a parasite upon the maternal organism from which it derives its nourishment throughout

FIG. 2.—MATURE OVUM, WITH FOLLICULAR CELLS, OF A WOMAN 36 YEARS OLD. (After Thompson.) ×500.



the remainder of the fetal period. With the establishment of this relation the ovum enters on a period of extremely rapid growth.

Formation of the embryonic disk.—Two spaces now appear in the inner cell-mass, an upper one, the amniotic cavity and a lower one, the yolk-sac cavity. These are separated by a plate of cells, the *embryonic disk*. At the same time a distinct layer of cells is differentiated on the outer surface of the cell-mass. This

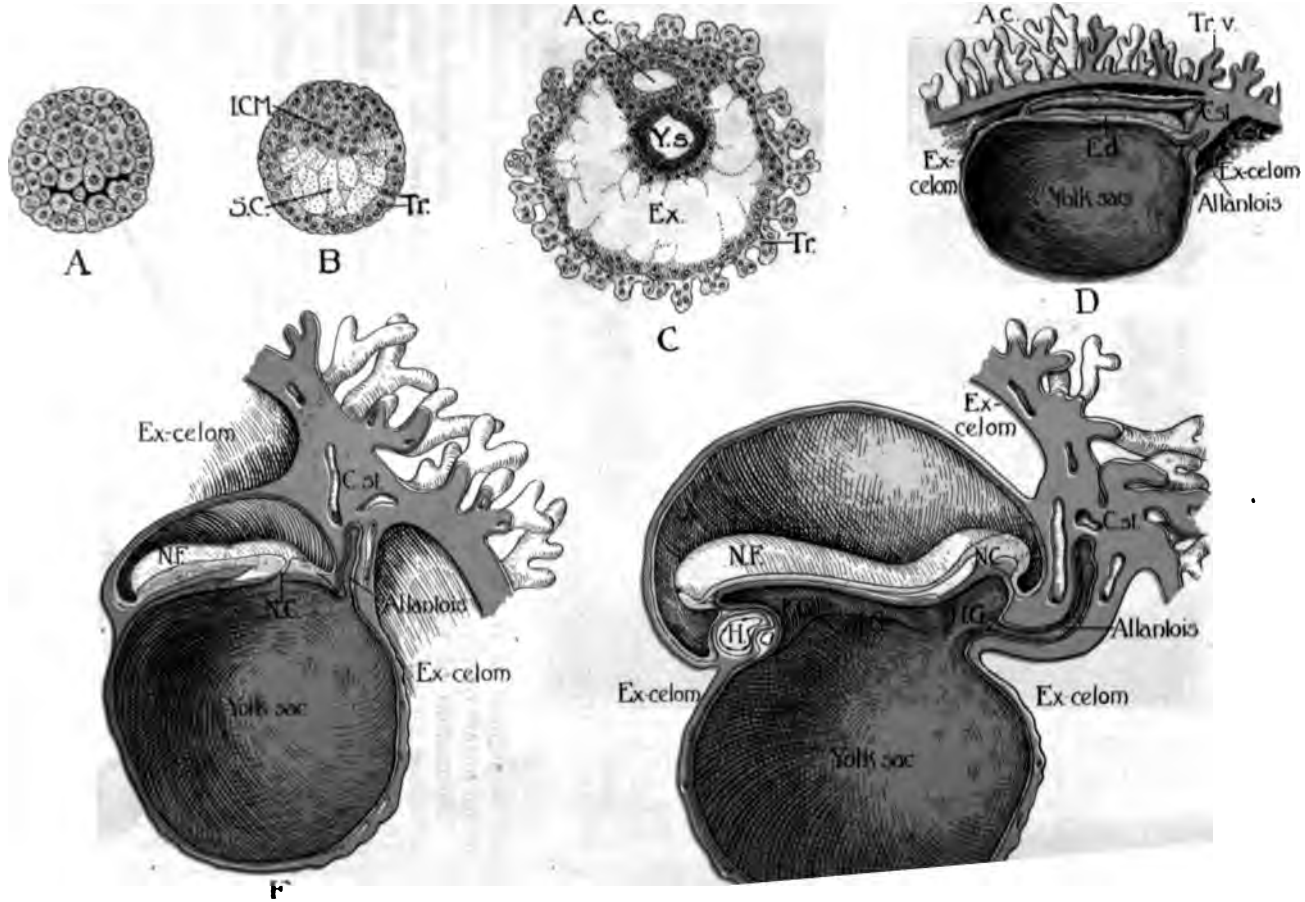
FIG. 3.—MATURE SPERMATOZOA.

A, frontal view showing broad surface of the head: B, anterior portion in side view. (After Broman.) ×2500.

layer is the extraembryonic mesoderm. It is probably formed in part from the cells of the inner cell-mass and the trophoblast and in part from the magma reticulare. The extraembryonic mesoderm forms a complete lining about the original cavity of the morula and this space is now termed the *extraembryonic celom*. As the extraembryonic celom is established the magma reticulare disappears and the connection between the inner cell-mass and the trophoblast is reduced to a short bridge of extraembryonic mesoderm, the connecting stalk (fig. 4).

FIG. 4.—A SERIES OF DIAGRAMS ILLUSTRATING THE LATER CHANGES IN THE OVUM AND THE FORMATION OF THE EMBRYO. (Based on the figures of Broman, Brödel, Dandy, Eternod, Lewis, Miller and Streete.)

A, morula (hypothetical). B, differentiation of the inner cell-mass and trophoblast (hypothetical). C, formation of the amniotic cavity, yolk-sac and extraembryonic celom. D, formation of the embryonic disk. E and F, formation of the archenteron and neural canal. A.c., amniotic cavity. C.st., connecting stalk. E.d., embryonic disk. Ex., extraembryonic celom. F.G., foregut. H., heart. H.G., hindgut. I.C.M., inner cell-mass. N.C., neurenteric canal. N.F., neural folds. S.C., segmentation-cavity. Tr., trophoblast. Tr.v., trophoblastic villi. Y.s., yolk-sac.

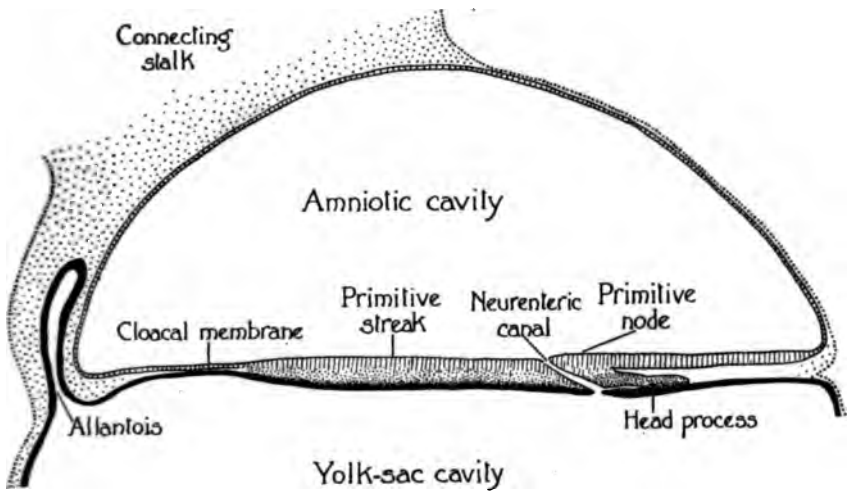


Our interest is centered in the embryonic disk, for the embryo is entirely a product of this structure: the remainder of the ovum gives rise to the supporting or nourishing structures for the developing embryo or else disappears comparatively early in prenatal life.

The embryonic disk in embryos of the third week is an oval plate having a maximum diameter of about 0.2 mm. It consists of three sheets of cells called the germ layers. The upper layer or ectoderm forms the floor of the amniotic cavity and becomes continuous with the walls of the amnion at the margins of the embryonic disk. The lower layer or entoderm forms the roof of the yolk-sac and is continued as the walls of this structure at the periphery of the embryonic disk. The middle layer or mesoderm forms an incomplete plate between the ectoderm and entoderm. At the margins of the embryonic disk it becomes continuous with the extraembryonic mesoderm which covers the outer surface of the inner cell-mass.

The subsequent history of the embryo is essentially that of the differentiation and the disposition of the germ-layers. Their contributions to the adult body are as follows:

FIG. 5.—DIAGRAM OF A LONGITUDINAL SECTION THROUGH THE LONG AXIS OF THE EMBRYONIC DISK AT THE TIME OF FORMATION OF THE PRIMITIVE STREAK AND NEURENTERIC CANAL. (Based in part on the figures of Ingalls and Streeter.)



From the ectoderm are formed:

The central and peripheral nervous system, the epithelial internal ear, the lens, iris and retina of the eye. The epithelial portion of the skin and its appendages.

The lining of the buccal, nasal, and a part of the pharyngeal cavities; the enamel of the teeth; the salivary glands.

The lining of the anal canal; the lining of the vestibule and a portion of the urethra in the male, with associated glands.

The anterior lobe of the hypophysis cerebri; the pharyngeal hypophysis. The paraganglia.

From the entoderm are formed:

The lining epithelium of the digestive tract, with the exception of the mouth, a part of the pharynx, and the anal canal; the parenchyma of the digestive glands, pancreas and liver. The lining of the larynx, trachea, bronchi and lungs.

The lining of a portion of the bladder; the lining of the female urethra and a part of the male urethra, with associated glands.

The parenchyma of the thyroid and parathyroid glands; the reticulum and the thymic corpuscles of the thymus.

From the mesoderm are formed:

The skeletal and muscular structures and the connective tissues of the body.

The vascular system; the lymphoid and sanguifactive organs.

The serous membranes.

The genital glands and their ducts and accessory structures. The kidneys, ureters and the greater part of the bladder.

The dentine and cementum of the teeth.

The cortex of the suprarenal glands.

Early changes in the embryonic disk.—The first indications of the establishment of the embryo on the germinal disk appear early in the third week. At this

time the ectoderm and entoderm in the posterior part of the longitudinal axis of the disk fuse forming a band of cells known as the primitive streak. The primitive streak is indented by a dorsal primitive groove (fig. 6). It terminates anteriorly in an enlargement, the primitive node, and from the node a mass of cells, the head-process, extends forward in the midline, fusing below with the entoderm of the yolk-sac in this region. A narrow channel, the neurenteric canal, pierces the primitive node and connects the amniotic cavity with the yolk-sac cavity. The neurenteric canal is continuous with a cleft in the head-process termed the head-process canal (fig. 5). As these changes take place on the germinal disk a small tubular outgrowth, the allantois, arises from the posterior end of the roof of the yolk-sac and grows upward, behind the amnion, into the connecting-stalk.

The primitive groove, the primitive streak, the primitive node, neurenteric canal, and head-process are ephemeral structures which may be regarded as representing a highly modified process of gastrulation in the human embryo. The primitive streak and node and the head-process join the mesoderm laterally and presumably contribute cells to this germ-layer. The head-process also gives rise to a longitudinal rod of cells, the notochord, which forms the median

FIG. 6.—DORSAL VIEW OF THE EMBRYONIC DISK AND YOLK-SAC OF AN EMBRYO OF THE EARLY PART OF THE THIRD WEEK. (After Streeter.)

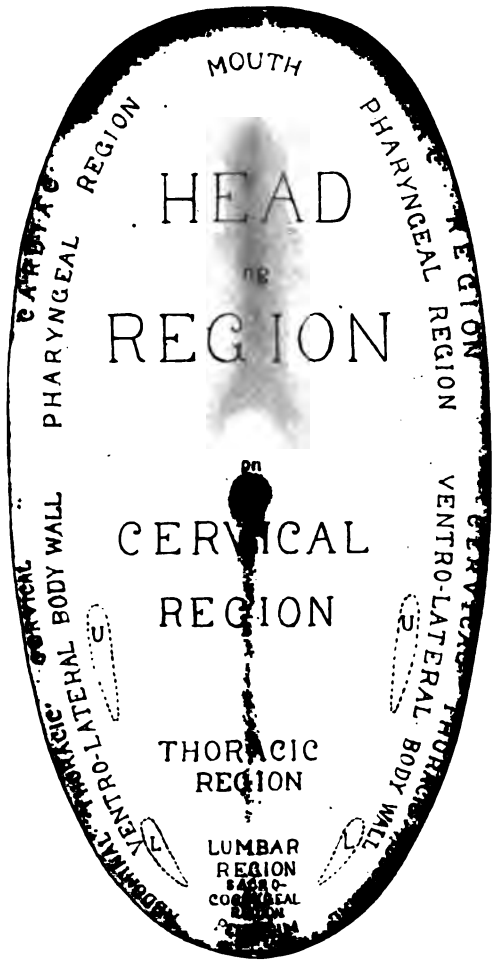
longitudinal axis of the embryo and is subsequently associated with the skeleton; possibly its ventral part is incorporated in the entoderm of the yolk-sac. With this distribution of its material the head-process disappears as a separate structure. The primitive streak becomes relatively shorter with the growth of the embryo anterior to it and the consequent migration backward of the primitive node. After the third week it is no longer recognizable. The neurenteric canal is normally obliterated in the third week.

The topography of the embryonic disk.—Although only slight signs of differentiation are visible on the surface of the embryonic disk in the third week it is possible to map out upon it more or less definite areas corresponding to all of the various regions of the future body, as shown in fig. 7. Beginning anteriorly, the head region is relatively enormous in size, occupying the entire area in front of the primitive node and forming about half of the entire disk. The cervical, thoracic, lumbar, and sacrococcygeal regions appear successively smaller, approaching the posterior end ('tail-bud') of the primitive streak. It is also a striking fact that the future dorsal region of the body wall, corresponding to the central portion of the disk, along each side of the midline, is now larger than the ventrolateral regions, which occupy a relatively narrow zone around the periphery of the disk.

Early changes in the germ layers.—The definitive embryo is formed by the rapid growth of the dorsal region of the embryonic disk and by a series of folds and cleavages of the germ-layers of this area. The **ectoderm** plays a most active part

in these early transformations. Shortly after the primitive streak is established, the ectoderm along the midline of the embryonic disk is thickened into a neural plate which extends from the primitive node to the anterior end of the disk. The lateral margins of the plate grow rapidly and rise from the surface of the disk as a pair of longitudinal neural folds or ridges which bound a shallow neural groove (figs. 8 and 12*A*). The neural plate is converted into the *neural tube* by the further growth of the neural ridges which fold over the neural groove and fuse in the midline. This process begins in the future cervical region and extends forward and backward from this level (fig. 12*A*). The extreme anterior and

FIG. 7.—TOPOGRAPHY OF THE EMBRYONIC DISK. Diagram of relations at the length of about 1 mm. ng, neural groove. pn, primitive node. pp, primitive pit. U, upper limb. L, lower limb.



posterior ends of the tube remain open for a time as the anterior and posterior neuropores. With their subsequent closure the walls of the tube are completed and its cavity is entirely separated from the amniotic cavity. The neural tube gives rise to the brain, spinal cord, and retinæ and optic nerves. Its further history is considered in connection with the nervous system.

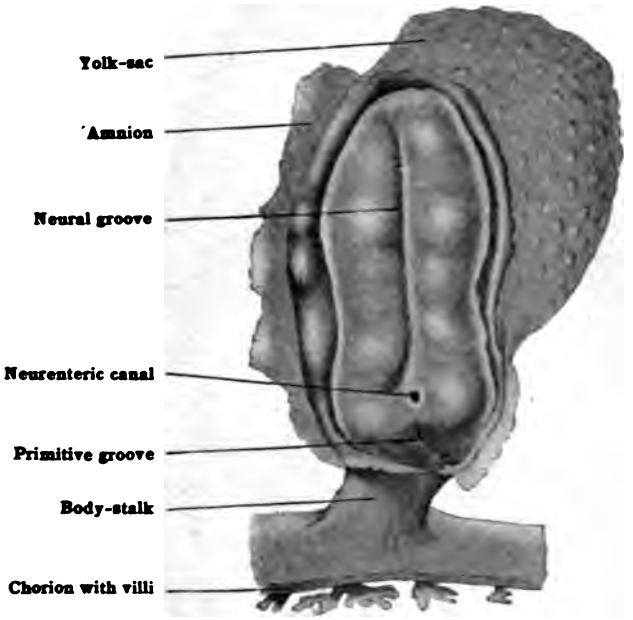
The ectoderm which covers the periphery of the embryonic disk is carried over the dorsal surface of the neural tube with the infolding of the neural ridges. It forms the external covering of the embryo.

The entoderm.—As the neural plate is formed from the ectoderm on the upper surface of the embryonic disk, the entoderm lying below this region is folded into the primitive digestive tube or *archenteron*. In embryos of the latter part of the third week three divisions, the *foregut*, the *hindgut*, and the *midgut* may

be recognized in this structure (figs. 4*E*, 4*F*). The midgut is a shallow groove still broadly connected with the yolk-sac, the foregut is a pocket-like projection from the midgut extending forward under the anterior part of the neural plate, and the hindgut is a similar but shorter projection which extends into the caudal region of the developing embryo.

With the further growth of the archenteron the foregut and hindgut become considerably elongated and the connection of the midgut with the yolk-sac is reduced to a short, wide yolk-stalk. In this process the upper part of the posterior wall of the yolk-sac is incorporated in the floor of the hindgut, and the allantois now takes origin from this part of the archenteron instead of the yolk-sac. The later history of the entoderm will be considered in connection with the development of the digestive and respiratory tracts.

FIG. 8.—HUMAN EMBRYO 1.54 MM. LONG. Viewed from above, the roof of the amniotic cavity having been removed. (Minot, after Graf Spee.)



The mesoderm.—The mesoderm of the human embryo appears to have a dual origin being formed primarily from the extraembryonic mesoderm of the inner cell-mass and secondarily from the primitive streak, primitive node, and head-process. After the formation of the notochord the mesoderm takes the form of a pair of plates which lie on either side of the longitudinal embryonic axis and which are continuous laterally with the extraembryonic mesoderm covering the amnion and yolk-sac. Behind the primitive node these plates fuse with the primitive streak across the midline of the embryonic disk but anterior to the node they are separated by a medial space which contains the notochord (figs. 9, 10.)

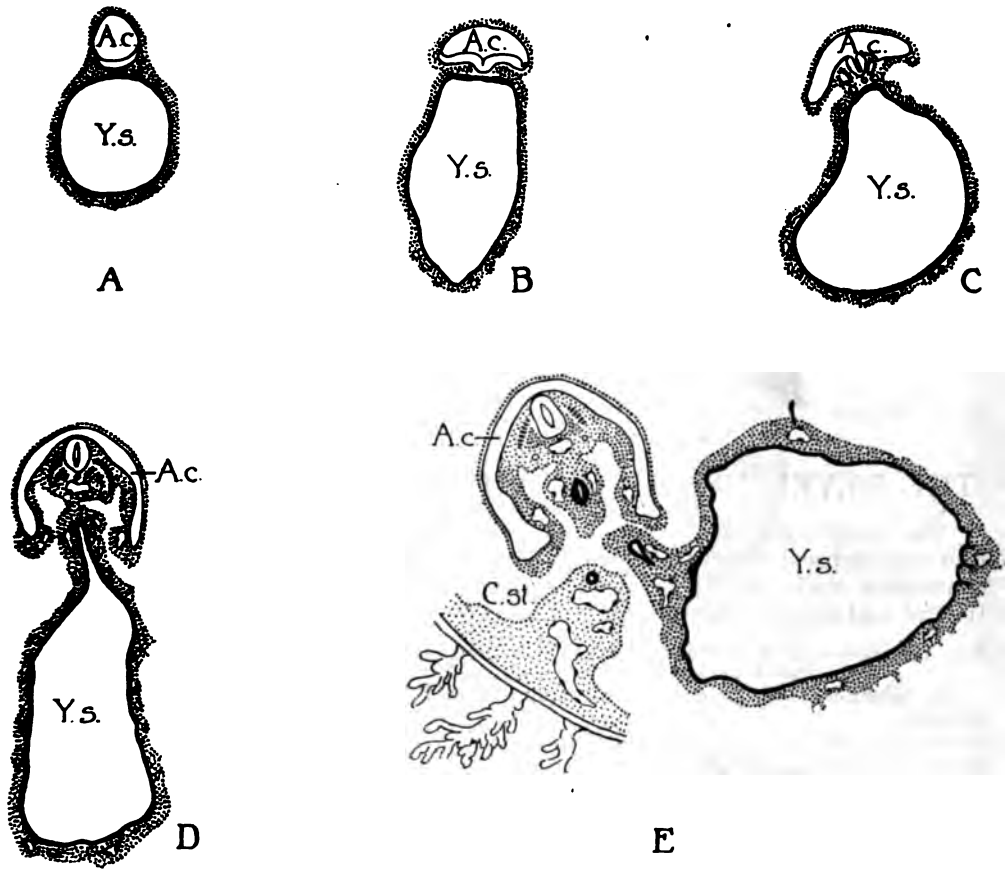
Some of the later changes in the mesoderm are shown in fig. 10. Each plate of mesoderm is divided by a longitudinal groove into three parts. These are (1) a narrow medial strip, the medial or paraxial mesoderm, (2) the intermediate mesoderm which forms a slender cord lying beneath the longitudinal groove, and (3) a broad band of lateral mesoderm. The *medial mesoderm* is subdivided by a series of transverse clefts into a row of blocks or segments known as the *mesodermic somites*. At the same time the lateral mesoderm splits into an upper (outer) or somatic layer and a lower (inner) or splanchnic layer. The space between these two layers is the embryonic body cavity or *celom*. It becomes continuous with the extraembryonic celom at the lateral margins of the embryonic disk.

The appearance of the mesodermic somites marks the beginning of metamerism, the arrangement of the body in successive segments or metameres. The somites form first in the occipital region and rapidly differentiate in the craniocaudal direction. In embryos 7 or 8 mm. in length about 40 pairs of somites can be distinguished.

The anterior end of the *medial mesoderm*, which is continued into the head region, does not undergo segmentation in the human embryo. From it are formed the cranial bones, certain of the muscles of the head and connective tissue.

FIG. 9.—CROSS-SECTIONS OF A SERIES OF YOUNG HUMAN EMBRYOS. All drawn at the same magnification. (Slightly modified from Graf Spee.)

A, embryo of the middle of the third week. B, embryo of the end of the third week. C, embryo of the early part of the fourth week. D, embryo of the latter part of the fourth week. E, embryo of the fifth week. A.c., amniotic cavity. C.st., connecting stalk. Y.s., yolk-sac. The mesoderm is indicated in stipple.



A small cavity, the *myocele* appears in the center of each somite and the wall separates into an upper lateral part, the *dermomyotome*, and a lower medial part, the *sclerotome*. From the dermomyotomes are formed the voluntary muscles of the trunk, neck, and a part of the head; while the sclerotomes take part in the development of the axial skeleton. Probably both parts of the somite contribute cells to the mesenchyma which forms the connective tissue of the body wall, and the supporting structures and voluntary muscles of the limbs.

The greater part of the *intermediate mesoderm* is also divided into segments or *nephrotomes* (corresponding to the somites), portions of which form the transitory uropoietic organs, the pronephros and mesonephros. The posterior part of the intermediate mesoderm remains unsegmented as the nephrogenic cord which is later involved in the development of the permanent kidney.

The *lateral mesoderm* shows no evidences of segmentation. The lateral cavities which are formed between its upper and lower layers soon lose their connection with the extraembryonic body cavity and fuse in the midline, forming the general celom to be described later.

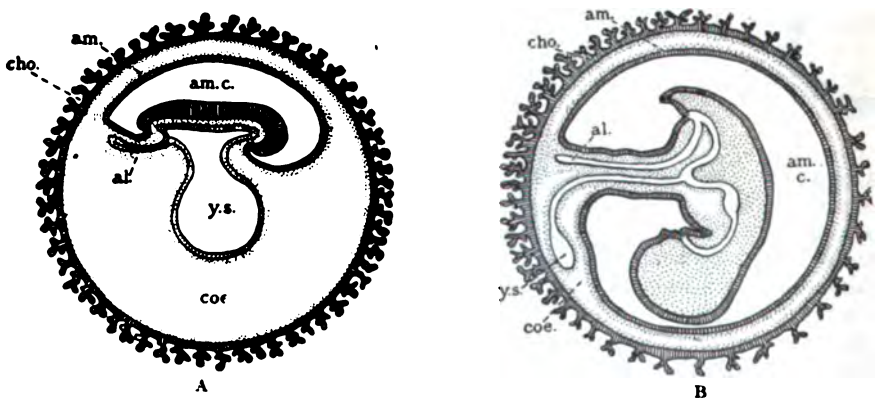
THE DEVELOPMENT OF THE EXTERNAL BODY-FORM

The early transformations of the germ-layers convert the embryonic disk into a cylindrical structure which is only partially connected with yolk-sac and connecting stalk (fig. 11). The cylindrical body wall now encloses two tubes (neural and enteric) with a longitudinal axis (notochord) between them, and is

FIG. 11.—DIAGRAMS ILLUSTRATING THE DEVELOPMENT OF THE EMBRYONIC MEMBRANES AND THE FORMATION OF THE UMBILICAL CORD. (After Lewis.) al., allantois. am., amnion. am.c., amniotic cavity. cho., chorion. coe., celom. Y.s., yolk-sac.

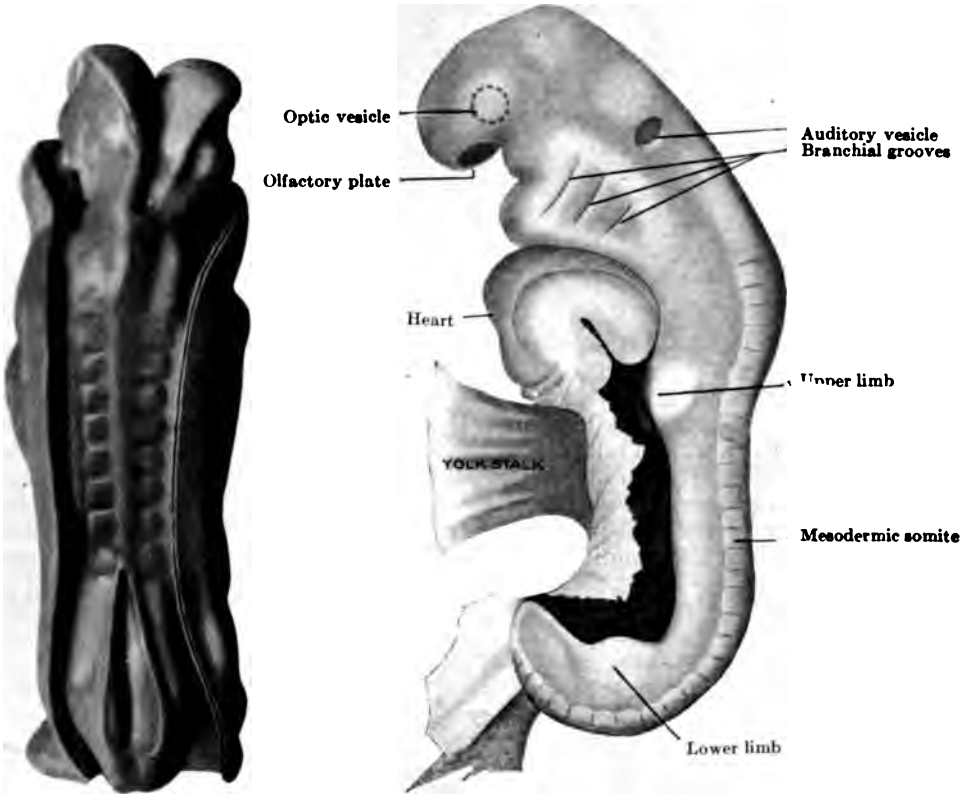


covered by an outer layer of skin-ectoderm which is continuous along the sides of the embryo with the ectoderm of the amnion. The head is relatively large and is separated from the disk below it by a deep head fold. The caudal end

of the embryo is prolonged into a short tail-bud which is also marked off from the disk by a shallow tail-fold. The middle portion or trunk is still widely connected with the disk, but its boundaries are indicated by distinct lateral folds.

The embryo becomes further separated from the other structures derived from the inner cell-mass by the deepening of the head, tail, and lateral folds; and its connection with these structures is reduced to a slender *umbilical cord.* This cord contains the allantois and yolk-stalk (with their surrounding mesoderm) and is covered by the ectoderm which is reflected from the amnion upon the external surface of the embryo.

FIG. 12.—A, HUMAN EMBRYO 2.11 MM. LONG. (FROM A MODEL BY ETERNOD.) B, HUMAN EMBRYO 4.2 MM. LONG, SHOWING THREE BRANCHIAL GROOVES. (After His.)



Coincident with these changes, the longitudinal axis of the embryo is modified by the formation of a series of flexures or bends. The head is flexed on the trunk first by an anterior cephalic flexure, and soon after by a more posterior cervical flexure, and the caudal part of the trunk and the tail are bent downward in a semicircular curve (fig. 12B). Later the rapid growth of the dorsal region throws the entire body into a partial spiral (coiled either to the right or left) so that its outline, when seen in lateral view, may be almost circular (fig. 13).

The ventral part of the body increases in size very rapidly in the second fetel month through the great growth of the contained viscera. With this growth the axis of the trunk is straightened and the cervical flexure partially e liminated The cephalic and caudal flexures are never completely obliterated, although the latter is obscured by the growth of the lower limbs; and the external evidences of the former are masked by the subsequent changes in the proportions of the head and face.

A well marked tail appears which in embryos 7 to 8 mm. long may be nearly one-sixth as long as the body. Regression of the tail structure begins in the sixth week and by the ninth week it has usually entirely disappeared.

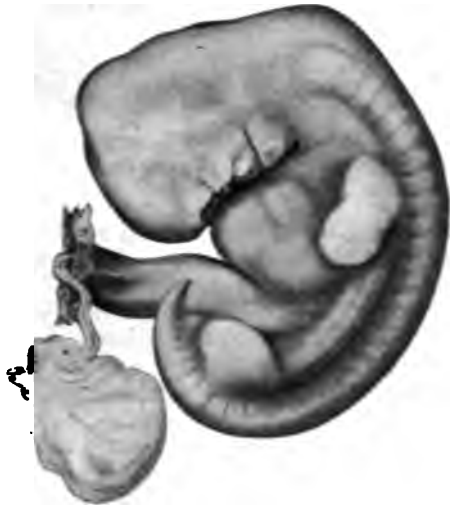
Deveploment of the head and neck.—The head is divisible from an early stage, into a neural portion including the brain, eyes and internal ears with their

supporting structures, and a facial or visceral part which contains the anterior termination of the digestive-respiratory tract. The growth and differentiation of these two portions are quite dissimilar. The neural portion is by far the larger in the young embryo and this predominance is never completely lost although it is greatly reduced during both fetal and postnatal life by the growth of the accessory structures of the mouth, nose and pharynx.

FIG. 13.—HUMAN EMBRYO 4.02 MM. LONG. (After Hochstetter.)

In the fourth and fifth weeks the visceral portion of the head undergoes marked external changes. A median *oral sinus* or embryonic mouth is formed on the ventral surface, and anterior to the sinus a pair of small ***nasal pits***. The nasal pits are bounded laterally by lateral nasal processes; and a broad medial process separates them and extends downward forming the middle part of the upper boundary of the oral sinus. The remainder of the margin of the oral sinus is formed from the mandibular and maxillary processes of the first branchial

FIG. 14.—HUMAN EMBRYO 11.5 MM. LONG. (After Minot.)

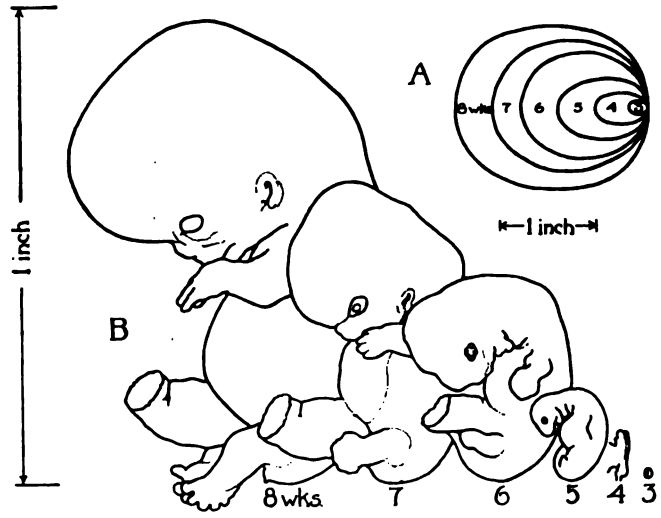


arch, the maxillary processes forming the lateral thirds of the upper boundary and the mandibular processes the entire lower margin. The maxillary and medial nasal processes are separated for the time by shallow lacrimal grooves (figs. 13, 14 and 17).

The margins of the sinus are completed by the coalescence of the mandibular processes below and the fusion of the maxillary and medial nasal processes above. The definitive *nose* is formed by the fusion of the lateral and medial nasal proc-

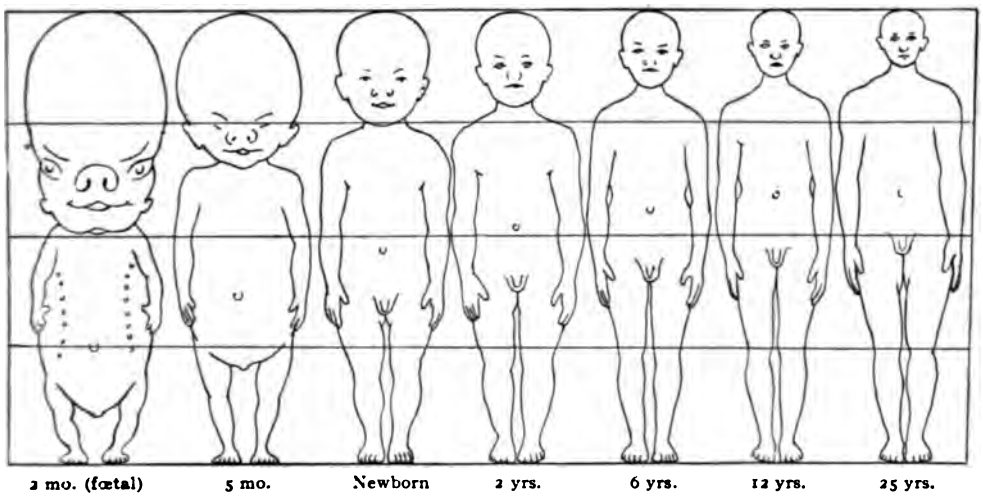
esses at the lower margins of the nasal pits and the subsequent growth of the medial process, particularly in the midline above the nares. The later development of the external features of the face is illustrated by the series of outlines in fig. 18.

FIG. 15.—A, OUTLINES OF AVERAGE HUMAN OVA FROM 3 TO 8 WEEKS OLD, ONE-HALF NATURAL SIZE. B, OUTLINES OF HUMAN EMBRYOS FROM THE THIRD TO THE EIGHTH WEEK, ENLARGED 2.5 TIMES. (After Evans.)



As these changes take place in the facial region the lateral surfaces of the neck are indented by a series of four (paired) *branchial* (visceral) *grooves* which are separated by the *branchial arches*. The upper part of the first of these grooves is deepened to form the *external auditory meatus*, the margins being elevated to form the *auricle*. The region corresponding to the second, third, and fourth grooves becomes depressed, forming the *cervical sinus* which soon closes over and normally disappears.

FIG. 16.—FIGURES ILLUSTRATING THE CHANGES IN PROPORTIONS DURING PRENATAL AND POSTNATAL GROWTH. (After Stratz.)

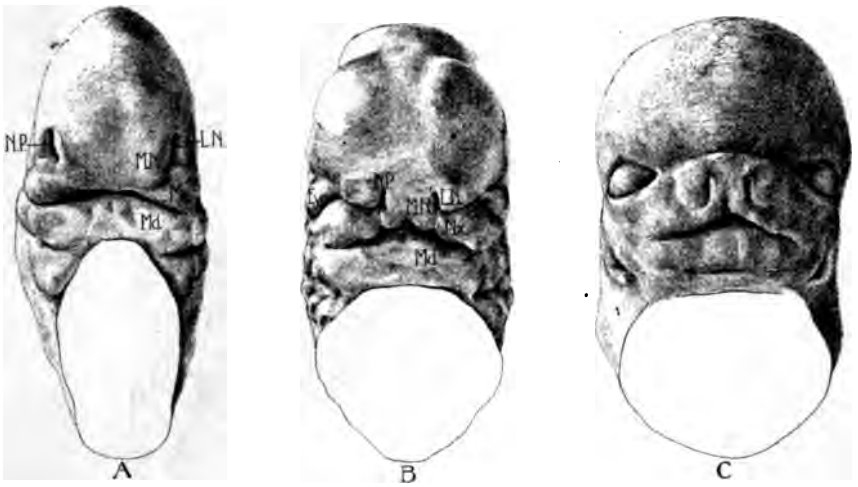


Development of the trunk.—In the young embryo the trunk appears as a cylindrical body flattened from side to side and exhibiting externally the modeling of the viscera contained within it. In fetal life, with the development of the skeleton and trunk musculature and the rounding of the visceral mass, it takes on an ovoid form largest at the level of the umbilicus and almost circular in cross section. In spite of the changes in the form and relative proportions of the

contained viscera, the relative proportions of the trunk remain almost unchanged from the close of the third fetal month until birth. In the early part of infancy, also, there is little change in the form of the trunk, but after the assumption of the erect posture there is a reduction of the relative anteroposterior diameter of both the thoracic and abdominal regions accompanied by a decrease in the relative size

FIG. 17.—DEVELOPMENT OF THE FACE IN THE SECOND FETAL MONTH. (From a series of models made in the Department of Embryology of the Carnegie Institution.)

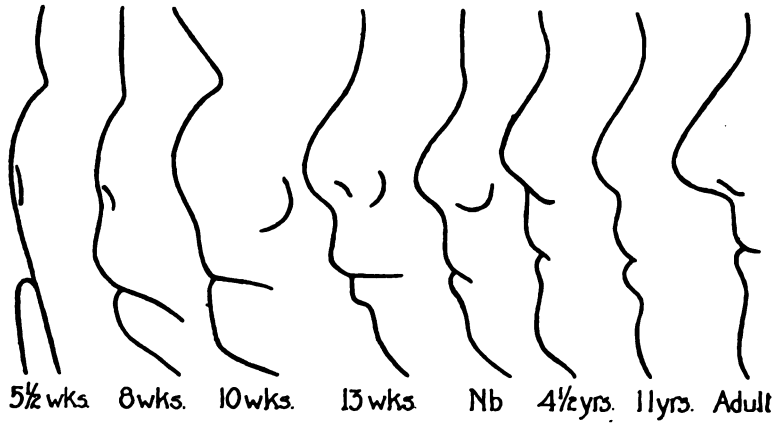
L.N., lateral nasal process. Md., mandibular process. M.N., medial nasal process. N.P., nasal pit. Mx., maxillary process.



of the umbilical region and a relative increase in the lumbar region. These changes continue throughout childhood and early adolescence.

Development of the extremities.—The limbs appear about the third week of fetal life as short ridges which project from the lateral surfaces of the cranial and caudal ends of the trunk. Each ridge is differentiated into a limb-bud in which may be recognized a flattened distal segment representing the hand or

FIG. 18.—A SERIES OF PROFILES ILLUSTRATING THE CHANGES IN THE FORM AND PROPORTIONS OF THE FACE IN THE DEVELOPMENTAL PERIOD. (After Peter.)



foot, and a rounded proximal segment representing the remainder of the limb. The latter is again divided by a slight constriction into a distal part, corresponding to the forearm or leg, and a proximal part corresponding to the arm or thigh. The digits are formed as radiating ridges on the lateral surfaces of the hand and foot segments. As these ridges grow more rapidly than the bodies of these segments they soon project beyond their margins as definitive fingers or toes.

The axes of the limbs undergo three main changes in position in their early development. At first the limb-buds project outward at right angles to the

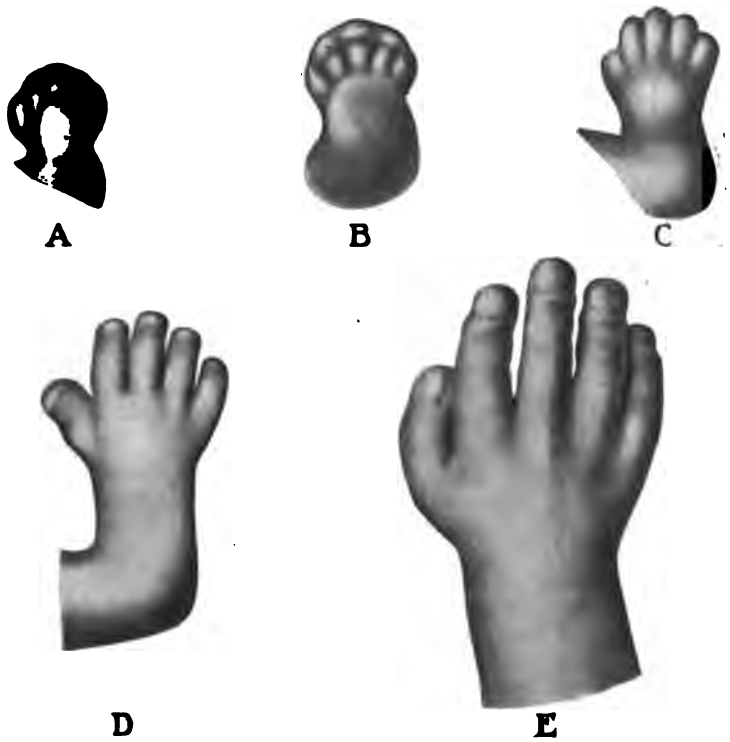

FIG. 20.—DEVELOPMENT OF THE LOWER EXTREMITY. (After Retzius.)

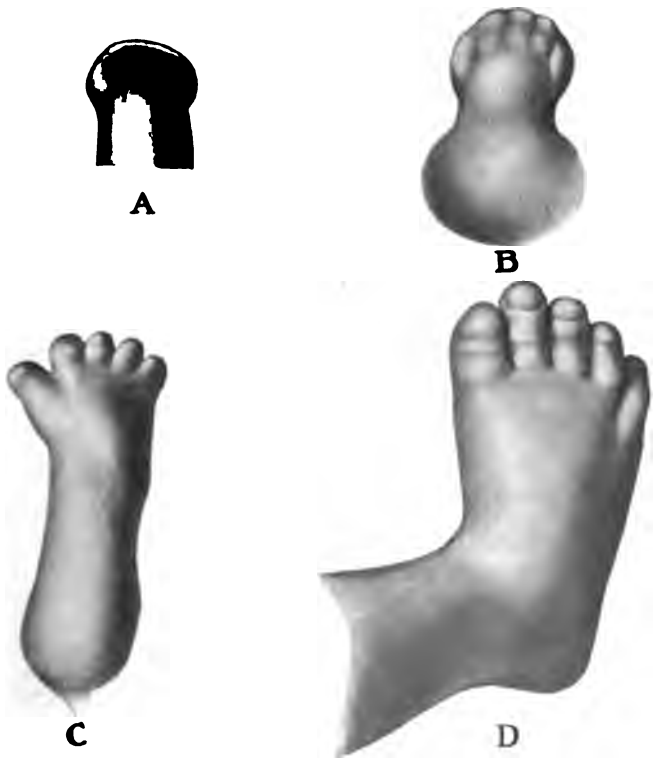
A, Posterior limb-bud of an embryo 17 mm. long. B, posterior limb-bud of an embryo 19 mm. long. C, leg and foot of an embryo 25 mm. long. D, foot of a fetus 52 mm. long. All ×6.



lateral surface of the body. Later they are bent caudally and ventrally so that their former ventral surfaces face medially. And finally each limb is rotated about its long axis through an angle of approximately 90 degrees. This rotation takes place in opposite directions in the arm and leg. The arm is turned outward so that the thumb comes to lie on the lateral (outer) margin of the limb and the palm faces ventrally (in supination), while the leg rotates inward and the great toe comes to lie on the medial margin of the limb, and the plantar surface of the foot faces dorsally.

In embryonic life the development of the arm precedes that of the leg and it is not until after birth that the lower extremity exceeds the upper one in length. In postnatal life the lower limb increases in length more rapidly than the upper; at about two years their length is equal and in the adult the lower limb is about one-sixth longer than the upper. The adult relations of the different segments of the limbs (arm, forearm and hand, and thigh, leg and foot) are practically established early in prenatal life although there is some reduction in the relative length of the hand and height of the foot in the postnatal period.

THE GROWTH OF THE BODY AND ITS PARTS

Growth of the body in weight.—The diameter of the ripe human ovum is approximately 0.1 mm. Consequently, if the egg-cell is considered as a perfect sphere, its volume is about 0.0000005 cc. and its weight, assuming the specific gravity to be 1.0, is about 0.0000005 gm. If the average weight of the body in the third decade be considered as 65 kilos (about 143 pounds) we may estimate the total increment in the body-weight during the developmental period at about 130 billion-fold. Considered from this point of view almost all of the weight increment takes place in prenatal life, for in this period the body increases in mass about 6.5 billion times while from birth to maturity the gain is but twenty-fold. From the standpoint of absolute growth, on the other hand, the body acquires about 5 per cent. of its adult weight before birth and about 95 per cent. thereafter. The growth of the body in weight is indicated in the following tables.

Growth in length.—Growth in length has certain characters in common with growth in weight although the relative lineal increase of the body in the developmental period is obviously much smaller than the relative growth in mass.

At the end of the first fetal month the length of the embryo is approximately 0.25 cm. This is increased 10-fold in the second fetal month but thereafter the relative rate of growth becomes progressively slower. The period of most rapid absolute growth in length is in the fourth fetal month, during which there is a gain of about 8 cm. (from 10 cm. in the twelfth week to 18 cm. in the sixteenth). After this there is a gradual decline in the absolute as well as the relative rate of lineal increase.

Birth	27	49	9	15
Two years	22	50.5	9	17.5
Six years	15	51	9	25
Maturity	7	53	10	30

The growth in length in fetal life is indicated in a preceding table (p. 20) and by the upper curve in fig. 21. The age of the fetus may be estimated from its standing height by 'Hasse's rule'; namely: that before the fifth month the age in fetal months is equal to the square root of the total (standing or crown-heel) height, while after the fifth month the age equals one-fifth of the standing height in cm. This give approximate results except for the first 2 months.

The length of the body at birth usually falls between 48 and 52 cm. (approximately 19 to 21 inches). The birth-length, like the birth-weight, is influenced by sex, race, and a number of other factors. In the neonatal period there is often a slight decrease in length due to changes in bodily proportions in the recovery from the molding effects of birth.

The curve of postfetal growth in length is a sinuous one similar to the curve of postnatal weight increase and the same phases may be recognized in it. Length increases about 30 per cent. (15 cm. or 6 inches) in the first six months and about 50 per cent. (25 cm. or 10 inches) in the first year (fig. 22). During early and middle childhood the lineal increase is very slow, averaging only about 6 or 7 cm. per year. The prepuberal length increase, like the weight increase, begins earlier in girls than in boys and is completed sooner. The body increases approximately 3.3 times in length during the postnatal developmental period. Growth in length usually ceases at about 18 years in females and soon after 20 in males.

FIG. 21.—CHART OF THE AVERAGE GROWTH IN LENGTH AND WEIGHT IN FETAL LIFE. (Based on the data of Mall, A. W. Meyer and Jackson.)

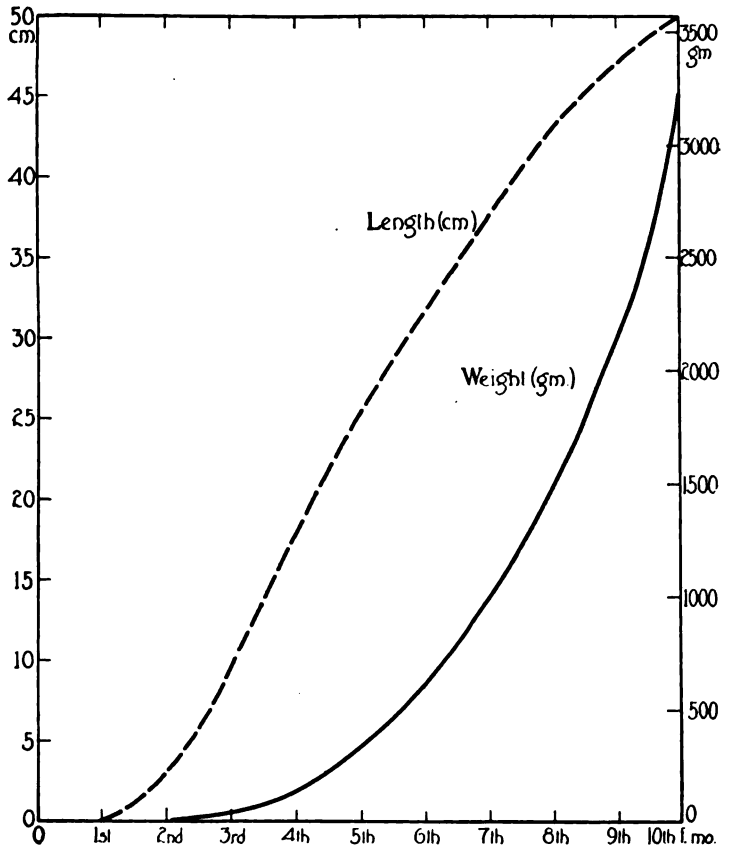

FIG. 22.—CHART OF THE AVERAGE GROWTH IN HEIGHT AND WEIGHT IN THE FIRST YEAR (Bedvel.)

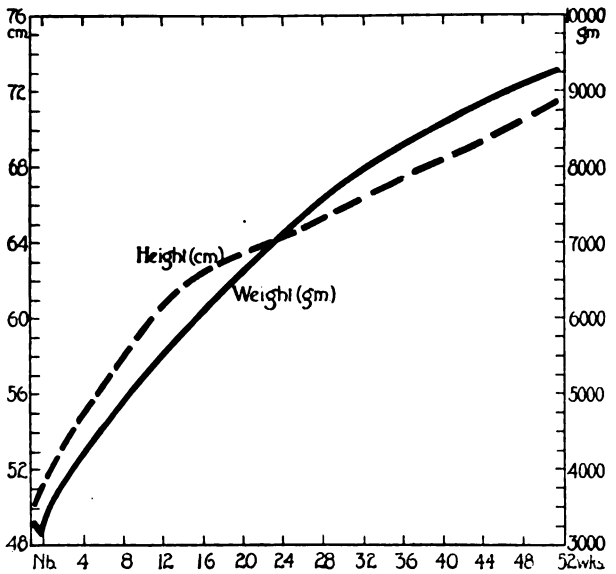
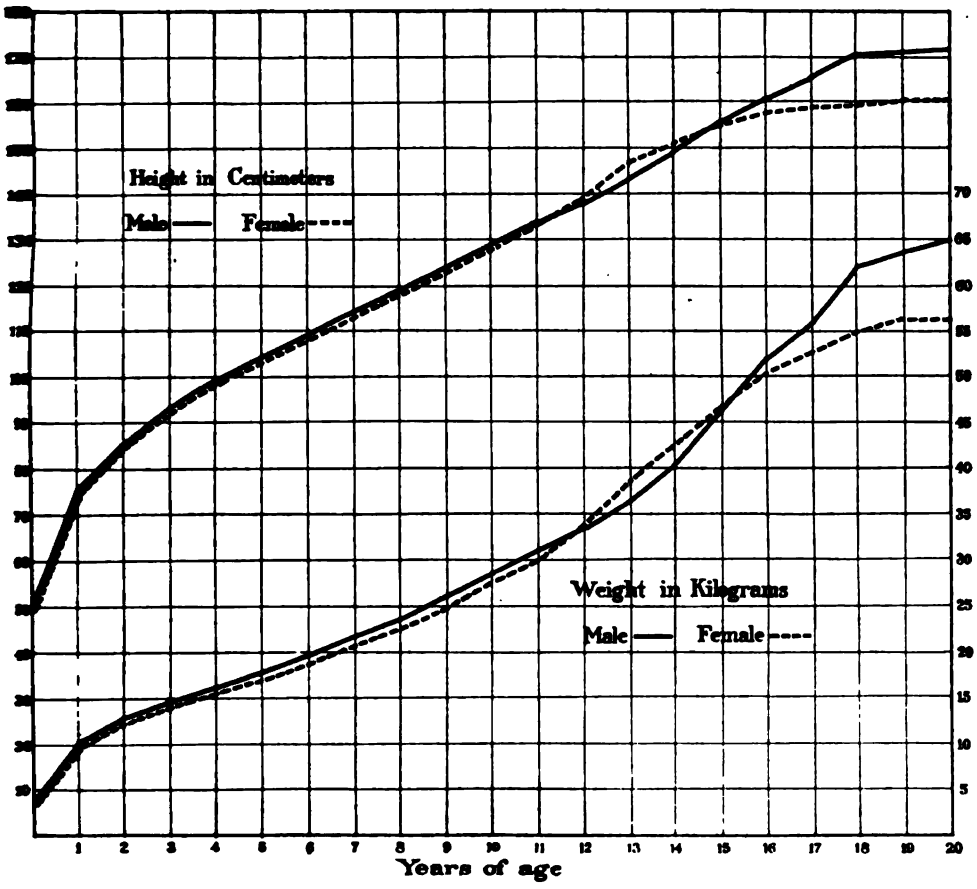


The relation between the length and the weight of the body changes greatly in the developmental period. In later fetal life and early infancy the mass of the body is much greater in proportion to its length than at any subsequent time. The decline in relative weight begins about the middle of the first year and continues until after puberty. Thereafter there is a period of relative mass increase which may continue throughout maturity. During infancy and childhood females are relatively lighter than males but after puberty they are relatively heavier.

The surface area of the body in the developmental period.—The metabolism of the body is greatly influenced by the relation of its surface or cutaneous area to its mass or volume, and this relation is greatly altered in the course of postnatal

FIG. 23.—CHART SHOWING AVERAGE POSTNATAL GROWTH IN HEIGHT AND WEIGHT. (After Stratz.)



development. The surface area of the average newborn child is about 2500 square cm. (400 square inches). This is doubled in the first year and is tripled in the middle of childhood. There is a period of rapid increase in surface area before puberty and the total gain between birth and maturity is about 7-fold. But the weight of the body increases approximately 20-fold in this time and there is consequently a great reduction in the ratio of surface area to mass or volume (from over 800 square cm. of surface area per kilogram of body weight in the newborn to less than 300 square cm. per kilogram in the adult.)

The relative growth of the parts of the body.—Growth and differentiation do not take place at the same time or rate in the various parts of the body and the changes in proportions which occur in the developmental period are dependent on this lack of uniformity. While each part passes through its own cycle of changes these changes as a whole tend to follow what is known as the *law of developmental direction;* for it is generally found that development (including

growth and differentiation), in the long axis of the body, appears first in the head region of the body and progresses toward the tail region and similarly development in the transverse plane begins in the mid-dorsal region and progresses lateroventrally (in the limbs proximodistally).

Some of the changes in the proportions of the body and the relative size of its several parts are indicated in figs. 15 and 16 and in a preceding table (p. 21). The *head* is the largest part of the body in earlier stages, forming about one- alf of the body in the second fetal month, about one-quarter at birth, and from 6 to 8 per cent. in maturity. The *trunk* as a whole remains of about the same relative size throughout the developmental period (45 to 50 per cent.) although the thoracic portion reaches its maximum in the earlier stages and the pelvic portion not until adolescence. The *lower limbs*, like the pelvis, develop slowly, forming about 3 per cent. of the body at the end of the period of embryo, about 15 per cent. at birth and reaching about 30 per cent. in the adult. The *upper limbs* also form about 3 per cent. of the body weight at the close of the embryonic period. They increase to 8 or 9 per cent. at birth and maintain thereafter about the same relative size.

These changes cause a great increase in the relative weight and volume of the caudal or lower part of the body; and with them the *midpoint* of the body (between crown and sole) is gradually shifted from the upper margin of the thorax at the end of the embryonic period to a level slightly above the umbilicus at birth, and to the level of the crest of the pubis in the adult. The center of gravity is also shifted caudally from the cervical region in the embryo to the point where the inferior vena cava pierces the diaphragm at birth, and to a point just in front of the sacral promontory in the adult.

The relative growth of systems.—There is a marked difference in the growth of the various systems of the body. The *skeleton* grows comparatively slowly during the greater part of prenatal life but increases much more rapidly in the last two fetal months. At birth it forms from 15 to 20 per cent. of the body. Its postnatal growth apparently proceeds with that of the body as a whole, the total increase in weight between birth and maturity being about twenty-fold. The *musculature* also grows rather slowly in the young embryo but increases to about 25 per cent. of the body at birth and to 40 or 45 per cent. in the adult. The blood-vessels apparently also increase in relative weight after birth. The *central nervous system*, on the other hand, is relatively enormous in the young embryo, decreasing from about 25 per cent. of the body in the second fetal month to about 15 per cent. at birth and to between 2 and 2.5 per cent. in the adult. Data for the peripheral nervous system and the skin are somewhat scanty and rather unsatisfactory, but it is evident that both undergo a considerable reduction in relative weight in the postnatal developmental period. The *visceral group* (as a whole) shows a slow but steady decrease in relative weight after the embryonic period, forming about 15 per cent. of the body weight in the second month, about 9 per cent. in the newborn, and from 5 to 7 per cent. in the adult.

Growth of organs.—While in general the individual organs follow the course of growth of the visceral group, each organ has its own characteristic scheme of relative growth. As a rule, after its appearance in embryo, each organ increases more or less rapidly to a maximum relative size, after which, although increasing in absolute size, it decreases in relative size through subsequent prenatal and postnatal life to maturity.

Curves of the absolute growth of the various organs in the period of the fetus all appear much alike, showing an initial period of slow increase followed after the fifth month by a terminal phase of rapid growth. This uniformity is lost at birth and most of the major organs, on the basis of the course of their postnatal growth, can be classified in 4 main groups—splanchnic, nervous, genital and lymphoid (fig. 24).

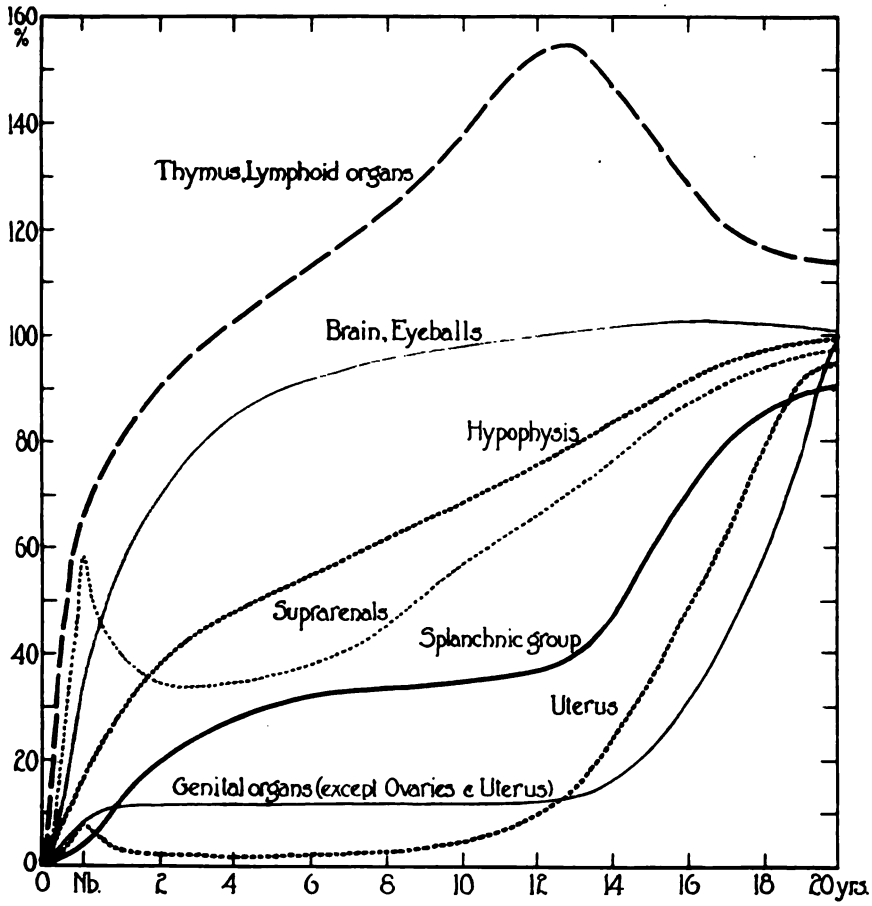
The *splanchnic group* includes the digestive, respiratory, urinary organs, the thyroid gland, the heart, and the spleen. These organs increase rapidly in weight in infancy and the first part of early childhood. In the latter part of early childhood and in middle childhood they grow quite slowly. They enter on a second phase of rapid growth in the prepuberal period, and this is followed by a terminal phase of slow increase in adolescence. In general the growth of the organs of this group is similar to the growth of the body as a whole.

The *nervous group* includes the brain, spinal cord, and eyeballs. These structures grow very rapidly in infancy and have completed over 90 per cent. of their postnatal increase by the close of early childhood.

The organs of the *genital group* (all genital organs with the exception of the ovaries and uterus) grow very slowly until the prepuberal period, when they enter on a phase of rapid increase which extends into or through adolescence.

The structures of the *lymphoid group* (excluding the spleen but including the thymus) are large at birth, grow rapidly until puberty, and then decline in absolute weight.

FIG. 24.—CHART ILLUSTRATING THE COURSE OF GROWTH OF THE VARIOUS TYPES OF ORGANS. The growth of the various organs is calculated in per cent. of their adult weight.



The organs which do not fall under any of the preceding categories are the suprarenal glands, the ovaries, the uterus and the hypophysis. Their growth is considered in connection with their development in the following sections.

THE SKELETON

The skeleton, including the bones, cartilages, ligaments, and joints, is derived from the mesoderm. The process is inaugurated by the formation, in the future skeletal regions, of masses of thickened mesenchyma known as scleroblastema. The hard parts of the skeleton, the bones and cartilages, arise in the more condensed parts of the scleroblastema while the joints are formed from the intervening portions. The majority of the thickened scleroblastemal masses are differentiated into cartilage. Certain of these cartilages persist throughout life while a few may be converted at a later time into fibrous tissue. But by far the greater number are replaced by bone during the later development of the skeleton.

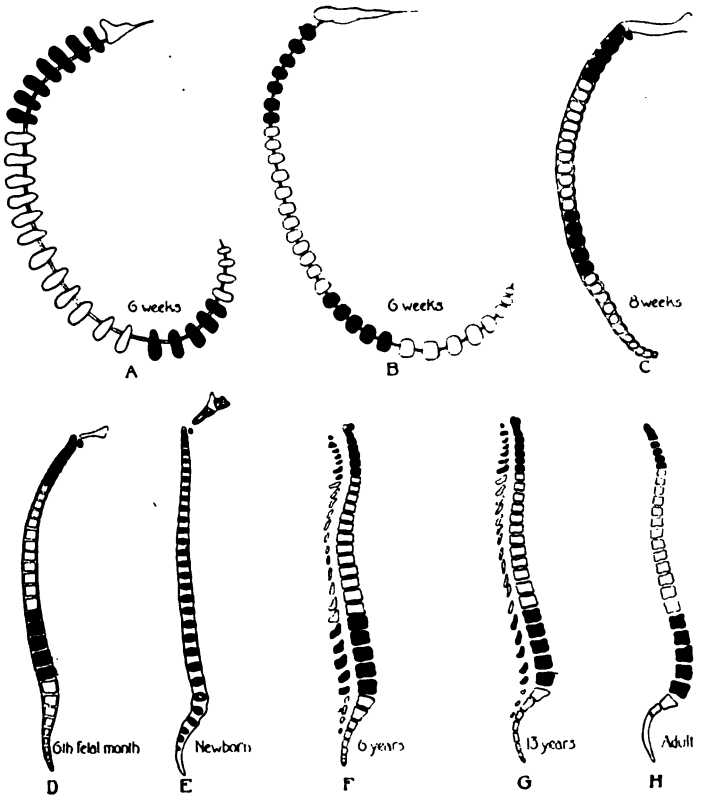
Most of the bones of the body arise through the replacement of previously formed bodies of cartilage by bony material, while a smaller number are formed directly in the membranous scleroblastema. The former are known as cartilaginous or replacement bones and the latter

are termed membranous or investment bones. All the bones of the extremities, the bones of the spinal column and thorax, the auditory ossicles, the hyoid bone, and the greater part of the bones of the base of the skull are cartilaginous bones. The bones of the face and the greater part of the vault of the skull are membranous bones. Certain of the skull bones are formed partly in membrane and partly in cartilage.

The **process of ossification** begins in discrete foci which are known as centers of ossification. These centers are formed from time to time throughout the developmental period, the first appearing in the clavicle in embryos of the sixth week and the last, in the epiphyses of the vertebral column, in the third decade of postnatal life. Over eight hundred centers are formed in the body and of these slightly more than half appear after birth.

Almost all bones of the adult are formed from one or more centers of ossification; the relation of the total number of bones in the mature skeleton to the total number of centers being approximately as 1 to 3. The ossification centers of all bones of the body with the exception

FIG. 25.—MEDIAN SAGITTAL SECTIONS OF THE VERTEBRAL COLUMN AT VARIOUS AGES ILLUSTRATING THE DEVELOPMENT OF THE NORMAL SPINAL CURVATURES. Cervical and lumbar vertebræ indicated in black. (Based in part on the figures of Bardeen, Williams and Cunningham.)



of those of the carpus, tarsus, skull, and sternum, may be divided into two general classes, the primary and secondary. The primary centers which form the greater part of the bone almost always appear before birth. Such centers, when located in long bones, are known as diaphyses. The secondary centers or epiphyses are, with one or two exceptions, formed during postnatal life. A further consideration of the nature of diaphyses and epiphyses will be found in the section on Osteology (p. 82).

As the formation of new centers and the fusion of older ones proceeds at unequal rates during the first two decades, the number of separate bone masses in the body varies from year to year during this period. The **number of bones** in the average newborn child is 270. This number is reduced in the first 2 or 3 years of life through the fusion of primary centers which are present before birth. From this time until puberty, however, the number increases steadily through the formation of epiphyses and the ossification of the carpus and tarsus. In the fourteenth year there are about 350 separate bony masses in the body. After puberty the number again increases rapidly until nearly the middle of the third decade. Often it is not until middle life that the number of bones is reduced to the usual quota of 206, excluding the smaller sesamoids.

The spinal column.—In the latter part of the first month the notochord is surrounded by a sheath of mesenchyme in which may be recognized segmentally arranged masses which represent the vertebræ and are formed from the sclerotomes of the mesodermic somites. Dorsal prolongations from these masses grow up on either side of the neural tube forming the arches

of the vertebræ, and at the same time lateral outgrowths appear which represent the various lateral projections of the vertebræ including the costal processes.

In the second and third fetal months the cervical and sacral regions form the greater part of the vertebral column (fig. 25). At birth the cervical part forms approximately one-fourth, the thoracic part one-half, and the lumbar part one-fourth of the entire movable spine. In the adult the thoracic portion continues to form approximately one-half of the free vertebral column, but the lumbar portion is increased to about one-third, and the cervical portion is reduced to one-fifth or one-sixth of the whole. It is probable that in most cases these proportional postnatal changes take place in the first 3 years.

During the first fetal month the vertebral column shows a pronounced ventral *flexion*. From this time until birth the free portion gradually becomes straighter while the sacral portion first becomes straighter and later acquires a second ventral curve. In the newborn child the free column forms a single gentle curve with an anterior (ventral) concavity extending from

FIG. 26.—DIAGRAM SHOWING THE CATEGORIES TO WHICH THE BONES OF THE SKULL BELONG. (After McMurrich.) The unshaded bones are membrane bones, the heavily shaded represent the chondrocranium, while the black represents the branchial arch elements.

the first cervical to the last lumbar vertebra, while the sacrum is directed somewhat posteriorly. The cervical curve appears when the infant begins to lift its head but neither at this time nor later does it become a fixed flexure. The lumbar curve appears as the child assumes the upright posture. It forms very slowly and throughout childhood and adolescence it may be effaced by stretching the spine. Later the lumbar curve is fixed, in a measure, by the anterior thickening of the lower lumbar vertebræ and the intervertebral disks between them. This process begins in later childhood and continues slowly until maturity. For further details on the curvatures, see p. 97.

The cartilaginous vertebræ are formed by the appearance of centers of chondrification of the blastemal vertebræ. There are four of these centers for each vertebra, two lateral ones which soon fuse in the body, and one for each side of the vertebral arch. The ossification of the vertebræ is considered in the section on **Osteology.**

The material between the vertebral masses is later converted into the outer portions of the intervertebral disks; and the segments of the notochord which occupy these regions form the nuclei pulposi. The vertebral portions of the notochord degenerate.

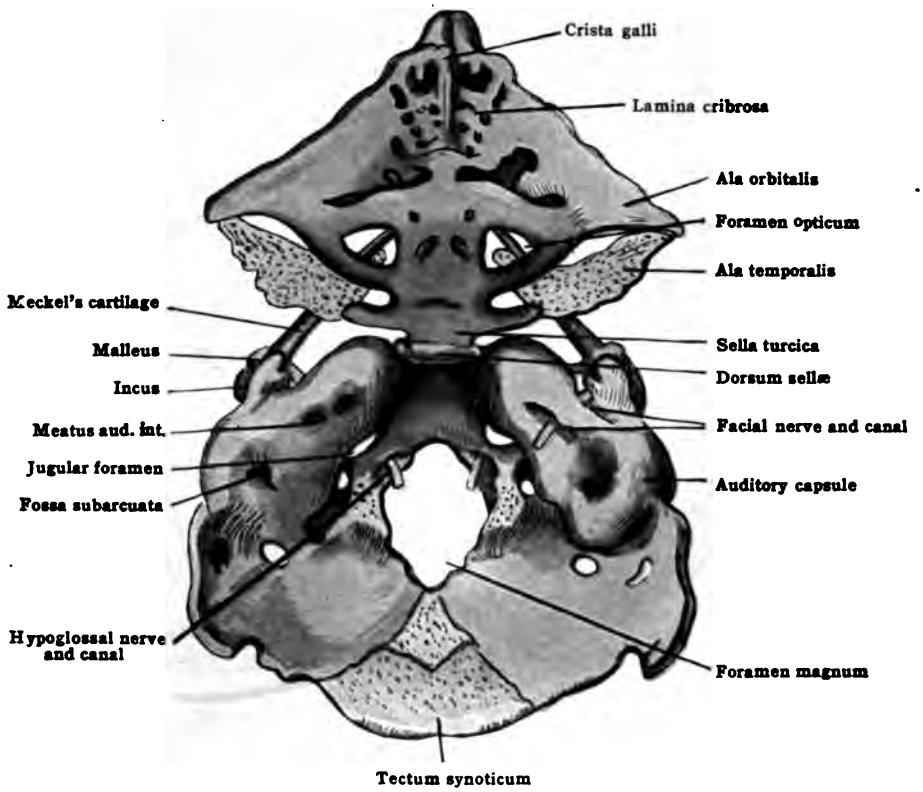
The *length* of the movable or free vertebral column (cervical, thoracic, and lumbar vertebræ) at the end of the second fetal month is about 2 cm. This is more than doubled in the third month, nearly quadrupled in the fourth, and increased almost 10-fold by birth when the average length is almost 20 cm. (8 in.). Between birth and maturity the movable vertebral column increases in length between 2 and 2.5 times, about two-thirds of this growth being accomplished

before puberty. After the second fetal month the vertebral column forms from 40 to 45 per cent. of the total length of the skeleton.

Development of the skull.—The bones of the skeleton of the head may be divided into three main categories (fig. 26): (1) the group of cartilage bones developed mainly in the base of the skull around and anterior to the cephalic portion of the notochord and about certain of the organs of sense; (2) the membrane bones which form the vault of the skull and the framework of the upper part of the face; and (3) the cartilage bones which have their origin from the cores of the branchial arches. The distinction between these three parts of the head skeleton is often imperfect, for their parts overlap and fuse during development and the relations between them are constantly shifted and modified.

In the skull, as in the other parts of the skeleton, three stages, the blastemal or membranous, the chondrogenous, and the osseogenous, may be recognized although they overlap considerably and do not proceed at the same rate in all parts of the head skeleton.

FIG. 27.—MODEL OF THE CHONDROCRANIUM OF A HUMAN FETUS 8 CM. IN LENGTH. Cartilage in blue. Viewed from above. (After O. Hertwig.)



Toward the end of the first month the brain is enclosed in a membranous sac formed by the condensation of the surrounding mesenchyma. The basal portion of this sheath forms a thickened plate which surrounds the cephalic portion of the notochord and projects forward beyond its anterior termination. The occipital portion of this plate is greatly expanded and is connected with the fibrous capsules around the developing internal ears. The anterior part of the plate extends forward into the nasal region.

The formation of the *chondrocranium* in the basal portion of the cranial blastema begins early in the second month and is practically complete by the close of the third (fig. 27). The caudal or occipital portion of the chondrocranium forms almost a complete ring around the foramen magnum and extends laterally about the base of the posterior part of the brain. Lying anterior to the occipital portion of the skull on either side are the cartilaginous auditory capsules. The contiguous borders of the occipital portion of the skull and the auditory capsules are partly fused, but lacunæ in this region indicate the position of the future hypoglossal and jugular foramina and transmit the structures which pass through these openings in the adult skull. A median bar of cartilage, which represents the basilar portion of the occipital bone and the body of the sphenoid, passes forward from the anterior margin of the foramen magnum and terminates in an expanded frontonasal plate. Two pairs of processes arise from this median mass. The posterior (alisphenoid) represents a part of the greater wing of the sphenoid and the anterior clinoid processes. The latter fuse with the frontonasal plate enclosing the optic foramina. The medial portion of the frontonasal plate extends forward into the nasal region forming the fundament of the ethmoid bone and a part of the nasal capsule. The lateral portions (orbitosphenoid) spread over the eyes and represent the lesser wings of the sphenoid.

The *visceral elements of the skull* are derived from cartilages formed in the branchial arches. That of the first arch is known as Meckel's cartilage. It extends from the outer surface of the auditory capsule through the mandibular process to the ventral median line. The upper portion of Meckel's cartilage is differentiated into two parts which form two of the auditory ossicles, the malleus and the incus. The lower part is enclosed in a sheath of membrane bone which forms the mandible (fig. 28). All of this part of the cartilage disappears with the exception of its medial tip which is probably involved in the formation of the mental protuberance. The upper portion of the cartilage of the second or hyoid arch forms a portion of the stapes and a part of the styloid process of the temporal bone while its lower segment gives rise to the lesser cornu and a part of the body of the hyoid bone. The upper portions of the third, fourth

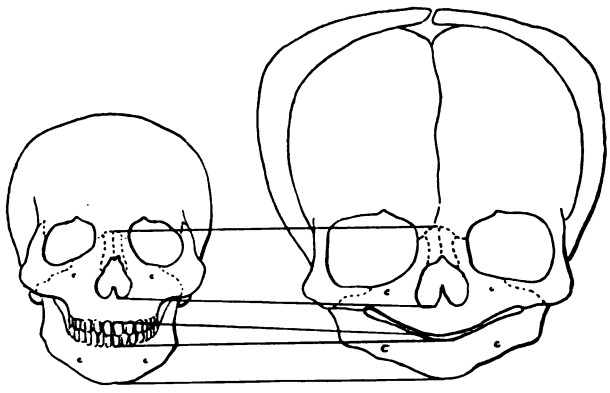
FIG. 28.—MANDIBLE SHOWING RELATIONS OF MECKEL'S CARTILAGE IN A HUMAN FETUS OF 8 CM. CROWN-RUMP LENGTH. (After Kollmann.)

and fifth arches form no permanent structures. The lower part of the third arch gives rise to the greater cornu and a part of the body of the hyoid bone, and the lower parts of the fourth and fifth arches are involved in the formation of the thyroid cartilage.

The further history of the ossification of the bones of the head will be found in the section on **Osteology.**

Growth of the skull.—The most striking characteristic of the fetal skull is the great predominance of the neural over the visceral portion. During the period of the chondrocranium the base of the cranium is large as compared with the roof or vault but with the growth of the cerebral hemispheres the vault becomes increasingly prominent. In early stages of development the occipital region forms by far the largest part of the cranium. Later the parietal portion enters on a period of rapid growth and becomes the predominant region, and finally in the last fetal months the frontal region becomes the center of most vigorous expansion.

FIG. 29.—SKULLS OF THE NEWBORN AND ADULT. Drawn to the same face height to illustrate the relative proportions of the facial and neural skeleton at birth and in maturity. (After Holl.)



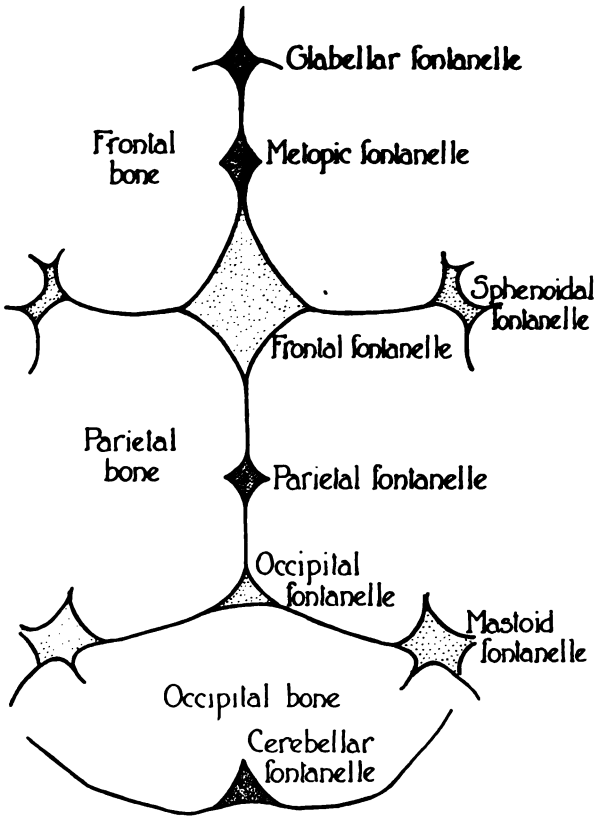
At birth the skull is large as compared with the rest of the skeleton. The neural portion is still much larger than the visceral or facial, the relation between the two being as 8 to 1 as compared with the ratio of 2.5 to 1 in the adult (fig. 29). The vault in comparison with the base of the cranium is also much larger than in later life.

The bones of the cranial vault are quite thin and are separated by narrow strips of membrane which are expanded at the angles of the parietal bones into areas of some size which are known as *fontanelles*. Theoretically fontanelles may be formed at any point on the calvarium which is equidistant from three or more contiguous centers of ossification. There are some 26 such points on the vault of the skull and constant or occasional fontanelles have been found in most of these locations. Two median and single fontanelles (the frontal and occipital), and two lateral and paired fontanelles (the sphenoidal and mastoid), are commonly present at birth. Their positions are shown in figs. 30 and 188–190. Besides these constant fontanelles, numerous accessory ones may be present. The more important ones, the parietal, cerebellar and metopic fontanelles, are all located along the sagittal suture.

The involution of the frontal fontanelle usually begins some months after birth generally completed early in the second year. The occipital fontanelle is generally clc the end of the first trimester. The sphenoidal fontanelle commonly closes in the first 6 1 and the mastoid fontanelle between 12 and 18 months after birth. The obliteration fontanelles takes place by the progressive ingrowth of the edges of the bone which bound but occasionally separate ossification centers may arise within them and form indep bones which occupy all or part of the original space.

The skull as a whole grows less in postnatal life than the other divisions of the sk the neural portion increasing in volume about 5 times and the facial portion about 1 Between birth and maturity the *cranial capacity* rises from 400 to 1500 c.c. and the hor circumference of the skull from about 32 cm. to 48 or 50 cm. Most of this growth take in the first two or three years after birth (fig. 31). The postnatal growth of the skull is associated with the growth of other structures of the head and particularly with those brain and eyeballs, the teeth and paranasal sinuses, and certain of the larger muscles.

FIG. 30.—DIAGRAM OF THE CALVARIUM AT BIRTH, SHOWING THE POSITIONS OF THE CO: AND THE MORE IMPORTANT ACCESSORY FONTANELLES. Constant fontanelles sha light stipple, accessory fontanelles in heavy stipple.



structures influence the growth of the skull at different periods: the brain and eyeballs i in infancy and early childhood, the teeth and paranasal sinuses mainly in middle an childhood, and the muscles mainly in adolescence.

During infancy all parts of the skull grow rapidly, the cranial capacity increasin 400 cc. at birth to 700 cc. at 6 months and over 1000 cc. at 18 months. The face grow more rapidly than the cranium in this period, the ratio between the two being reduced to 8 at birth to 1 to 6 in the second year. Most of the early growth of the face is due expansion of the orbits, which accomplish over half of their postnatal growth in the first 2 but there is also a marked growth of the maxillæ and mandible in connection with the de ment of the deciduous dentition.

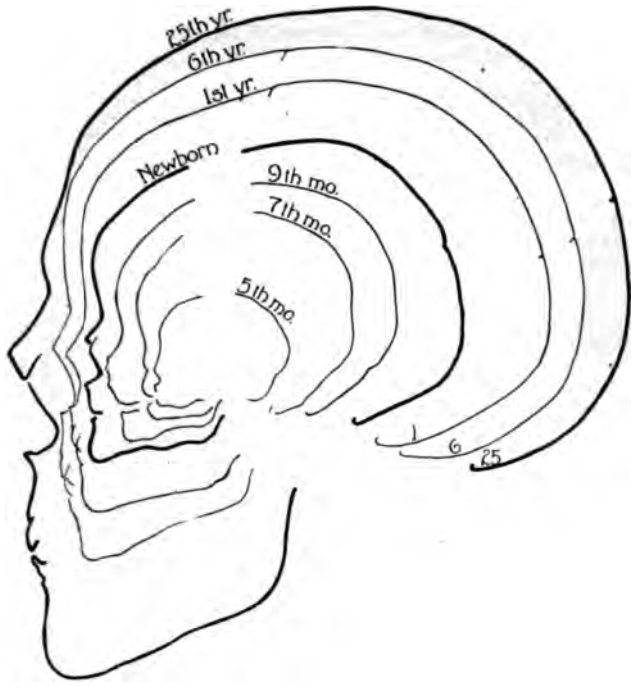
From 2 to 7 years the growth of the skull is continued, although less rapidly than in in The cranium expands slowly, the vault growing more than the base. The facial skeleton more rapidly than the neural portion and by 5 years the ratio between them is 1 to 5. of the growth is in the lower part of the face and is due to the expansion of the dental and the development of the maxillary sinuses.

In middle and later childhood the skull grows little, aside from the lengthening of t which accompanies the establishment of the permanent dentition. In adolescence the of the skull again increases. The cranium enlarges slightly in all diameters, mainly t the increase in the thickness of the bones of the vault, and the face completes its growt

the full development of the paranasal sinuses and the upper and lower dental arches. As a rule these later changes are more extensive in the male than in the female skull.

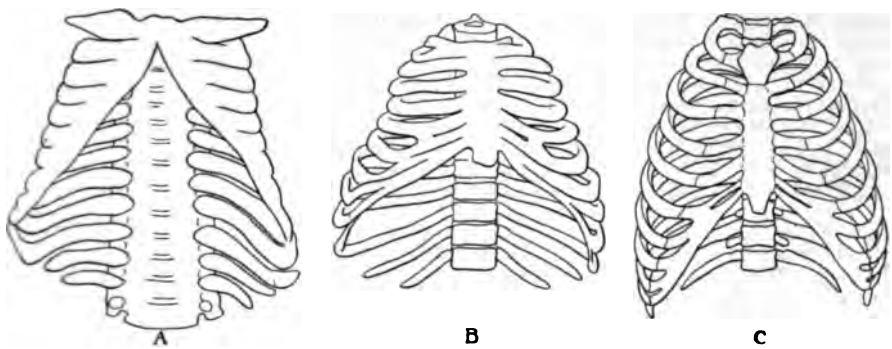
The thorax.—The formation of the thorax is first indicated in the blastemal period by the development of the costal processes of the thoracic vertebræ. These structures represent the future ribs. They assume a rod-like form and rapidly grow ventralward in the thoracic body

FIG. 31.—TRACINGS OF MEDIAN SAGITTAL SECTIONS OF THE SKULL AT DIFFERENT AGES, ILLUSTRATING THE RATE OF GROWTH OF THE CRANIUM. (Based on the figures of Corrado and Welcker.)



wall. Their distal ends unite craniocaudally, forming longitudinally directed sternal bands on either side of the ventral midline. The fundament of the unpaired sternum is formed by the side-to-side union of these bands, together with a small mass (the episternum) which is derived from a band of thickened mesenchyma connecting the sternal ends of the developing clavicles.

FIG. 32.—ANTERIOR VIEWS OF THE SKELETAL THORAX.
A, of an embryo 15 mm. long. (After Müller.) B, of a newborn child. C, of an adult. All drawn to the same absolute size.



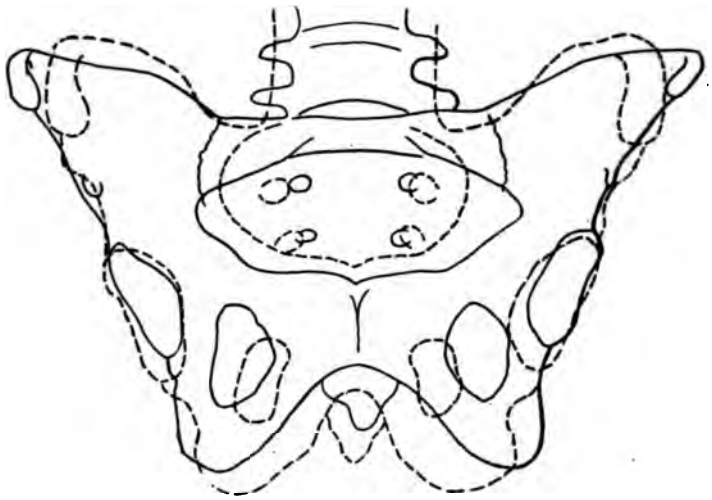
Some of the later changes in the *form of the thorax* are shown in figs. 32, A, B and C. In early stages the thorax is conical and is nearly circular in cross-section. At the time of their origin the ribs lie parallel with one another and are almost horizontal, but they soon incline downward (figs. 44, 45). After birth and particularly after the erect posture is assumed there is a progressive reduction of the relative anteroposterior diameter of the thorax and its base is relatively contracted. These changes are possibly due in part to the effect of gravity on the viscera and to the reduction in relative size of the organs of the upper abdominal region.

The postnatal growth of the thorax, as determined by external measurements, particularly of the horizontal chest circumference, seems to follow the course of the growth of the body in height and weight. There is a period of rapid increase in infancy and a part of early childhood, a period of slow growth in middle childhood, followed by a phase of rapid growth in prepuberty and perhaps early adolescence, and finally a terminal period of slow increase to maturity.

The pelvis.—The pelvis is formed in part from the fixed vertebræ of the sacrum and coccyx, which are developed around the lower portion of the notochord, and in part from the blastemal ossa coxæ which are developed from the proximal portions of the mesenchymal cores of the lower limb-buds. These elements are not closely associated at the time of their differentiation and the complete pelvic girdle with definite fundaments of the pubic symphysis and the sacroiliac articulations is not established until about the end of the second month. In early fetal life the pelvis is relatively small. After the third month all of the pelvic diameters grow at approximately the same rate and there are no great changes in the shape of the pelvis from this time to birth.

The *pelvis of the newborn* differs from that of the adult in a number of particulars (fig. 33). It has a distinctly conical form and its length is greater in proportion to the transverse and conjugate diameters. The pelvic cavity is relatively as well as absolutely much smaller than in the adult. The superior aperture approaches a circle more closely than in later life, although

FIG. 33.—DRAWING OF ANTERIOR VIEWS OF THE PELVES OF AN ADULT MALE AND A MALE NEWBORN DRAWN TO THE SAME ABSOLUTE SIZE AND SUPERIMPOSED. Adult pelvis in solid line, newborn pelvis in broken line. (After Merkel.)



even at birth the transverse diameter is greater than the conjugate. The dimensions of both the lesser pelvic cavity and the inferior aperture are smaller in proportion to the superior aperture than at maturity. The sacrum forms a greater portion of the pelvic circumference and is less depressed between the ilia. The sacral promontory is less marked, but a second prominence may be indicated at the level of the linea terminalis. There is little indication of the sacral concavity. The acetabula are very large and shallow at birth while the obturator foramina are relatively small. The pelvis is more vertical in position than later, the plane of the superior aperture forming an angle of 80° in the horizontal as compared with 50° to 60° with the adult, while the long axis of the symphysis pubis is more nearly perpendicular.

During the first 2 years of life the pelvis grows rapidly in all dimensions. This growth is continued at a slower rate from 2 to 5 years, but there is comparatively little increase between 5 and 10 years. There is a second period of more rapid growth in later childhood and adolescence, and by the end of the second decade the pelvis has almost obtained its adult dimensions, although many of the pelvic epiphyses do not unite with the main bones until the twenty-fifth year.

Until the infant assumes an erect position, the pelvis changes but little in form. As this position becomes habitual, the sacrum descends between the ilia and the promontory is definitely established. With this there is a relative expansion of the ala of the ilia, an increase in the pubic angle and a bending of the sacrum backward. The increase in the transverse diameter of the pelvis is brought about mainly by the growth of the sacrum and the posterior parts of the ilium. Growth also takes place along the line of apposition of the three divisions of the os coxæ in the acetabulum, but there is probably comparatively little growth, at least in males, at the symphysis pubis. The pelvic growth which occurs after puberty is practically all epiphyseal.

Sexual differences in the pelvis appear about the sixth fetal month, mainly in the form of differences in the pubic angle and the shape of the ilia. The pelvis of the newborn male is larger than that of the female, the sacrum is relatively wider, the ilia less vertical, the pubic angle more acute and the acetabula shallower and more horizontal. The sexual differences of the newborn pelvis, aside from those of size, are usually masked in the early period of rapid

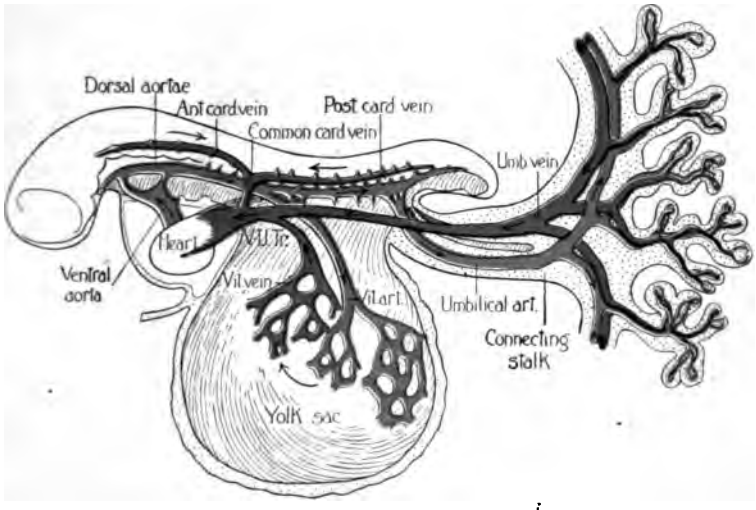
growth and do not reappear until the prepuberal period. During the first decade the pelvic measurements of boys are usually larger than those of girls, but after this time the dimensions of the female pelvis are generally the greater.

THE VASCULAR SYSTEM

In this section the consideration of the vascular system will be limited to a description of the establishment and course of the early embryonic circulation, an account of the fully established circulation of the late fetus, and the changes in the circulatory system at birth; including an outline of the general growth of the vascular structures. The morphologic changes by which the various segments of the embryonic circulatory system are transformed to the adult structures are described in connection with the VASCULAR SYSTEM (pp. 668 and 724).

In man and the higher mammals the development of the vascular system is extremely precocious, due to the small amount of food substances stored in the ova of these forms and the consequent necessity of a system of vessels which can draw nourishment and oxygen from the maternal circulation and distribute them to the tissues of the embryo.

FIG. 34.—DIAGRAM OF THE CIRCULATION OF A YOUNG HUMAN EMBRYO. (Based in part on the figures of Watt and Brödel.)



Fundaments of the first vessels in man appear in the form of cords, cellular strands, and cysts in the extraembryonic mesoderm at a stage preceding the establishment of the embryo on the germinal disk. These structures are organized into two sets of anastomosing cords; one, the umbilical or allantoic, which is associated with the connecting stalk, allantois, and the trophoblast; and the other, the vitelline, which spreads out in the mesoderm of the yolk-sac. Trunks formed from these networks pass, in the mesoderm, to the margin of the germinal disk. As the tubular embryo is formed from this structure, they enter the developing body either as definite trunks or as capillary plexuses, and form the framework of the embryonic vascular system.

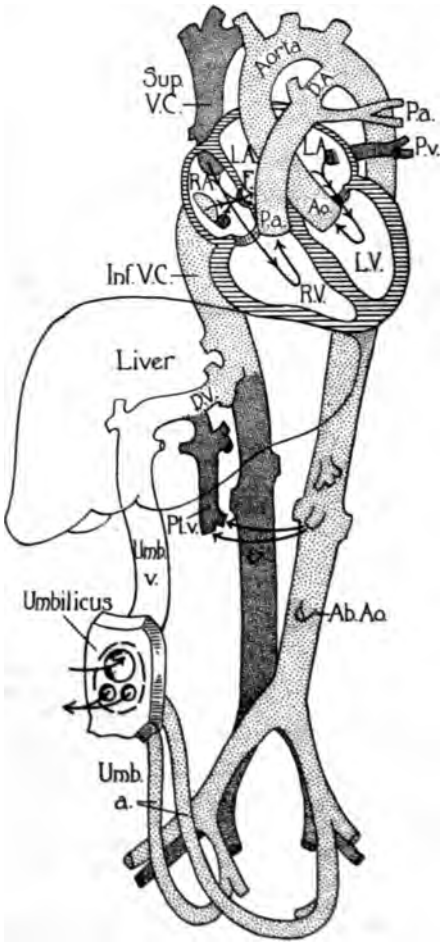
The course of the embryonic circulation.—The form of the circulatory system in the young embryo is illustrated by fig. 34. The blood from the capillaries of the chorion (the modified trophoblast) passes to the embryo through the paired umbilical or allantoic veins. Before entering the embryo these vessels are joined by the vitelline veins which collect the blood from the yolk-sac. These vessels form the vitelline-umbilical trunks (V.U.Tr.) which enter the body, on either side, in the splanchnic mesoderm below the foregut and join in the tubular heart, which is formed from them. From the heart the ventral aortæ pass below and then around the anterior part of the foregut and gaining its dorsal surface run backward as the paired dorsal aortæ. The dorsal aortæ give off the vitelline arteries (Vit. art.) which return blood to the capillaries of the yolk-sac and finally terminate in the umbilical or allantoic arteries which run to the chorion through the connecting stalk and end in the chorionic capillaries. The dorsal aortæ also give rise to a number of segmentally placed arterial sprigs which supply the tissues of the embryo. The blood from these vessels is collected by venules which empty into longitudinal venous trunks, the anterior and posterior cardinal veins. The cardinal veins on either side drain into a short common cardinal vein (duct of Cuvier) which opens into the posterior part of the heart-tube in common with the vitelline-umbilical trunks.

The umbilical veins are the nourishing vessels of the embryo, since they carry blood from the chorionic capillaries where it has received oxygen and food-stuffs (by osmosis) from the maternal circulation. These substances are absent from the vitelline veins, since the yolk-sac of the human embryo contains no reserve food material. Theoretically, at least, there is a mixture of arterial blood from the umbilical vessels and venous blood from the common cardinal veins in the posterior end of the heart; but the actual difference between the arterial and venous blood in the young embryo is probably very slight since the volume of the blood-stream is relatively large and the rate of circulation presumably very rapid.

The fetal circulation.—The course of the blood in the late fetus is shown in diagrammatic fashion in figs. 35 and 586. The pure or arterial blood from the placental capillaries enters the body by the single umbilical vein, and passes through this vessel to the liver where it is joined by a branch of the portal vein carrying venous blood. The blood from the sinus formed by the union of these two vessels passes through the *ductus venosus* which joins with the inferior vena cava (either directly or through the left hepatic vein). As the vena cava is carrying blood from the capillaries of the lower part of the body there is a further mixture of venous and arterial blood at this point. The stream of mixed blood now passes through the terminal portion of the vena cava and enters the caudal portion of the right atrium. The superior vena cava also enters the right atrium, bringing back venous blood from the head and superior extremities. The opening of the superior vena cava with its valves is so placed that the stream from this vessel is directed toward the *foramen ovale* between the right and left atria.

FIG. 35.—DIAGRAM OF THE FETAL CIRCULATION.

Ab.Ao., abdominal aorta. Ao., ascending aorta. D.A., ductus arteriosus. D.V., ductus venosus. F., foramen ovale. Inf. V.C., inferior vena cava. L.A., left atrium. L.V., left ventricle. P.a., pulmonary arteries. Pt.v., portal vein. P.v., pulmonary veins. R.A., right atrium. Sup.V.C., superior vena cava: Umb.a., umbilical arteries. Umb.v., umbilical vein.



Despite this anatomical arrangement, however, experimental evidence indicates that the blood of the inferior and superior venæ cavæ is completely mixed in the right atrium. The blood from the right atrium flows in part into the left atrium, where it is joined by a small stream of venous blood, returning from the lungs through the pulmonary vein. It then passes into the left ventricle and thence to the systemic circulation through the arch of the aorta. A portion of the blood from the right atrium passes into the right ventricle and through it to the pulmonary artery. A small part of this stream is diverted to the right and left pulmonary arteries to supply the lungs, but the main current passes through the *ductus arteriosus* (Botalli) to pass into the descending arch of the aorta, joining the stream from the left ventricle which has come through the aortic arch. The blood passing through the aorta continues downward through this vessel, and such as remains after supplying the aortic branches flows into the umbilical arteries and thence back to the capillaries of the placenta.

Several *peculiarities of the fetal circulation* which are particularly striking may be enumerated. But one vessel in the body of the fetus, the umbilical vein, carries strictly arterial blood, and this vessel supplies no part of the body directly, except a small portion of the liver. The blood entering the right atrium from the inferior vena cava has already received venous mixtures from three sources (the portal vein, the inferior vena cava, and the vena azygos major). There is a complete mixture of blood from the superior and the inferior vena cava in the right atrium and a further addition of venous blood from the pulmonary vein in the left atrium. Thus the circulating blood of the fetal body is throughout mixed, venous and arterial. Its efficiency under these conditions probably depends: (1) on its very large quantity compared with the volume of the fetus; (2) on the rapidity of its circulation; and (3), on the relatively slow rate of catabolism (and hence slight amount of waste products) in the fetal organism.

The establishment of the adult circulation.—The change from the fetal to adult type of circulation is brought about by the closure of the fetal blood-passages, the umbilical vessels, the ductus venosus, the ductus arteriosus, and the foramen ovale. In this closure two processes can be recognized; the physiologic occlusion, which takes place immediately after birth, and the anatomical obliteration which occur days, months, or even years later. With the establishment of respiration the ductus arteriosus collapses, and all the blood from the pulmonary artery is forced through the branches of these vessels into the capillary bed of the lungs. This leads to an increased flow from the pulmonary veins into the left atrium and pressure in this chamber rises so that the valve of the foramen ovale is forced against the margin of the interatrial septum and the communication between the two chambers is interrupted. At the same time, with the tying of the umbilical cord, or in most cases even with the simple interruption of this structure, the fetal ends of the umbilical arteries and veins are contracted and their lumina obliterated. With this change, blood no longer flows through the umbilical vein and the current of blood through the ductus venosus ceases.

The actual obliteration of the fetal blood-passages rarely begins in the first fortnight of postnatal life. The obliteration of the ductus venosus is brought about through the interruption of its epithelial lining and invasion of its lumen by the connective tissue of the tunica media and tunica interna. The vessel is generally completely closed by the end of the first month. Obliteration of the ductus arteriosus takes place in much the same way, generally in the first half year of postnatal life, but sometimes not before the close of the first year. The occlusion of the foramen ovale is apparently brought about by the proliferation of connective tissues in the valve and at the margin of the foramen, through the mechanical irritation of these structures by friction in the movements of the heart. At the close of one year the foramen is obliterated in about one-half of all cases, but the opening remains patent to the probe in nearly one-third of adult hearts. The obliteration of the umbilical arteries and vein begin shortly after birth with the organization of the thrombus at the cut end of the vessel; but the process is not complete throughout the intra-abdominal portion of these vessels until several weeks after birth. For changes in the umbilicus, see p. 1403.

The growth of blood-vessels.—In the young embryo the blood-vessels have very thin walls and their caliber is relatively enormous; that of the dorsal aorta, for example, is nearly one-fifth the transverse diameter of the body in the third week. In fetal and postnatal life the blood-vessels continue to increase in absolute diameter even to very old age, but their relative diameter is steadily reduced, at least until maturity. In the developmental period, the different vascular trunks constantly adjust to the changing volumes of the areas which they supply and to modifications in the caliber of vessels which drain from them. Thus the arterial trunks to the head increase in size during the period of rapid growth of this part while those of the lower limbs grow slowly in early life but increase rapidly when these members enter a period of active growth. And the abdominal aorta undergoes an actual decrease in diameter for a period after birth when the umbilical arteries which drain it are obliterated.

The walls of arteries in the fetal period are relatively thicker, compared with the diameters of their lumina, than in postnatal life; but their absolute thickness increases slowly to an advanced age. In fetal life the growth of the walls of arteries takes place almost entirely in the tunica media and tunica externa, the tunica interna remaining almost unchanged from the fourth fetal month until birth. After birth, however, the relative growth of the interna is much more rapid than that of the other coats. Apparently there is little growth of the tunica media after puberty although the interna increases throughout postnatal life.

There are but few observations on the growth of vessels in length, but these seem to indicate that the lineal growth of blood-vessels is closely correlated with the lineal growth of adjacent structures.

Growth of the heart.—In the second fetal month the heart forms about 3.6 per cent. of the body. The relative weight decreases to about 0.7 per cent. at the close of fetal life. With the great increase in the weight of the body in the first year the relative heart-weight drops to about 0.5 per cent., and from this time there is very slow decrease until the middle years of adult life when the average relative weight of the heart is 0.4 to 0.45 per cent. It should be remembered that during fetal life the heart not only sends the blood through the capillaries of the body but also through those of the fetal portion of the placenta. The relation of the weight of the heart to the combined weight of the body and placenta in the latter fetal months is not far from the adult ratio of heart-weight to body-weight (0.47 to 0.45 per cent.).

The growth in absolute weight of the heart in postnatal life follows the course of the visceral group of organs. The birth-weight of the organ (20 to 25 grams) is doubled in the first year, tripled in 4 years and increased 6 to 8-fold by puberty. The total postnatal gain in absolute heart-weight is usually about 12-fold.

The mass of the walls of the various chambers of the heart is distinctly modified in the developmental period. The atria form a considerably larger proportion of the heart-weight in the fetus than in the adult, the reduction in their relative weight taking place mainly in early infancy. In the fetal period the weight of the right ventricle is equal to or greater than that of the left. But the additional work which falls to the left ventricle after the separation of the

systemic and pulmonary circulations at birth causes this portion of the heart to grow so rapidly that by the close of the first year it is nearly twice the weight of the right ventricle.

The lymphoid and sanguifactive organs.—The first *blood-cells* of the human embryo are differentiated in connection with the developing blood-vessels of the yolk-sac: but the liver soon becomes a seat of blood-formation and remains a sanguifactive organ until birth. The *bone-marrow* appears as the primary marrow cavities are formed in the course of the ossification of the different bones, and since the first ossification centers do not appear until the sixth week there is little differentiation of bone-marrow until after the period of the embryo. The *spleen* appears in the fifth week as a thickening of the layers of splanchnic mesothelium of the dorsal mesogastrium, the splenic pulp being differentiated from a mass of dense mesenchyma formed by the proliferation of cells from the splanchnic layer of the region. The fundaments of lymph-glands appear in the third month as collections of lymphoid cells about plexuses of lymphatic capillaries. The formation of lymph-glands continues through fetal life and probably for an indefinite time after birth. For development of the lymphatics in general, see LYMPHATIC SYSTEM, p. 739.

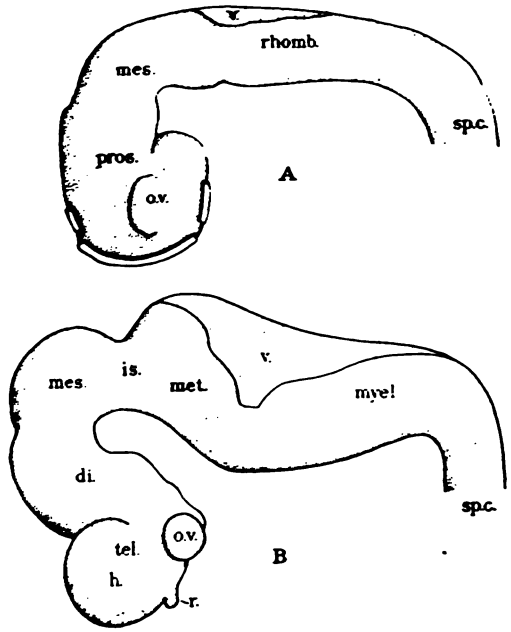
The growth of lymphoid tissue has been considered in connection with the growth of organs. It is characterized by a relatively great amount of lymphoid tissue at birth, an increase in absolute amount until about puberty and a subsequent decline in amount both absolute and relative (fig. 24). The spleen, however, does not follow this course. It is relatively small in early fetal life but increases in the latter part of the period, forming about 0.3 per cent. of the body at birth. During postnatal life it declines in relative weight, forming less than 0.2 per cent. of the body in the adult. The increase in the absolute weight of the spleen in postnatal life follows the course of the splanchnic group of organs.

THE NERVOUS SYSTEM

The early development of the brain.—Even before the neural plate is folded into the neural tube it is differentiated into an anterior expanded portion which represents the brain and a narrower posterior part which represents the spinal cord. As the anterior part of the plate becomes tubular it is further divided by grooves into three swellings or vesicles, the forebrain, midbrain, and hindbrain (figs. 36A and B). As these chambers differentiate, the axis of the

FIG. 36.—A, THE BRAIN OF A 4.0 MM. HUMAN EMBRYO. (From Lewis, after Bremer.) B THE BRAIN OF A 10.2 MM. EMBRYO. (From Lewis, after His.)

Except the isthmus, is., the principal subdivisions of the brain are indicated by prefixes of the term encephalon. sp.c., spinal cord. h., hemisphere. o.v., optic vesicle. r., rhinencephalon. v., roof of the fourth ventricle.



cephalic portion of the tube is bent first at the level of the midbrain (the cephalic flexure) and soon after at the juncture of the hindbrain at the cord (the cervical flexure). The floor of the middle portion of the hindbrain is curved ventrally at a much later time, forming the third or pontine flexure. For further details and figures of the early development of the brain, see pp. 11, 790.

Before the forebrain is completely closed it is expanded transversely forming lateral outpouchings, the optic vesicles. Each optic vesicle forms a distal optic cup which produces the retina of the eye, while its proximal optic stalk remains attached to the forebrain as the optic

nerve. The point of attachment of the optic stalks marks the line of division of the forebrain into two secondary vesicles, an anterior telencephalon and a posterior diencephalon. Somewhat later a second pair of lateral outpouchings are formed from the walls of the telencephalon dorsal to the optic evaginations. These are the cerebral vesicles. They form the cerebral hemispheres and (secondarily) the olfactory lobes and tracts. The diencephalon forms a smaller part of the forebrain. Its floor is depressed posterior to the optic stalks, forming the embryonic infundibulum from which are differentiated the posterior lobe of the hypophysis, the mammillary bodies, the tuber cinereum, and the infundibulum of the adult. The lateral walls of the diencephalon are thickened forming the thalamus and geniculate bodies. The roof becomes membranous anteriorly to form the epithelial layer of the tela chorioidea; posteriorly it forms the pineal body.

The walls of the mesencephalon become greatly thickened, their dorsal portion forming the corpora quadrigemina and their ventral portions the greater part of the cerebral peduncles (crura cerebri).

Three secondary divisions can be recognized in the hindbrain or rhombencephalon: (1) a narrow isthmus, which is continuous with the mesencephalon anteriorly; (2) a short middle segment, the metacephalon; and (3) a large posterior portion, the myelencephalon. The isthmus changes little in form in later development. It is represented in the adult by a portion of the brain-stem which includes the anterior medullary velum, and parts of the brachium conjunctivum (superior cerebellar peduncles) and of the cerebral peduncles. The metencephalon forms an expanded and thickened ring of the brain-tube immediately behind the isthmus. Its dorsal part forms the cerebellum and its ventral portion the pons. In early stages the myelencephalon forms a widely expanded chamber with a membranous roof and a thick floor which is continuous with the cord without any sharp line of demarcation. The myelencephalon becomes the medulla oblongata, a part of the roof forming the posterior medullary velum.

The spinal cord.—In the young embryo the spinal cord extends to the extreme caudal end of the body; but with the regression of the tail in the latter part of the second fetal month there may be recognized an anterior or trunk portion which will form the definitive spinal cord, and a posterior or caudal segment which undergoes partial involution, forming the filum terminale. The distinction between these two portions is definitely established before the middle of the third month. The cervical and lumbar enlargements of the cord can be recognized by the end of the third month. For relations at various stages, see figs. 43–48.

The cerebrospinal cavities.—The central lumen of the neural canal is never lost but exists throughout life in a modified form as the central canal of the spinal cord and the ventricles of the brain. The lumen in the lower end of the trunk portion of the spinal cord remains as a chamber of some size, the *ventriculus terminalis*, but in the remainder of the cord it is reduced in relative size through the fusion of the dorsal part of the lateral walls to the minute central canal. In the myelencephalon and the metencephalon the lumen is expanded, forming the fourth ventricle; while in the isthmus and mesencephalon it is reduced to a narrow channel, the Sylvian aqueduct. The third ventricle represents the expanded anterior end of the canal in the forebrain and the lateral ventricles its lateral extensions which are produced with the evagination of the cerebral vesicles, the points of origin of these extensions being represented by the interventricular foramina. The epithelial layers of the choroid plexuses which project into the third and fourth ventricles are formed by the invaginations of the membranous wall of the brain in these regions and the morphologic continuity of the walls of the canal is not interrupted, at least during the embryonic and the early fetal periods. The so-called fifth ventricle (cavum septi pellucidi) has no developmental relation to the cerebrospinal cavities, being formed much later between the apposed medial walls of the hemispheres.

Growth of the central nervous system.—The relative weight of the central nervous system in the developmental period has been considered in connection with the general growth of systems. The absolute weight of the *brain* at the end of the third fetal month is about 3.5 gm. This is increased about 10-fold by the middle of the fetal period and about 100-fold by birth. The weight of the *brain* is more than doubled in infancy and is increased about 3-fold by the close of the first period of childhood. Thereafter the rate of absolute growth is very slow, the adult weight, which is about 3.6 times that of the newborn, being commonly attained by the close of the fifteenth year.

The *spinal cord* weighs about 0.15 gm. at the close of the third fetal month, increasing about 5-fold by the middle of the fetal period and 20-fold by birth. The cord increases about 8-fold in postnatal life, most of this growth taking place in infancy and early childhood. The spinal cord forms about 15 per cent. of the central nervous system in the second fetal month but thereafter it forms a decreasing proportion until birth when it is less than 1 per cent. In postnatal life, on the other hand, this ratio gradually rises to about 2 per cent.

The parts of the brain also show changing relations in relative size during the developmental period. The *brain-stem* follows the course of the cord, forming a larger proportion of the brain in fetal life, a gradually decreasing proportion in the later part of prenatal life, and a small relative increase after birth. The *cerebellum*, on the other hand, grows very slowly in early fetal life but in the later fetal months enters a period of rapid relative growth which continues through infancy and early childhood. It forms about 3 per cent. of the brain in the third fetal month, about 6 per cent at birth, and about 10 per cent. in maturity. For topography of the developing brain, see figs. 43–48, also fig. 746.

The development of the peripheral nerves.—When the neural tube separates from the surface ectoderm there is left between these two structures a narrow plate of ectodermal cells known as the neural crest. These cells give rise to all of the sensory nerves of the cerebrospinal system, with the exception of the optic and olfactory nerves whose development is considered in connection with the sense organs. The motor nerves and the motor portions of the mixed nerves, on the other hand, are all formed as processes from cells located in the ventral or ventrolateral portion of the neural tube. The course of development of the spinal and cranial nerves is described in the section on the NERVOUS SYSTEM.

The eye.—Four elements enter into the formation of the main structures of the eye. These are: (1) the optic vesicle, derived from the lateral wall of the forebrain; (2) the lentic or optic placode, formed by a thickening of the surface ectoderm over the optic vesicle; (3) a zone of surface ectoderm immediately surrounding the lentic placode but which does not share in its thickening; and (4) the head mesenchyma which surrounds the optic vesicle and placode.

The optic vesicle gives rise to the retina (both nervous and pigmented layers), the epithelium covering the posterior surface of the iris and ciliary body and the optic nerve. The lentic placode is converted into a lentic vesicle which later forms the lens. The surface ectoderm immediately surrounding the lentic placode produces the anterior epithelial layer of the cornea, the epithelium of the conjunctiva and the parenchyma of the lacrimal gland. The surrounding mesenchyma forms the sclerotic and choroid coats of the eye and their derivatives. The vitreous body is probably derived in part from the ectodermal and in part from the mesenchymal elements of the eye. The further history of the eye is described in connection with the section on the SPECIAL SENSE ORGANS (p. 1114).

The ear.—As has been previously described (pp. 17, 29), the outer ear is formed from the first branchial groove or cleft, the middle ear is a derivative of the first branchial pouch, and the auditory ossicles are formed from the upper ends of the cartilages of the first and second branchial arches. The inner ear is formed from the otocyst, a closed sac formed from the otic or auditory placode which appears as a thickening of surface ectoderm above the first branchial arch. The development of the ear is considered in more detail in the section on the SPECIAL SENSE ORGANS (p. 1129).

The ear in childhood.—The ear of the newborn and infant differs from that of the adult in several important details. The external auditory meatus is relatively short and straight and there is no true bony meatus. The tympanic membrane is slightly smaller than in the adult, but it acquires its full size in infancy. It is slightly more horizontal in early life. The tympanic cavity and ossicles have reached their full size at birth and the epitympanic recess and antrum are quite as large as in maturity if not larger. The antrum lies entirely above the tympanic cavity and its lateral wall is only about 1 mm. thick. The mastoid process does not develop until after the first year and the mastoid cells usually appear in later childhood. The auditory (Eustachian) tube has about one-half of its adult length at birth but its diameter is quite as great as in maturity. The tube is almost horizontal in the infant, the oblique course of the adult tube being acquired with the growth of the nasopharynx in middle and later childhood. The internal ear has practically its adult dimensions at birth.

The olfactory organ.—The organ of smell is developed from the epithelium of the upper part of the nasal fossæ, whose history is described later in connection with the development of the digestive tract. The olfactory nerve is formed by the processes of specialized cells which remain in the olfactory mucosa. A rudimentary olfactory organ, the *organ of Jacobson*, is represented in the embryo by a pair of small pouches in the nasal septum. These usually disappear in the later part of fetal life.

THE DEVELOPMENT OF THE DIGESTIVE TRACT

Early development.—In the early embryo four main structures may be recognized which play a part in the later development of the digestive and respiratory tracts. These are: (1) the nasal pits and (2) the oral sinus, which are lined with ectoderm derived from the covering of the inferior surface of the head; (3) the archenteron, formed from the entoderm of the roof of the yolk-sac; and (4) the cloacal membrane. These elements form the epithelial linings of the digestive and respiratory tracts and the parenchyma of the glands connected with them. At a later time there is associated with them a considerable amount of mesenchyma which gives rise to the muscular wall and the connective tissue investments of the tubes and to the supporting framework of the associated glands.

Some of the general changes in the development of the digestive tract are shown in figs. 37, 43, 44, 45 and 46. The oral sinus is deepened and its roof gives rise to a median pocket (Rathke's pouch), which later separates and forms the anterior lobe of the hypophysis. At the same time the *buccopharyngeal membrane* separating the sinus from the cephalic end of the pharynx disappears and the ectoderm and entoderm becomes continuous in this region. The foregut is differentiated into an upper expanded pharynx and a lower tubular segment which later forms the esophagus, stomach, and a portion of the duodenum. The *midgut* elongates and its connection with the yolk-sac is reduced to a slender yolk-stalk. The *hindgut* is differentiated into an upper tubular portion and a lower chamber, the *cloaca*. The latter gives origin to the allantois and its floor is formed in part by the cloacal membrane. The cloaca is later divided, in the frontal plane, into a dorsal rectum continuous with the midgut and a ventral urogenital sinus which receives the allantois.

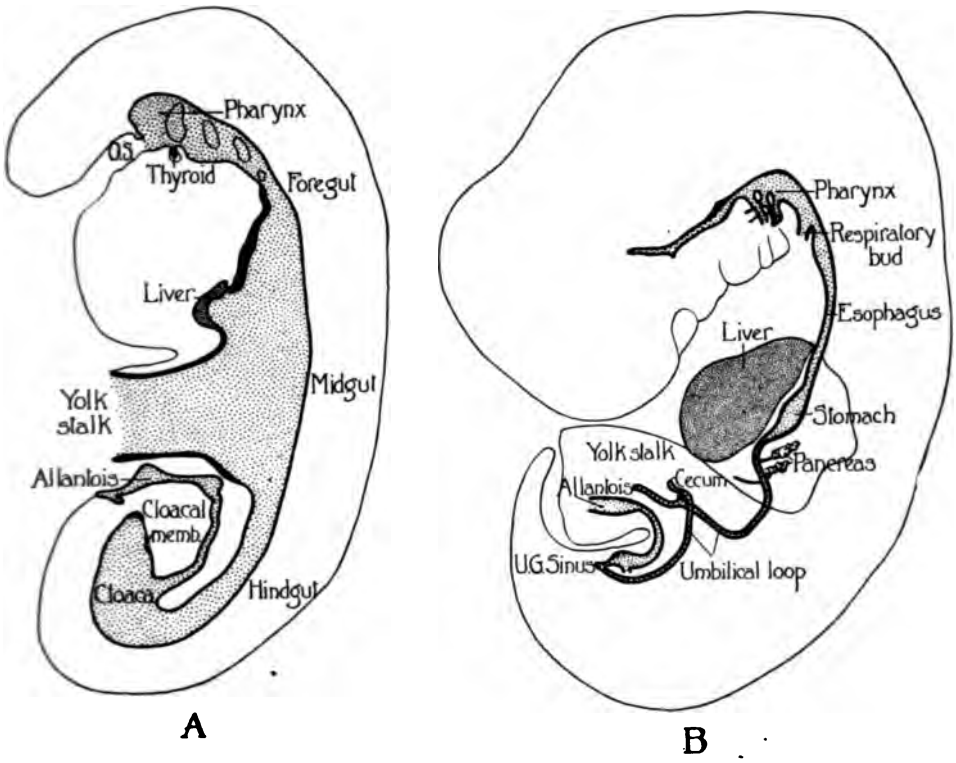
The mouth.—The floor of the embryonic mouth or oral sinus is formed by the inner surfaces of the mandibular processes. The margins of its roof are formed laterally by the maxillary processes and anteriorly by the medial nasal process; and its central portion includes two membranous plates which separate the oral cavity from the *nasal pits* above. These plates soon disappear and the oral sinus communicates with the nasal chambers by paired *primitive choanæ* (fig. 38). The definitive palate is formed by the growth of the paired *palatine shelves* which arise from the medial borders of the maxillary processes and grow toward each other, fusing in the midline. In this manner the upper part of the original oral cavity is left above the palatine shelves, forming the inferior portions of the permanent nasal fossæ. The formation of the boundaries of the mouth has been considered in connection with the development of the face (p. 16). After their establishment they are invaded by ridges of oral epithelium which form the oral vestibule separating the lips and cheeks from the alveolar processes.

The teeth.—The teeth are formed in part from the oral ectoderm and in part from the mesoderm of the cores of the maxillary and mandibular arches. The ectodermal portion arises as

vertical outgrowths from oral epithelium known as dental shelves, which extend into the alveolar processes and lie parallel with and medial to the labial grooves. A series of twenty cup-shaped expansions, the *enamel organs*, form on the free edges of the dental shelves. Each of these covers, in part, a small mass of condensed mesenchyma, the *dental papilla* (figs. 39 and 40).

FIG. 37.—RECONSTRUCTIONS OF THE DIGESTIVE TRACT.

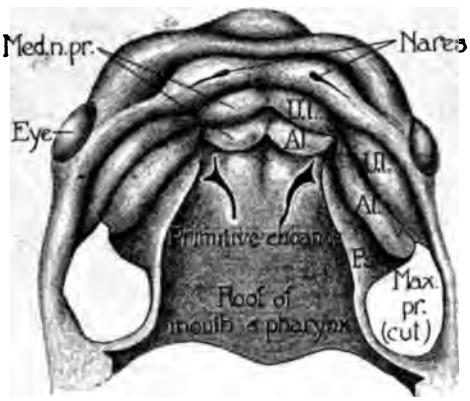
A, of an embryo 2.5 mm. long. (After Thompson and Lewis.) B, of an embryo 10 mm. long. (After Phisalix.)



The enamel organs enlarge rapidly and their connections with the dental shelves are reduced to slender necks. Each organ is differentiated into three parts: (1) a thin outer membrane attached by the neck to the dental shelf; (2) an inner membrane composed of a single layer of

FIG. 38.—RECONSTRUCTION OF THE ORAL REGION OF AN EMBRYO OF THE SECOND MONTH. (From Schaeffer after Kollman and Keith.)

Al., alveolar processes. Max.pr., maxillary process. Med.n.pr., medial nasal process P.s., palatine shelves. U.l., upper lip.

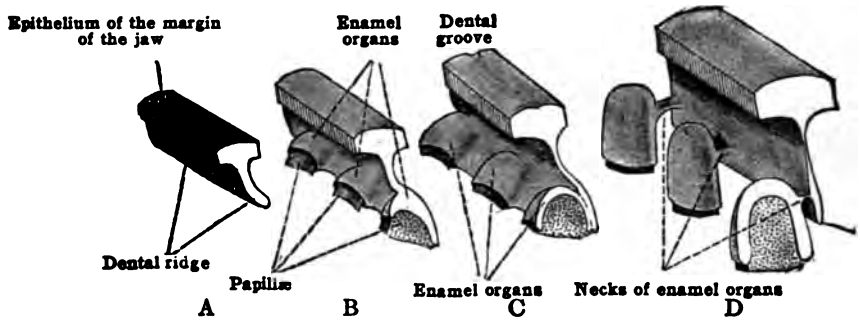


high columnar cells or ameloblasts; and (3) an intervening spongy mass, the enamel-pulp. Coincident with these changes the dental papilla is differentiated into a peripheral layer of columnar cells or odontoblasts, which immediately underlies the inner layer of enamel organ, and a dense central core which is highly vascularized.

The portion of the dental shelves which is not involved in the formation of the deciduous teeth gives rise to a second set of enamel-organs for the permanent dentition.

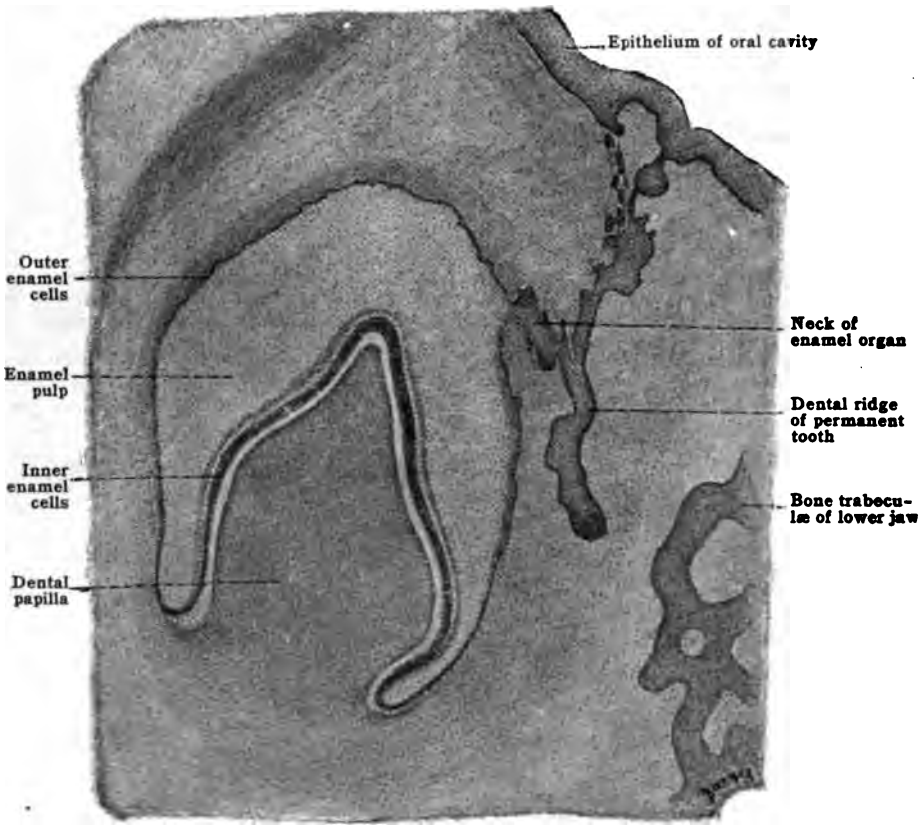
The *calcification* of the teeth begins in the eighteenth fetal week after the crowns are well outlined (fig. 40). The process starts at the crown of the tooth and extends toward the root. Simple teeth, such as the incisors, have single centers of calcification while teeth with two or more cusps have separate centers for each cusp, which soon fuse in a single mass. Calcification

FIG. 39.—DIAGRAMS SHOWING THE EARLY DEVELOPMENT OF THREE TEETH. One is shown in vertical section. (After Lewis and Stöhr.)



takes place in both the ectodermal and the mesodermal parts of the tooth germ. The cells of the inner layer of the enamel organ (ameloblasts) become greatly elongated and a deposit of enamel, in the form of fine globules, appears at their outer margins and gradually fills the cells, converting them into the *enamel-prisms*. The peripheral cells of the dental papilla (odontoblasts) likewise assume a columnar form and a deposit of dentine is laid down between them

FIG. 40.—SECTION SHOWING LATER STAGES OF TOOTH DEVELOPMENT. (After Szymonowicz.)



and the ameloblasts. As this material increases the odontoblasts retreat toward the center of the dental papilla, but processes which extend from them remain imbedded in the dentine as the dentinal fibers. The *cementum* which covers the dentine of the root is produced in connection with the surrounding mesenchyma in a manner similar to the formation of membrane-bone. The center of the dental papilla with its blood-vessels, lymphatics and nerves remains as the *pulp* of the tooth.

At the time of birth the germs of all the deciduous teeth and of all the permanent teeth, except the second and third molars, are present, and those of the deciduous teeth and the first permanent molars are partially calcified. The germs of the second permanent molars are formed in the second postnatal month but those of the third molars do not appear until about the fifth year. The later history of the teeth, including the chronology of their eruption, is considered in connection with the digestive tract (p. 1154).

The tongue.—The anterior part of the tongue is formed from a pair of lateral lingual swellings which appear in the floor of the mouth, at the level of the first branchial arch, early in the second month. These fuse together medially, replacing an earlier median swelling in this region, the *tuberculum impar*. The posterior part of the tongue is formed from the medial portion of the second, and possibly the third, branchial arch. The *musculature* of the tongue arises in situ from the thickened mesenchyma of the lingual region but its innervation (by the hypoglossal nerve) as well as its comparative development indicate that it was originally derived from certain of the occipital somites. The epithelium of the tongue is probably partly of ectodermal and partly of entodermal origin, the terminal sulcus indicating the boundary between the two layers.

FIG. 41.—DIAGRAM TO SHOW THE DERIVATIVES OF THE BRANCHIAL POUCHES.

The salivary glands.—The parotid gland is formed from a shelf-like outgrowth of the epithelium at the angle of the mouth between the maxillary and mandibular processes; and the submaxillary and sublingual glands are formed from similar outgrowths from the medial and lateral angles of the grooves between the tongue and lower alveolar processes. The general scheme of the later development of submaxillary and parotid glands and the major portion of the sublingual gland is much the same. Each grows backward as a keel-like flange which becomes detached from the oral epithelium except for a small anterior connection which represents the future ostium of the duct of the gland. The proximal portion of the outgrowth forms the main duct of the gland, the distal expanded portion giving rise, by repeated divisions, to the smaller ducts and alveoli. The minor sublingual mass is developed from a series of separate outgrowths.

The pharynx.—The pharynx forms a considerable portion of the digestive tube in the young embryo. Its relative size undergoes a marked decrease in fetal life, followed by a slower reduction after birth. During infancy and childhood the length of the pharynx increases rapidly while the anteroposterior diameter grows slowly and the width remains almost unchanged. All diameters increase in middle and later childhood but the growth in length is still the most rapid. In adolescence there is a limited growth of all diameters.

During the fourth week four pairs of *branchial* (*pharyngeal*) *pouches* are formed from the lateral walls of the pharynx and a single median outgrowth (the thyroid diverticulum) appears in its floor. The pharyngeal pouches correspond in position to the branchial grooves, which are formed on the external surface of the neck, and are separated by the branchial arches. They give rise to a number of structures which are quite dissociated in later life (figs. 41 and 56).

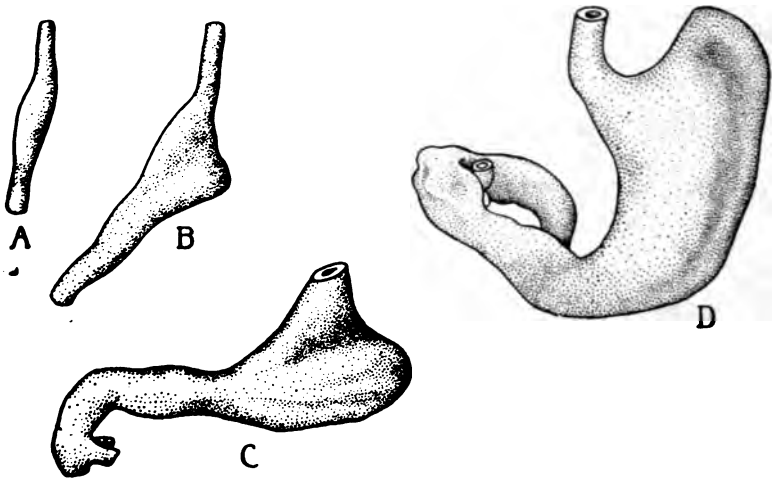
The *first pouch* is directed dorsally and laterally. Its outer extremity is expanded forming the tympanic cavity of the middle ear, while its proximal part is converted into the auditory (Eustachian) tube. A dorsal recess from the *second pouch* forms the tonsillar sinus and the epithelial portion of the palatine tonsil. The histories of the *third* and *fourth pouches* are similar. Both form dorsal and ventral diverticula, the former giving rise to the parenchyma of the parathyroid glands and the latter to the reticulum and thymic (Hassal's) corpuscles

of the thymus. The stalks of these pouches merge in the piriform recess. A pair of small *ultimobranchial bodies*, which possibly represent a fifth pair of pouches, arise from the lateral walls of the pharynx behind the fourth pouches. They form epithelial masses which migrate into the cervical region and are intimately associated with the thyroid. It is improbable that they form any part of this structure but they may give rise to small epithelial masses known as the *glandula insularis cervicalis*.

The palatine tonsils.—About the fourth fetal month solid epithelial buds from the floor of the second pouch invade the surrounding connective tissue. These are later converted into the fossulæ and glands of the palatine tonsil. Lymphoid cells are found in the mesenchymal tissue under the tonsillar epithelium in the sixth fetal month, but definite lymphoid nodules are not present until nearly the time of birth. The postnatal growth of the palatine tonsil is extremely variable. In many cases they reach their highest development in the fifth or sixth year and involution takes place in later childhood. Apparently, in other instances, their growth may continue to puberty or early adolescence. Early in the third fetal month the *plica triangularis* arises from the floor of the pharynx opposite the second pouch and grows upward over a portion of the tonsillar sinus. At the time of birth the plica triangularis forms a fold which surrounds the tonsil, except for a small portion of its posterior border, and covers a part of its free surface. The fusion of the plica triangularis with the walls of the tonsillar sinus is already under way at this time and many specimens show the characteristic subdivisions of the cavity which are found in the adult. In later fetal life and at birth the tonsil lies somewhat higher in the sinus than in later life and its axis is horizontal. The tonsil descends during infancy and its longer axis becomes vertical.

FIG. 42.—DEVELOPMENT OF THE STOMACH.

A, embryo 5 mm. long. B, embryo 8 mm. long (after Broman). C, embryo 10 mm. long. D, embryo 19 mm. long (after Lewis).



The pharyngeal tonsil and bursa.—Early in the second fetal month there appears in the roof of the pharynx a small pouch, the *pharyngeal bursa*, from which there develop a series of radiating folds which extend anteriorly nearly to the nasal openings. In the later fetal months these are invaded by lymphoid tissue and are converted into the *pharyngeal tonsil*. The structure reaches its maximum development in early childhood. Its involution generally begins in the prepuberal period and is completed in early adolescence. The bursa pharyngea is commonly converted into a small closed cyst which remains throughout adult life.

The esophagus.—The esophagus in young embryos is a short tube of relatively large caliber, flattened from side to side. During the early part of the second month it becomes considerably elongated but is reduced in relative diameter and assumes a cylindrical form. At birth the tube is 8 to 10 cm. (3 to 4 in.) in length from the cricoid cartilage to the cardia. Its length is doubled in the first three years and tripled by puberty, but there seems to be little longitudinal growth thereafter.

The stomach.—The stomach appears in the fourth week as a spindle-shaped enlargement of the lower part of the foregut. This is soon subdivided by the *incisura angularis* (or gastric angle) into an upper expanded cardiac and a lower tubular pyloric portion (fig. 42). The fundus develops as an outpouching of the cardiac portion in the latter part of the second month and the gastric canal ('Magenstrasse') is established about the same time. A little later the pyloric portion is subdivided into pyloric canal and antrum. As these changes take place the stomach is bent to the right at the level of the incisura angularis, and the entire organ is rotated from left to right through about 90 degrees. After this time the stomach changes little in form until distended by its contents, either before or immediately after birth, when there is a considerable expansion of the fundus, body and greater curvature.

In early stages, the long axis of the stomach is vertical. With the establishment of the incisura angularis it often becomes transverse or oblique but it commonly returns to the vertical position in late fetal life. With the distension which occurs at birth the long axis again becomes obliquely transverse and this position is usual until the erect posture is habitually assumed,

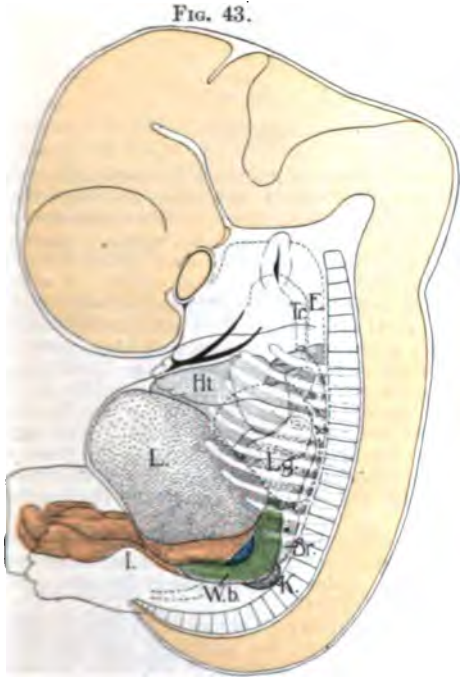

FIG. 45.

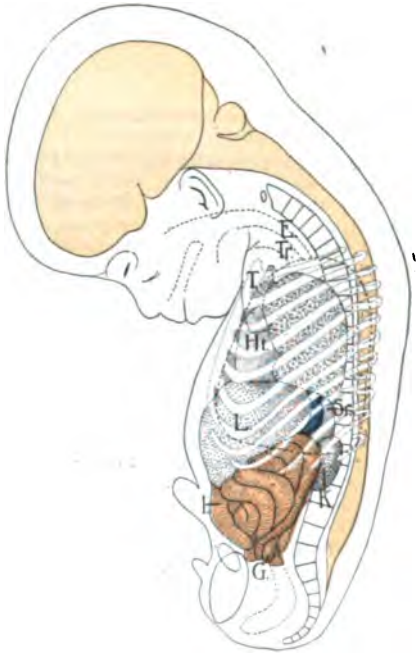

FIG. 46.

when the vertical position again becomes the more common. At the time of its differentiation the stomach lies in the upper part of the thorax but in early fetal life it descends to the upper abdominal region. There is little later change in the positions of the orifices of the stomach but with its subsequent growth in size and changes in form the lower margin gradually descends in the abdomen during the greater part of childhood.

The stomach grows with great rapidity in the latter part of fetal life and this rate is continued in the first trimester of postnatal life. The stomach increases in weight about 24 times between birth and maturity, its postnatal growth following the course of the splanchnic group of organs. The capacity of the stomach at birth is about 30 cc. It rises rapidly to about 90 or 100 cc. at the end of the first month and thereafter increases more slowly to 250 to 300 cc. at the end of the first year.

The development of the intestines.—With the separation of the archenteron from the yolk-sac the intestinal tract is established as a short and relatively straight tube extending from the stomach swelling to the cloaca. This tube in its rapid elongation is thrown into three main or primary loops and a number of secondary ones. The primary loops are: (1) the gastroduodenal loop which forms the upper portion of the duodenum; (2) the enterocolic

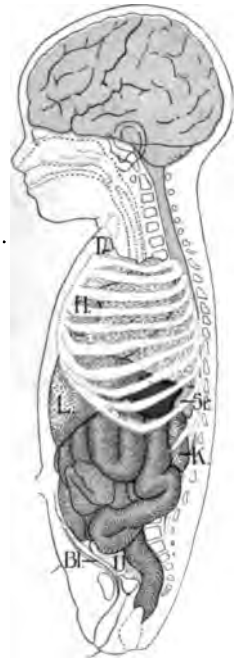

FIG. 47.

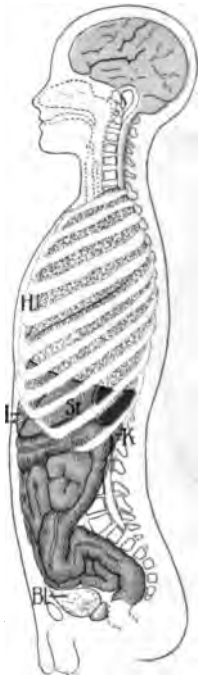

FIG. 48.

or umbilical loop which gives rise to the distal portion of the duodeum, the jejunoileum, and the cecum, ascending colon and a part of the transverse colon; and (3) the left colic loop which forms the remainder of the large intestine. The gastroduodenal loop is short and simple needing no further description. The umbilical loop first lies in the median sagittal plane of the body. It consists of a cranial and a caudal limb and a yolk-stalk arises from its summit which projects into an extension of the body-cavity, the umbilical celom. A slight swelling on the caudal limb marks the position of the cecum and the division between small and large intestines. In its further growth the umbilical loop turns on its axis and its caudal limb is carried first to the left, then anteriorly and later to the right of the proximal one, carrying the cecum with it. The development of the coils of the small intestine (see page 1194) takes place partly in the abdominal and partly in the umbilical celom. During the middle of the fourth month they return rather suddenly to the abdominal cavity and following this the first part of the colon and the cecum pass ventrally over the small intestines to lie in the right hypochondriac region below the liver. Later the cecum descends into the right iliac fossa to a level a little below that occupied in the adult. Its final position is acquired in early childhood after a slight ascent which is probably associated with the postnatal growth of the lumbar region.

The left colic loop is formed by the bending of the lower part of the intestinal tube to the left side of the abdominal cavity some time after the formation of the other primary intestinal loops. Secondary curves in this loop form the left colic (splenic) and sigmoid flexures. For further details on the development of the intestines, see p. 1204.

The cecum and vermiform process (appendix).—The formation of the swelling which represents the cecum was mentioned above. After the rotation of the umbilical loop the cecal swelling is extended as finger-like projection from the ventral surface of the gut. A small diverticulum which represents the vermiform process arises from the apex of this projection in the third fetal month (fig. 50). The vermiform process grows rapidly, reaching its full rela-

tive length (as compared to the length of the intestine) by the middle of fetal life. In the fourth month the cecal projection is bent at right angles to the main axis of the segment of the intestine from which it arises and the ileocecal valve is formed by invagination of the terminal portion of the walls of the ileum at this point. At birth the cecum is relatively small. Its

lower end becomes directly continuous with the vermiform process without a sharp line of demarcation and the cecal sacculations are generally absent. The appendix usually lies directly below the cecum at this time, or is bent upward at an acute angle along its medial margin. The development of the cecal sacculations and the formation of a distinct cecal fundus usually takes place in early childhood (generally in the third or fourth year).

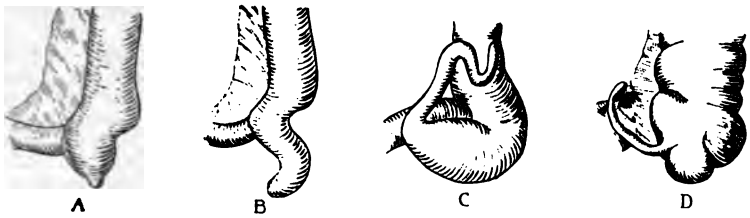
A, embryo at the end of the second month. B, fetus of the third month. C, child ten weeks after birth. D, child of 5 years.



The rectum and anal canal.—The rectum is formed from the dorsal portion of the cloaca which is separated from the urogenital sinus by the formation of the urorectal septum. At the same time the posterior part of the cloacal membrane is separated from the anterior portion and forms the *anal plate* which is later invaginated forming the anal canal. The rectum and anal canal are separated until comparatively late in the development by the *anal membrane* which lies at the level of the future anal valves. A want of rupture of the anal membrane is known as congenital atresia of the anus.

Growth of the intestines.—The growth of the intestines in the early part of prenatal life is very rapid. At birth they form about 1.5 per cent. of the body as compared with 0.75 per cent. in maturity. The absolute length of the intestines at birth is usually between 350 and 400 cm. (12 to 14 feet). The intestinal tract grows about 50 per cent. in length in the first

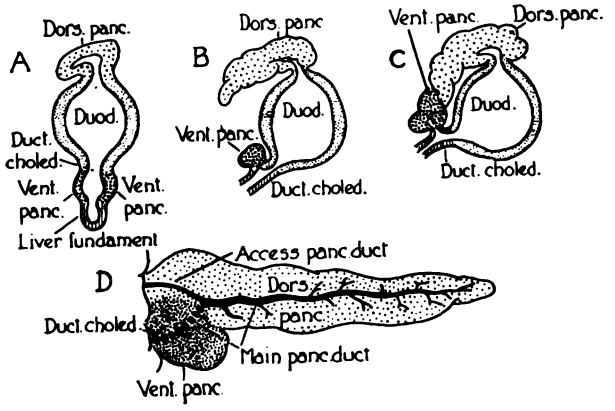
year. Thereafter the increase is much slower, the length in the adult being about 2.5 times that of the newborn.

In the early part of the embryonic period the large intestine forms nearly one-half of the length of the intestinal tract. But by the fourth fetal month it is reduced to about one-fifth of the total length of the intestines and this ratio is maintained throughout the remainder of life, except for a period of increase in the length of the colon in the latter fetal months due to its distension by meconium.

The liver.—The liver arises in the third week as a thickened area in the floor of the posterior part of the foregut (figs. 37A, 43, 51, 62). This area forms a small, thick-walled pouch in which

FIG. 52.—A, B, C, DIAGRAMS ILLUSTRATING THE DEVELOPMENT OF THE PANCREAS. (After Laguesse.) D, DIAGRAM ILLUSTRATING THE EMBRYONIC CONSTITUENTS OF THE ADULT PANCREAS. (After Charpy.)



may be recognized an anterior hepatic and a posterior cystic portion. The cystic part forms the common bile-duct, the gall-bladder and cystic duct, and probably the main hepatic ducts. The hepatic portion gives rise to a large number of cellular cords which anastomose freely interdigitate with the neighboring veins, and form the parenchyma of the liver. Certain of these cords, which lie close to the developing portal veins, form the minor hepatic ducts. For further details on the development of the liver, see p. 1215 and figs. 918, 963.

The liver grows with great rapidity in the embryonic period forming over 7 per cent. of the body in the second and third fetal months. After this time the relative weight declines to about 4 per cent. at birth, 3 per cent. in childhood and 2.5 per cent. in maturity. The postnatal growth of the liver in absolute weight follows the general course of the splanchnic viscera

and the total increase between birth and maturity is about 13-fold. In fetal life the gall-bladder is small in proportion to the liver, being more or less buried in its substance, but it grows rapidly in infancy and the adult relation between these structures is established by the end of the second year.

The pancreas.—The pancreas (fig. 52) arises in the fourth week from two thickenings of the wall of the posterior part of the foregut. The first of these to appear is the dorsal pancreas which is formed from the roof of the primitive duodenum caudal to the fundament of the stomach. The second or ventral pancreas, which is sometimes a paired structure, arises from the floor of the gut at the cephalic end of the liver-pouch. Both diverticula differentiate into proximal stalks and distal expanded portions, the former forming the main ducts of the gland and the latter giving rise to the minor ducts and alveoli. Both pancreatic diverticula turn to the right in their growth and, passing around the right side of the intestine, come in contact near the point of origin of the ventral pancreas. Later, in connection with the rotation of the intestinal tube, the pancreas is shifted to the left of the duodenum. A fusion of the two elements takes place through the anastomosis of their main ducts. In later life the ventral pancreas is represented by the proximal portion of the main pancreatic duct and the lower part of the head of the pancreas. The remainder of the parenchyma of the gland, the accessory pancreatic duct (when present) and the distal portion of the main duct are derived from the dorsal pancreas. The relation of the pancreas to the primitive mesentery is shown in figs. 918 and 966.

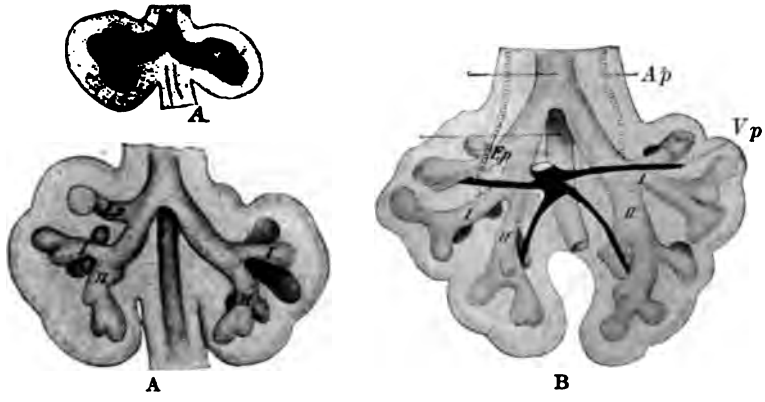
The pancreas grows relatively slowly until the sixth fetal month when it enters on a period of more rapid growth which extends well into the first year of postnatal life. The organ increases in weight nearly 30 times in postnatal life. Its general course of growth is that of the splanchnic group of viscera.

THE RESPIRATORY SYSTEM

Early development of the respiratory system.—The entodermal fundament of the respiratory system arises in the third week as a median groove in the hind part of the floor of the pharynx. The cranial portion of this groove, which represents the larynx, remains attached to the pharynx while the caudal portion grows downward as a respiratory bud which represents the trachea and the lungs (figs. 37B, 43). The free end of the respiratory bud is expanded into a rounded vesicle which immediately bifurcates into right and left branches or lung-buds.

FIG. 53.—RECONSTRUCTION OF THE LUNG OUTGROWTHS OF EMBROYOS OF (*A*) 4.3, (*B*) 8.5., AND (*C*) 10.5 MM.

Ap, Pulmonary artery; Ep, eparterial bronchus; Vp, pulmonary vein; I, second lateral bronches; II, main bronchi.—(His.)



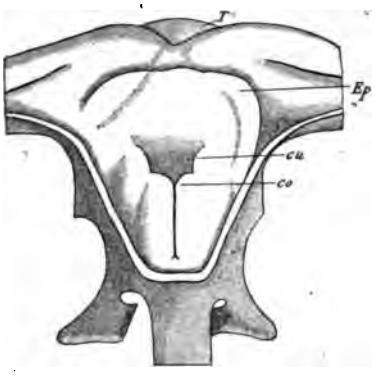
The larynx.—The cranial end of the respiratory groove forms a T-shaped cleft which is bounded anteriorly by a transverse ridge, the fundament of the epiglottis, and laterally by paired arytenoid swellings which represent the cuneiform and corniculate tubercles and the arvepiglottic folds. The epithelial surfaces of the arytenoid swellings soon fuse, forming a plate which obliterates the upper part of the respiratory groove. The cavity of the larynx is reestablished in the second month by the disintegration of the central cells of this plate. The ventricle and ventricular and vocal folds are formed by lateral extensions of the laryngeal cavity in this region.

The **laryngeal cartilages** are differentiated in the mesenchyma surrounding the epithelial tube of the larynx. Their chondrification begins in the second fetal month but is not completed until shortly before birth. The derivation of the thyroid cartilage is considered in connection with the development of the branchial skeleton (p. 29).

The larynx is relatively large in the fetus and newborn. At birth the absolute vertical dimensions are a little less and the transverse dimensions a little more than one-third those of the adult (fig. 55). Three phases can be recognized in the postnatal growth of the larynx: (1) a period of general rapid growth from birth to 2 or 3 years: (2) a succeeding period to prepuberty in which growth proceeds rather slowly although there are some alterations in form: and (3) a second period of rapid growth (most noticeable in males) in later childhood and adolescence. Sexual differences are said to appear in the larynx in the third year and after this time the male larynx is larger than the female. The larynx gradually descends in the neck during the fetal period and childhood.

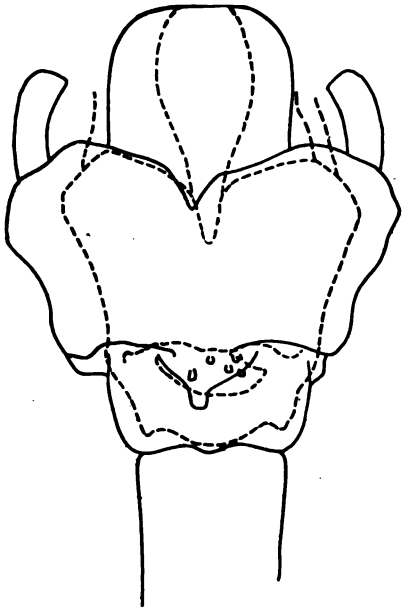
The trachea.—The trachea is formed from the portion of the respiratory bud lying between the laryngeal groove and the lung-buds. The tracheal cartilages and musculature develop in the second month from the mesenchyma surrounding the tube, and the tracheal glands first appear towards the close of the third month. The length of the trachea is nearly tripled between birth and maturity. The diameter of the trachea increases 4 or 5-fold after birth.

FIG. 54.—RECONSTRUCTION OF THE OPENING INTO THE LARYNX IN AN EMBRYO OF TWENTY-EIGHT DAYS. Seen from behind and above, the dorsal wall of the pharynx being cut away. (From McMurrich after Kallius.) co, Cornicular, and cu, cuneiform tubercle. Ep, epiglottis. · T, unpaired portion of the tongue.



The lungs.—The lining of the bronchial tree and the alveoli (air-cells) of the lungs is formed by the repeated division of the lung-buds and their branches (fig. 53). While the terminal branches of the bronchial tree arise from the larger stems by typical dichotomous division the main trunks are formed by monopodial division, straight or but slightly curved while the smaller arise as side branches from them. From an early stage the lung-buds are asymmetrical, the right being larger than the left and directed more caudally. The early branching of the

FIG. 55.—OUTLINE DRAWINGS OF THE LARYNGES OF AN ADULT AND A NEWBORN. Reduced to the same size and superimposed, showing the differences in proportions at birth and in maturity. Adult in dotted line; newborn in solid line.



buds is also dissimilar, the right bud forming two side buds (representing the bronchial ram or the upper and middle lobes), the left bud forming but one (representing the bronchus of the upper lobe).

The formation of alveoli from the tips of the terminal branches of the bronchial tree begins in the sixth fetal month. Their number grows rapidly but they increase little in size before birth. At birth, with the establishment of respiration the alveoli expand vigorously their lining epithelium being reduced from a columnar to a squamous type. Aside from the possible growth of a few air-cells from the walls of the terminal bronchioles there are no new alveoli formed after birth. The size of the alveoli, however, continues to increase throughout life, even to extreme old age.

The visceral *pleura* is formed from the splanchnic mesoderm of the parietal part of the celom which carries the lung-buds as they push their way into this cavity, and the stroma of the lung is probably derived from cells of this layer. The connective tissue of the lung is extremely abundant in the early part of the fetal period but the relative amount is greatly reduced in the last fetal months by the increase in the number of alveoli and still more so by the expansion of the alveoli at birth.

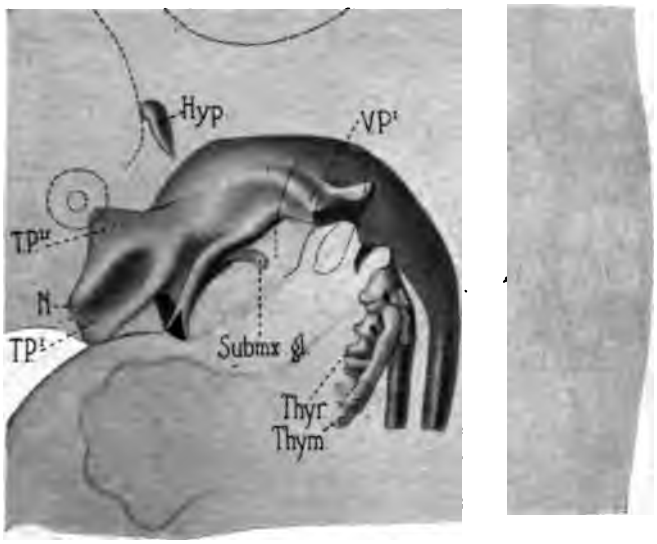
The lungs are formed in the upper cervical region but in their development they descend at first rapidly and then more slowly into the thoracic cavity. There is little change in the position of the lungs in infancy but a slow descent in childhood.

The lungs reach their highest relative weight in the fourth fetal month when they form about 3.3 per cent. of the body. In the newborn they form about 1.7 to 2.0 per cent. and in the adult about 1 per cent. of the body-weight. The growth of the lungs in absolute weight during postnatal life follows the scheme of the splanchnic group of organs.

The nose and paranasal sinuses.—The formation of the nasal pits, development of the external nose, and establishment of the hard palate have already been considered (p. 38). In the early part of the second month the nasal fossæ are represented by the two nasal pits which open to the surface of the face through the embryonic nares (fig. 17) and are separated medially by the primitive nasal septum. They communicate with the oral sinus through the primitive choanæ (fig. 38).

FIG. 56.—LATERAL VIEW OF A MODEL OF THE NOSE AND PHARYNX OF AN EMBRYO OF 6 WEEKS. (After Sudler.)

Hyp., anterior lobe of the hypophysis. N., nasal cavity. Submx.gl., submaxillary gland. Thym., thymus. Thyr., thyroid. T.P^1,. inferior concha. T.P^2,. middle concha. V.P., first branchial (pharyngeal) pouch.



The floor of the definitive nasal fossæ is formed by the fusion of the palatine shelves of the maxillary processes. During this change the primitive choanæ are merged in the nasal fossæ and the definitive choanæ are formed, eventually assuming their final position between the posterior ends of the nasal fossæ and the nasopharynx. At the same time the lower parts of the nasal fossæ are completely separated by the union of the lower margin of the nasal septum with the upper surface of the fused palatine shelves (fig. 38).

The agger nasi and inferior concha arise as processes from the lateral walls of the nasal fossa and the conchæ above them from both the medial and lateral walls of the upper parts of the fossæ. The conchæ are developed in part by the actual outgrowth of shelves from the wall and in part by the formation of grooves which limit these processes. The formation of the conchæ begins in the seventh week. For further details on the development of the nose, see p. 1238.

When the definitive nasal fossæ are first established they are quite short anteroposteriorly but their height and breadth are relatively great. During fetal life the length of the chambers grows more rapidly than the height and at birth the fossæ are relatively long, broad and low. The height of the fossæ increases nearly one-half in infancy but grows much more slowly thereafter. At 7 years it is about twice and in the adult 2.5 to 3 times as great as in the newborn. Apparently the length of the nasal fossæ is about doubled in the first decade and increases little thereafter. The breadth of the nasal cavity, on the other hand, increases very slowly in early childhood.

The *paranasal sinuses* arise as evaginations of the nasal mucous membrane in the latter part of the third and in the fourth fetal months. Their subsequent history is considered in connection with their adult anatomy (p. 1238).

THE UROGENITAL SYSTEM

All three germ-layers are involved in the formation of the urogenital system. The mesodermic contribution is derived from the intermediate mesoderm, the entodermal from the caudal ends of the cloaca and allantois, and the ectodermal mainly from the cloacal membrane.

The excretory portion of the urogenital system is derived entirely from the intermediate mesoderm. In man, as well as in other mammals, and in reptiles and birds, there are formed successively in the embryo three sets of excretory organs or kidneys. The first of these, the pronephros or head-kidney, is a rudimentary structure even in the embryo and disappears

completely except for its duct. The second, the mesonephros or Wolffian body, becomes a functional excretory organ in the embryo, but later degenerates with the exception of certain portions which are retained as parts of the male genital system and others which remain as vestigial structures. The third, the metanephros, remains as the permanent kidney.

The pronephros.—The pronephros arises as a series of outgrowths from the intermediate cell-mass of the cervical region. These sprouts develop into tubules which connect medially with the body-cavity and end blindly laterally. The blind ends of the tubules are directed caudally and growing backward fuse with one another forming a solid cord. The pronephros is a transitory structure and by the fifth week all of its tubules have degenerated; but the longitudinal cord formed from them persists, acquires a lumen, and, growing backward, connects with the lateral wall of the cloaca. It is now called the Wolffian duct.

The mesonephros and the Müllerian ducts.—The mesonephros arises as a series of tubules from the intermediate mesoderm of the lower cervical, thoracic, and the greater part of the lumbar region. These tubules become disconnected from the intermediate cell-mass, their lateral ends joining the Wolffian duct while their medial extremities are expanded into cup-shaped vesicles which enclose a capillary tuft derived from arterial sprigs which pass to them from the

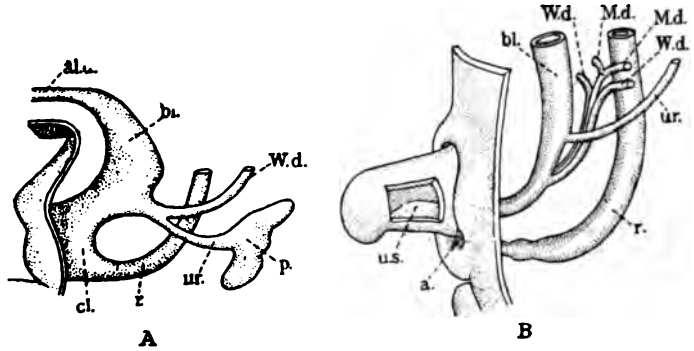
aorta. When fully developed the Wolffian or mesonephric tubules form a pair of large masses projecting from the dorsal wall of the abdominal cavity on either side of the mesentery (figs. 43–45, 57A). These masses, the Wolffian bodies, reach their greatest development in the sixth or seventh week and thereafter undergo a rapid involution, except for certain parts which are retained in connection with the genital glands.

At the time when the Wolffian body has almost reached its highest development the peritoneum near its cranial end on the medial surface is invaginated forming a second longitudinal duct, the Müllerian duct, which lies parallel with the Wolffian duct. The Müllerian ducts grow posteriorly and join the urogenital sinus. In the lower part of their course the Müllerian ducts lie side by side. They subsequently fuse into a single tube in this region and open into the urogenital sinus through a single ostium. Their upper parts, which are associated with the Wolffian bodies, remain paired and separate.

The metanephros.—The metanephros or permanent kidney is formed from the metanephric bud (primitive ureter), which is an outgrowth from the Wolffian duct, and from a thickened mass of mesenchyma, the metanephric blastema, derived from the lower part of the intermediate mesoderm. The metanephric bud arises from the lower part of the Wolffian duct in the fourth week. It grows backward and upward behind the Wolffian body where its distal end encounters and becomes imbedded in the metanephric blastema. The distal end forms the renal pelvis while the proximal portion remains as the ureter. The renal tubules are formed in part from the renal pelvis and in part from the metanephric blastema, the former giving rise to the straight and arched collecting segments and the latter to the remainder of the tubule. The metanephric blastema also forms the stroma of the kidney. The renal tubules are formed in a series of 14 to 18 generations, the last formed tubules occupying the periphery of the kidney. All of the renal tubules have been formed at birth and the subsequent increase in the renal parenchyma (about 90 per cent. of the total growth) takes place entirely through tubule hypertrophy.

FIG. 58.—DEVELOPMENT OF THE UROGENITAL SINUS. (From Lewis after Keibel.)

A, embryo 11.5 mm. long (4½ weeks). B, embryo 25 mm. long (8½ to 9 weeks). a, anus. al.d., allantoic duct. bl., bladder. cl., cloaca. M.d., Müllerian duct. p., pelvis of kidney. r., rectum. ur., ureter. u.s., urogenital sinus. W.d., Wolffian duct.



The position of the kidneys changes greatly during development. Starting in the sacral region they gradually pass into the abdominal region in the second month. In later fetal life they are shifted downward so that their lower poles are usually in the pelvis at the time of birth, but in infancy there is commonly a second upward shifting of the kidneys. The later changes in the position of the kidneys are probably passive, dependent on the growth of the posterior wall of the trunk.

The kidneys form about 0.7 per cent. of the weight of the body at birth. They decrease to about 0.46 per cent. in maturity, their total postnatal increase being about 14-fold. Their growth in absolute weight follows the general course of the splanchnic group of organs.

The urogenital sinus.—In young embryos the hindgut and the allantois unite in a common cloaca. This chamber is joined on either side by the Wolffian ducts and its ventral wall is formed, in part, by the cloacal membrane. The cloaca becomes divided, in the frontal plane, by the rectourethral septum into a dorsal (posterior) rectum and a ventral (anterior) urogenital sinus. This partition extends to the cloacal membrane which is differentiated into a ventral portion, associated with the later development of the urogenital sinus and a dorsal (posterior) part which forms the anal canal (see p. 38). The Wolffian ducts remain connected with the urogenital sinus when the cloaca is divided, and the ureters which spring from the Wolffian ducts separate from them and acquire independent openings in the urogenital sinus cranial to the ostia of the Wolffian ducts. At this time also the Müllerian ducts form a connection with the sinus medial to the openings of the Wolffian ducts.

The urogenital sinus is later differentiated into three segments. The upper portion (pars vesicalis) is an expanded chamber receiving the ureters and continuous with the allantois cranially. The middle portion (pars urethralis) is a short tube into which the Müllerian and Wolffian ducts open. The lower segment (pars phallica) is widely expanded and is floored by the ventral portion of the cloacal membrane.

The *pars vesicalis* forms the bladder. Its lining epithelium is of entodermal origin except in the region of the future trigone which is derived from the mesoderm of the proximal ends of the ureters. The connection of the allantois with the bladder is lost in the second fetal month and the cranial third of the bladder is obliterated in fetal life, remaining as a fibrous band, the

urachus. At birth the bladder is mainly an abdominal organ, its base lying behind the symphysis pubis and its apex extending halfway to the umbilicus, the long axis of the contracted organ being almost vertical at this time. During postnatal life the bladder shifts backward and downward in the pelvis. Three stages can be recognized in this process; a period of rapid descent in infancy and early childhood, a stationary phase in middle and later childhood, and a final period of slow descent in adolescence.

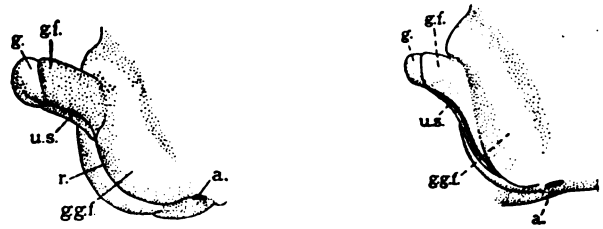
The *pars urethralis* forms the entire urethra in the female and the proximal portion of the urethra in the male. In the third fetal month the pars urethralis gives rise to a series of longitudinal folds from which are formed the prostatic tubules of the male and the corresponding but rudimentary paraurethral (Skene's) glands of the female. All of the prostatic glands are formed by the middle of fetal life.

The *pars phallica* enlarges in the second fetal month, encroaching on the pars urethralis and forming a shallow vestibule into which the urethra and the Müllerian ducts open independently. In its further development (which is considered in connection with external genitalia) the pars phallica is converted into the distal part of the urethra in the male and the vestibule in the female. A pair of evaginations from the lower part of the pars phallica in the fourth fetal month gives rise to the bulbovestibular glands in the female and to the bulbourethral glands in the male.

The external genitalia.—The formation of the external genitalia takes place through the development and transformation of a series of external elevations at the margins of the cloacal membrane. Each of these structures consists of a central core of mesenchyma covered by an outer layer of the ectoderm of the perineal region. A median elevation, the cloacal tubercle, is formed at the anterior end of the cloacal membrane in the fifth or sixth week. This is differentiated into an apical phallus, the genital eminence, and a basal portion, the genital tubercle, which surrounds the root of the phallus and extends caudally on either side of the cloacal membrane as the paired genital swellings. At the same time, the cloacal membrane forms a deep urethral groove the lips of which are converted into a second pair of longitudinal ridges termed the genital folds, which lie medial to the genital swellings. The urethral groove between them is converted into a longitudinal slit which connects the vestibule of the urogenital sinus with the exterior.

FIG. 59.—DIAGRAMS OF THE EXTERNAL GENITAL ORGANS. (A) of a male embryo. (B) of a female embryo. (After Lewis.)

a., anus. g., glans clitoridis and glans penis. g.f., genital folds. g.g.f., genital swellings. r., raphe. u.s., urogenital sinus.



In the female the phallic part of the cloacal tubercle forms the clitoris while the basal portion forms the mons veneris cranially and the labia majora caudally. The median slit becomes the rima pudendi and the genital folds at its margins the labia minora.

In the male the phallic portion of the cloacal tubercle forms the greater part of the penis. The genital folds are not so fully developed in the male but the margins of the urethral groove bend medially over this depression and fuse along the median line converting it into the proximal urethra. The anterior extremity remains open as the external urethral orifice. The genital swellings disappear in the male, being replaced by an unpaired scrotal swelling.

Origin of the testis and ovary.—In their earlier stages no differences can be recognized between the ovary and testis. The undifferentiated sex-gland appears as a ridge on the medial side of the Wolffian body extending from the middle thoracic through the abdominal region. This ridge consists of a covering epithelium and an inner solid core formed by the ingrowth of this covering. Two types of cells may be recognized in the gland, those having their origin from the epithelium of the body cavity, and larger and less numerous germ-cells whose origin in man is uncertain.

Development of the testis and its ducts.—In the transformation of the indifferent genital gland into the testis the inner part of its epithelial core is converted into a network of solid cords, and the outer part forms a layer of dense mesenchyma which underlies the covering epithelium and represents the tunica albuginea testis. The network of solid cords is converted into the tubuli contorti (seminiferous tubules), the tubuli recti, and probably a portion of the rete testis.

With this differentiation of the genital gland the Wolffian body is also greatly modified. A number of the upper mesonephric tubules become connected with the rete testis and form the efferent ducts of the testis. The tubules above and below this group lose their connection with the Wolffian duct and remain as vestigial structures, certain of the upper ones forming the appendix testis and possibly the appendix epididymidis, and the lower ones the paradidymis. The Wolffian duct remains in its entirety as the ductus epididymidis, the ductus deferens, and the ejaculatory duct. The seminal vesicles arise as outgrowths of the ejaculatory duct. The Müllerian duct degenerates in the male, except for its lower extremity which remains as the ostatic utricle (the homolog of the vagina) and for its upper or cranial end which may give e to the appendix epididymidis (fig. 1051).

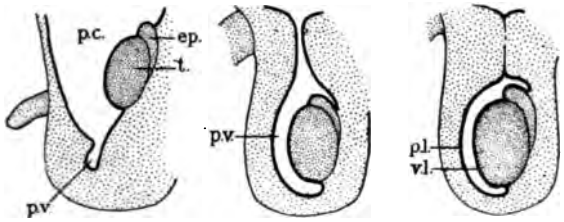
Development of the female genital tract.—In the female the core of the genital ridge forms the stroma of the ovary, the cells of the general covering epithelium give rise to the follicular cells, and the germ-cells which lie in the epithelium develop into the primitive ova (see fig. 1040).

The early changes in the Wolffian body resemble those of the male. The upper tubules degenerate with the exception of one or two which remain as the cystic *appendices vesiculosi* of the adult. The middle group of tubules form the *epoöphoron* (fig. 1042), a structure homologous with the efferent ducts of the testis but without function, which persists and increases in size until maturity. The lower group of tubules undergo a more complete involution although remnants of them persist in postnatal life as the *paroöphoron* (the homolog of the paradidymis). The Wolffian duct in the female loses its connection with the urogenital sinus but portions of it may be retained as the longitudinal duct of the epoöphoron or the duct of Gartner (homolog of the ductus deferens and ductus epididymidis).

The Müllerian duct is retained in its entirety in the female, the unpaired portion forming the uterovaginal canal and the paired portions the uterine tubes (fig. 1051). For the development of the broad ligament, see fig. 1040, p. 1297.

Descent of the testis and ovary.—In the latter part of the second fetal month the testes extend along the posterior wall of the trunk from the thoracic to the sacral region. In the third month they are found in the iliac fossæ, from the fourth to the seventh month at the level of the future internal abdominal ring, and in the eighth month they usually pass into the scrotum (fig. 60). The causes of the descent of the testes are obscure. Much of the early change in position is due not to the actual shifting of the organs but to the involution of their cranial parts. The later changes may be due in part to the contraction of the gubernaculum testis, an associated ligament of the fetal testis which contains smooth muscle.

FIG. 60.—DIAGRAMS OF THE DESCENT OF THE TESTIS. (From Lewis after Eberth.)
ep., epididymis. p.c., peritoneal cavity. p.v. processus vaginalis. t., testis. p.l., parietal layer of the tunica vaginalis. v.l., visceral layer of the tunica vaginalis.



The passage of the testes through the inguinal canal is preceded by the invasion of the solid strotum by a pocket of peritoneum, the saccus vaginalis, which later partially surrounds the cestis as the tunica vaginalis. The connection between the saccus vaginalis and the abdominal peritoneal cavity is usually patent in the newborn, being commonly closed in the first 6 months after birth. For further details, see p. 1287.

The ovaries, like the testes, shift from an abdominal to a pelvic position in the early part of fetal life (fig. 49), although their final position is usually acquired in childhood. In their passage the axes of the ovaries are shifted first from the longitudinal to the transverse plane of the body and finally into the sagittal plane. The canal of Nuck, the homolog of the saccus vaginalis, is found in the labia majora in the female fetus. It is generally open at birth but is obliterated in early infancy.

The growth of the male genital organs.—The male organs of generation follow without exception the scheme of growth of the genital group of organs. They are characterized by rather rapid increase in the later fetal months and this phase may extend into the first months of postnatal life. Thereafter there is little change in their absolute weights until the prepuberal period, when a stage of rapid growth begins which may extend through adolescence into early maturity. Most of the male generative organs increase over thirty-fold in absolute weight in the postnatal period, being relatively heavier in the adult than in the newborn. However, the relative size of the testes is probably greater at the close of the embryonic period than at any subsequent time.

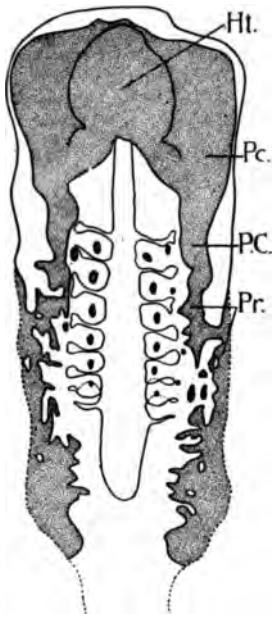
The growth of the female genital organs.—All of the female genital organs grow rapidly in fetal life and are relatively large at birth. In postnatal life the growth of the vagina, uterine tubes, and epoöphoron seem to follow the usual course of the genital organs. The postnatal growth of the ovaries is extremely irregular, the weight being influenced by the development of the ovarian follicles, a process which is active in childhood as well as in maturity. The uterus in the neonatal period undergoes a marked reduction in weight—a change which has been attributed to the withdrawal of a placental hormone at the time of birth. After this initial decrease there is little change in the size of the organ until the prepuberal period when it again enters on a phase of active growth. The adult dimensions are probably attained by puberty in the majority of cases. The paroöphoron does not increase in size after birth.

THE CELOMIC CAVITY

The general plan of the development of the celom as a cavity formed between the splanchnic and somatic layers of the lateral mesoderm has been outlined in connection with the development of the mesoderm (p. 12). In the higher mammals, including man, the celom first makes its appearance in the region of the heart as irregular clefts in the mesoderm on either side of

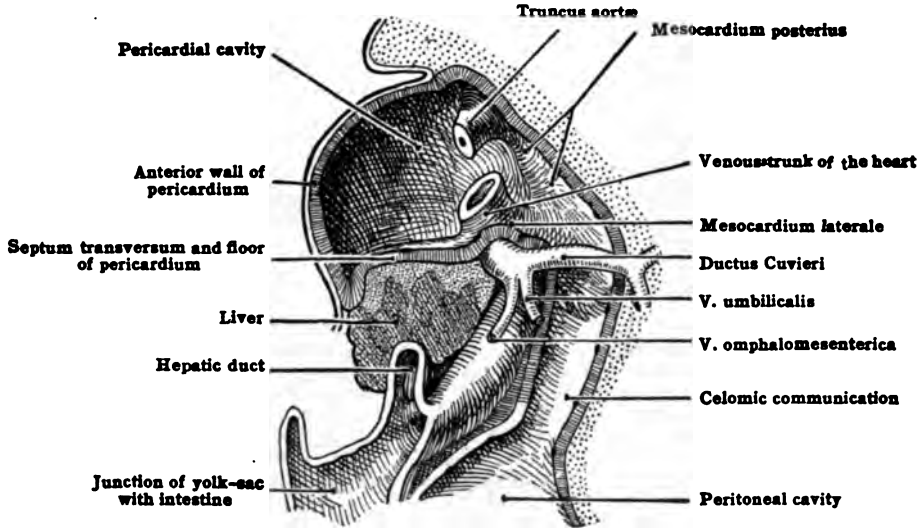
the body. These spaces unite with one another by the formation of a communication which crosses the midline of the body below the heart. The common cavity formed by this fusion is known as the pericardial celom (fig. 61). The pleuroperitoneal portion of the celom is

FIG. 61.—DORSAL VIEW OF A RECONSTRUCTION OF AN EMBRYO ABOUT 2 MM. LONG, SHOWING THE EXTENT AND DIVISIONS OF THE EMBRYONIC CELOM. (After Dandy.)
Ht., heart. P.c., pericardium. P.C., parietal (pleural) canal. Pr., peritoneal cavity.



formed by the caudal extension of the celom in the lateral plates of the mesoderm on either side of the body. The peritoneal celom communicates freely with the extraembryonic celom at the margins of the embryonic disk.

FIG. 62.—SAGITTAL SECTION SHOWING THE PRIMITIVE PERICARDIAL AND CELOMIC COMMUNICATION, SEPTUM TRANSVERSUM, LIVER, ETC., IN A HUMAN EMBRYO of 3 MM. (After Kollmann, from a model by His.)



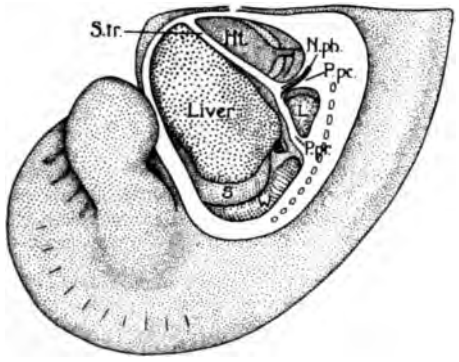
A single peritoneal cavity is formed from the two lateral ones as the embryo separates from the embryonic disk, and the ventral abdominal wall is formed. During this process the abdominal portion of the archenteron is enclosed between the right and left layers of splanchnic mesoderm which are reflected upon it from the dorsal and ventral abdominal walls. These layers remain dorsal to the archenteron as the dorsal mesentery. They also remain ventral to the archenteron from the end of the cavity to the umbilical region as the ventral

mesentery. Caudal to the umbilicus, however, the ventral mesentery disappears and the right and left peritoneal cavities become confluent. The formation of the ventral body-walls also separates the peritoneal cavity from the extraembryonic celom, although an extraembryonic extension of the peritoneal cavity, the *umbilical celom*, remains in the root of the umbilical cord through the embryonic period.

The separation of the peritoneal, pericardial and pleural cavities.—The final divisions of the celom are separated by the formation of the diaphragm and the lateral walls of the middle mediastinum. As will be seen from figs. 61 and 62, the pericardial celom communicates with the peritoneal portion of the celom only by a pair of lateral passages, the *parietal canals*. These channels are separated in the midline by the anterior part of the yolk-stalk and by the vitelline-umbilical trunks which pass along this structure to reach the heart. The media partition formed by these structures with their covering of splanchnic mesoderm is called the septum transversum and is the fundament of the greater part of the diaphragm. In the later shifting of the septum transversum the cranial parts of the parietal canals become funnel-shaped spaces which are invaded by the lung-buds and which form the fundaments of the *pleural cavities*. The pleural cavities become separated from the pericardial cavity by the *pleuropericardial membranes* which arise from the dorsal and lateral walls of the parietal cavity enclosing the phrenic nerve. The caudal openings of the pleural cavities into the peritoneal cavity become closed by the *pleuroperitoneal membranes* which arise from the dorsal margin of the septum transversum and extend dorsolaterally to unite with the dorsal abdominal wall (fig. 63).

FIG. 63.—LATERAL VIEW OF AN EMBRYO 11 MM. LONG, SHOWING THE PLEUROPERITONEAL (P. pr.) AND THE PLEUROPERICARDIAL MEMBRANES. (P. pc.). (After Mall.)

Ht., heart. L., lung. N.ph., phrenic nerve. S., stomach. S.tr., septum transversum. W, Wolffian body.



The fundament of the diaphragm is formed in the upper cervical region and rapidly shifts caudally in the embryonic period. The musculature of the diaphragm is derived from premuscle masses which are formed in the cervical region.

The further history of the peritoneum is considered with its adult anatomy (p. 1172). The development of the tunica vaginalis is outlined in connection with the descent of the testes (p. 53). For relations to hernia, see p. 1397.

THE DUCTLESS GLANDS

The several varieties of ductless glands have little in common in their germ-layer origin, in the method of their early development, or in the course of their subsequent growth.

The thyroid gland.—The thyroid gland appears in embryos of the third week as a shallow median depression of the floor of the pharynx at the level of the first and second branchial pouches (fig. 37*A*). This outgrowth is converted into a solid mass which for a variable period remains connected with the pharynx by a solid stalk, but which eventually becomes detached and migrates into the region of the neck occupied by the definitive thyroid gland (cf. p. 1316). The solid mass is broken into a number of fenestrated epithelial plates from which the thyroid follicles are developed. Colloid appears in the thyroid follicles about the third fetal month. The disappearance of the colloid at birth and also the desquamation and partial destruction of the follicular epithelium have been described, but are of doubtful significance.

The thyroid assumes its bilobed form at an early stage (fig. 41). Its stalk may persist in part as the pyramidal lobe of the gland and portions of it occasionally remain as isolated thyroid masses in the upper cervical region or in the base of the tongue. The foramen cecum of the tongue presumably marks the point of its pharyngeal attachment.

At birth the thyroid weighs from 2 to 3 grams and its weight increases 10 to 15-fold in postnatal life. The postnatal changes in weight follow the course of the visceral group of organs.

The parathyoid glands.—The parenchyma of the parathyroid glands is formed from the thickened lateral walls of the dorsal extremities of the third and fourth pharyngeal pouches (fig. 41, Ep. III and Ep. IV). These masses become detached from the pouches in the second month and then migrate to their adult position. For further details, see p. 41.

The pineal body.—The pineal body (epiphysis cerebri) arises in the fifth week as a diverticulum from the caudal extremity of the roof of the diencephalon (fig. 641). The distal

portion of this pouch becomes the body of the epiphysis. The proximal portion remains as the stalk. Ingrowths of connective tissue from the pia mater later divide the body of the organ into lobules. At birth the structure is relatively large and by 12 years it has obtained its full size. Structural involution of the pineal body begins about the sixth or seventh year and is practically complete by puberty.

The hypophysis cerebri.—The anterior or glandular lobe of the hypophysis cerebri (pituitary body) is formed from the extremity of Rathke's pouch from the oral sinus, while the posterior or neural lobe is formed from a part of the infundibular depression in the floor of the forebrain. These two structures come in contact in the fourth week. The extremity of Rathke's pouch soon becomes detached and partially incloses the neural portion. In the second month the walls of Rathke's pouch are differentiated into cords and tubules which form the trabeculæ and acini of the hypophyseal parenchyma and obliterate the greater part of its central cavity. The infundibular portion undergoes less extensive changes. The greater part of the stalk of Rathke's pouch usually disappears but a portion of its lower part probably forms the *pharyngeal hypophysis*, a constant glandular mass resembling the anterior lobe of the hypophysis and located in the region of the pharyngeal tonsil (see fig. 1069).

The hypophysis weighs about 0.12 grams in the newborn and its mass increases 5 or 6 times between birth and maturity. The curve of the postnatal increase in the absolute weight of the hypophysis is shown in fig. 24. It is characterized by a rapid rise in infancy and early childhood and a slow but steady growth thereafter to maturity.

The thymus.—While a part of the thymus is of branchial origin and the organ is commonly classed with the ductless glands, both its finer structure and the course of its growth indicate a close relationship with the lymphoid organs. In man the thymus first appears as outgrowths of the walls of the third and (inconstantly) of the fourth pair of branchial pouches (fig. 41). Usually the lower portion of the third pouch is converted into a long epithelial tube the lumen of which is soon obliterated. Its walls are reduced to a reticular network whose meshes are invaded by numerous lymphocytes. The thymic (Hassal's) corpuscles are formed by the secondary aggregation of reticular cells of entodermal origin. For further details, see p. 1321.

In its growth the thymus follows the typical course of a lymphoid organ (fig. 24). At birth it forms about 0.42 per cent. of the body. This relative weight drops to 0.12 per cent. in later childhood, 0.09 per cent. in adolescence and 0.05 to 0.02 per cent. in early maturity. The absolute weight rises from about 13 grams at birth to about 38 grams at puberty and then declines. The weight of the thymus is at all periods subject to great individual variation. After birth the parenchyma forms a constantly decreasing proportion of the thymus.

In the fetus the thymus occupies the anterior part of the superior mediastinum and often a little of the lower cervical region. Its thoracic portion is usually widely expanded coming in contact with the anterior chest wall over a considerable area. With the establishment of respiration at birth the gland is pressed between the expanding medial borders of the lungs and moulded into the more elongate form which is characteristic of infancy and childhood (figs. 1058, 1059).

The chromaffin bodies.—The cells of the various masses of chromaffin tissue (aortic bodies, carotid bodies, cardiac bodies, etc.) have their primary origin in the neural crest (see p. 1321) and form a part of the stream of cells which migrate to the ventral side of the vertebral column. These walls give rise both to cells of the sympathetic ganglia and to the chromaffin cells, the distinction between the two becoming evident in the latter part of the second month. The chromaffin bodies form prominent structures in the fetus and newborn, the largest being the aortic bodies which are located on either side of the abdominal aorta (fig. 1066). After infancy they undergo partial involution.

The suprarenal glands.—The suprarenal glands have a dual origin, the medulla being formed of chromaffin tissue (vide supra) and the cortex from the lining of the celom. The cortex appears in the fourth week as buds of celomic epithelium which project from the root of the mesentery into the loose mesenchyma. These form a compact isolated mass of epithelial cords lying on either side of the aorta. The medulla is formed by the migration of chromaffin cells into the center of the mass of cortex. This process begins in the second month and continues through the greater part of the fetal period. For further details, see p. 1324.

The suprarenals follow a peculiar growth-cycle (fig. 24). Growing rapidly in fetal life they acquire an average weight of about 7 grams at birth. During the period of the newborn they undergo a rapid decrease to about one-third of their natal weight. There is little increase in weight in infancy or early childhood but apparently a rapid phase of growth in middle or later childhood and a slower gain thereafter. The relative weight of the suprarenals is approximately 0.46 per cent. of the body-weight from the fourth fetal month until birth. Following the postnatal decrease it drops to about 0.15 per cent., rising again to about 0.2 per cent. in the adult. The neonatal decrease of the suprarenals is caused by the involution of the middle and inner cortical zones, which are not regenerated from the outer zone until after the middle of the first period of childhood.

THE SKIN AND APPENDAGES

The skin.—The epidermal portion of the skin is formed from the surface ectoderm of the embryo while the dermis is derived from the underlying mesenchyma. In an early stage the epidermis consists of two layers, a surface layer of flattened cells, the periderm, and a basal layer of columnar germinative cells. The layers of the epidermis recognizable in the adult skin do not appear until about the middle of the of fetal life. The dermis becomes distinguishable from the underlying tela subcutanea in the third month but its division into reticular and papillary layers does not occur until late in fetal life. The hair-follicles are formed from solid downgrowths of the germinal layer of the epidermis. The first appear at the close of the second month but the general hair-coat does not form before the fourth month. New hair-

follicles are formed until birth and probably for some time thereafter. The first hairs or fetal lanugo are soon shed, the process beginning before birth, and a second shedding of the infantile hair, including the hair of the eyelashes and crown, takes place about the end of the first year. After this time there is a constant hair-change but no definite periods of shedding can be recognized. The sebaceous glands arise as lateral outgrowths of the developing hair-follicles. The sudoriferous glands (sweat glands) are formed as solid downgrowth of the epithelium in the fourth or fifth months. All of the sudoriferous glands are formed in fetal life. For further details on the development of the skin, see pp. 66, 69.

The areas occupied by the nails are marked out on the dorsal surface of the digits in the early part of the third month. The epithelium at the proximal margin of the nail-area is invaginated forming the proximal or posterior nail-fold which projects into dermal mesenchyma, and smaller folds are formed at the lateral margins of the nails. The middle cells of the invagination form the horny layer of the nail and the lower cells form the germinative layer. The upper cells or periderm form a superficial covering, the *eponychium*, which is later thrown off except for a narrow proximal margin which persists through life. The dermal mesenchyma underlying the epithelial nail forms the nail-bed. For the growth of the nails, see p. 70.

The mammary glands.—In the fourth week a thickening of the surface ectoderm, the mammary line, is formed on either side of the trunk extending from the anterior to the posterior limb-bud. The portion of the mammary line in the region of the future mammary gland forms a solid mass of epithelium, the mammary hillock. The lactiferous ducts develop as outgrowths from the basal portion of the mammary hillock and the minor ducts and alveoli of the gland are formed through the further growth and subdivision of the lactiferous ducts. For further details, see p. 79.

Soon after birth a slight secretion (witch's milk) is formed in the lactiferous ducts of the mammary glands of both male and female infants. Ordinarily this secretion ceases by the close of the third postnatal week. There is little change in the structure of the mammary gland in childhood but in the latter part of the prepubertal period in the female there is a rapid growth of the gland parenchyma together with an increase in the adipose and elastic tissue.

SECTION II

THE SKIN AND MAMMARY GLANDS

LARGELY REWRITTEN FOR THE SIXTH EDITION

BY CHARLES R. STOCKARD, M.S., PH.D., SC.D.

PROFESSOR OF ANATOMY IN THE CORNELL UNIVERSITY MEDICAL COLLEGE

THE SKIN

THE bodies of all animals present a modified surface layer inclosing and protecting their more delicate inner parts. The existence of the individual largely depends upon the integrity of this limiting envelope and through it exchanges between the environment and the individual must take place. In the lowest animals such a modified surface layer is known as the ectoplasm, perisarc, theca, coat, etc. while in man and higher animals it is the skin. When an area of skin is destroyed the fluids of the body flow out freely and the elements of the environment invade the exposed parts. If the destruction of skin be too extensive, the individual is unable to maintain itself and actually disintegrates into the environment. On the basis of such a conception, the skin becomes one of the most important and complicated organs of the body, both as to structure and functions.

The human skin, or **common integument** [integumentum commune], covering the entire surface of the body and blending with the epithelial lining of the inner tubes at their orifices is so constructed as to maintain wide physical and chemical differences between the internal structures on the one side and the external environment on the other. At the same time the skin permits exchanges of fluids and, through special modifications, supplies all sensory communication and appreciation of the surrounding world.

The *primary function of the skin* is protective, but in addition and in connection with this function it supplies the mechanism for regulating or maintaining the body-temperature, the sensory apparatus for receiving impressions, widely distributed glands for the secretion of sweat and sebum, local glands secreting waxes and the milk-glands on which the existence of the race has depended. The skin also possesses slight powers of excretion, respiration and absorption. Its outer layer further gives rise to the hair and nails which are protective in nature.

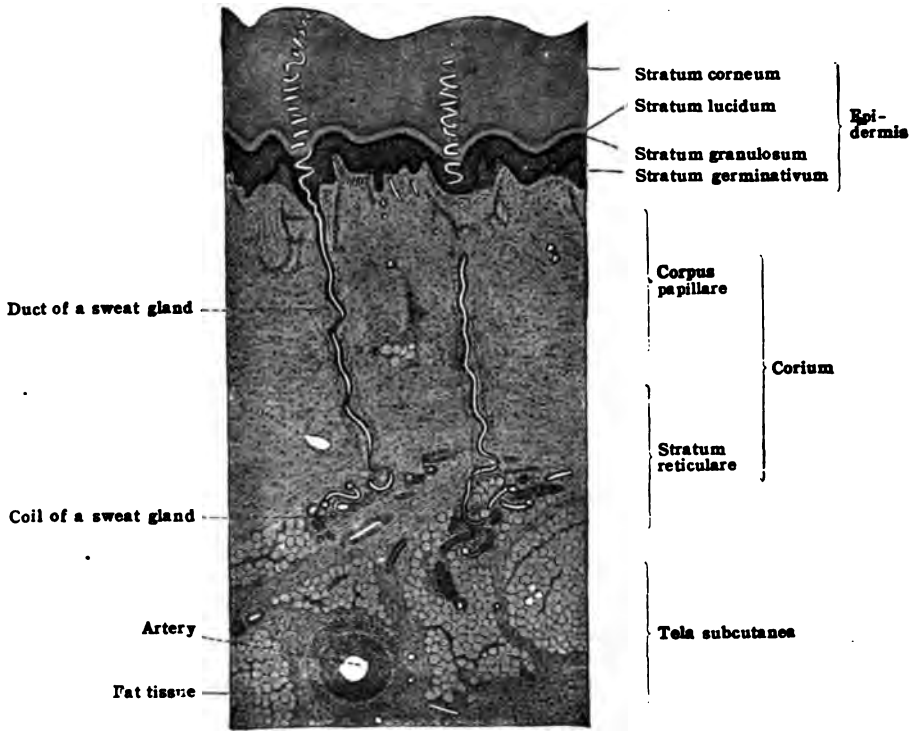
The receptor portions of the organs of special sense are developmental modifications of the embryonic skin. Thus all means of acquaintance with the world about must depend primarily upon skin-organs. And finally the stimuli received by the organs of special sense are conveyed to the central nervous system, the brain and spinal cord, which in evolution and embryonic development represent a modified portion of the embryonic skin or ectoderm. The skin of animals, broadly speaking, is the protective and sensory sheath enclosing the body.

Layers.—The skin consists of two principal layers. The outer layer, **epidermis** or scarf-skin, contains no vessels and is derived from the ectoderm. This is truly the protecting layer and from modifications of it the hair, nails and skin-glands as protective organs are derived, although these may later extend deep into the underlying tissues (fig. 64). Immediately below this outer epithelial epidermis lies the **corium** (cutis, derma) or connective tissue skin. This is richly supplied with blood and lymph-vessels and from these the epidermis is nourished. Sensory

end-organs and nerves are also very abundant in the corium. Further details of structure of the corium and its relation to the surface patterns of the epidermis are described later. The corium passes imperceptibly into a deeper, looser connective tissue layer, the **tela subcutanea** or superficial fascia, which serves to connect more or less loosely the corium or skin proper to the deep fascia or underlying tissues.

Thickness.—In general the skin on the more exposed or extensor surfaces of the body and extremities is thicker and less sensitive than on the ventral surfaces yet on the palms and soles it is thicker than in any dorsal region except the neck and interscapular back region. At the same time the palm and sole skin is highly sensitive. The average thickness is from 1 to 2 mm.; but over the tympanic membrane and eyelids it may be less than 0.5 mm., while on the back it may reach almost 5 mm. in thickness.

FIG. 64.—VERTICAL SECTION OF THE SOLE OF THE FOOT OF AN ADULT. ×25. (Lewis and Stöhr.)



The **color** of the dorsal skin and also of the dorsal hair, which includes the head-hair, is darker than the ventral skin and ventral hair, such as the beard. An individual may have black crown hair and a lighter or red beard but rarely, if ever, the reverse arrangement.

The color of the skin has considerable general significance and the races of mankind are roughly separated on such a basis into Caucasian or white, Mongolian or yellow, Malay or brown, Indian or red, Ethiopian or black. The hair and eye-color are very dark brown or black in all races except the white. This race of mankind alone shows golden or flaxen hair and blue eyes. The color of the skin varies with the amount of melanin pigment present in the deepest layers of the epidermis, being black in the negro where it is most abundant and decreasing in the different races to the scantest amount in the blonde Caucasian. The blood in the cutaneous vessels also affects the color of the skin, giving the pinkish complexion to the albino and blonde; in the brunette often producing a dark color below the eyes and about the lips. The influence of the blood on skin-color is readily appreciated by noting the blueness of the lips and fingers when very cold, the scarlet flush of anger, and the pallidness of fear.

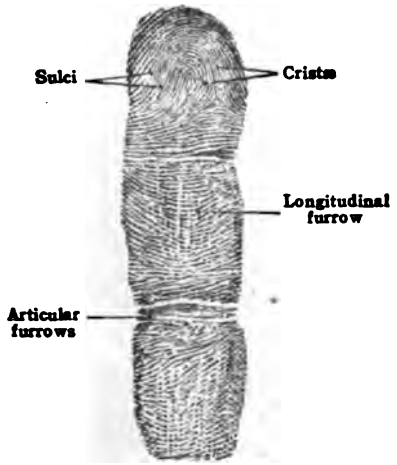
The skin of blondes on exposure to strong sunlight or cutting winds becomes red, and usually shows later irregular pigmented spots or *freckles*. Darker individuals become uniformly pigmented or *tanned* on exposure. Both tan and freckles are more or less transient and generally disappear when the body is no longer exposed.

Complete absence of pigment from the skin gives the condition known as albinism. Partial

absence of pigment or white spots at times occur; if congenital the condition is known as leukoderma, if acquired it is called vitiligo.

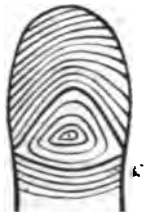
Young children of darker races, e. g., Japanese and Chinese, occasionally present a bluish pigmentation known as 'blue Mongolian spots' of the skin over the sacral, coccygeal and ischial regions. This also occurs rarely in white children. The appearance is due to the presence in the corium of spindle-shaped or stellate pigment cells, chromatophores, resembling the pigment cells of the choroid layer of the eyeball. Similar cells are found distributed generally in the corium of monkeys' skin and their occurrence in man has been thought to be of possible phylogenetic significance.

FIG. 65.—FINGER PRINT (NATURAL SIZE) SHOWING CRISTÆ AND SULCI.



The **elasticity and strength** of the skin are due to the corium, and this layer when tanned or cured gives leather. The skin is more elastic or stretchable over certain regions than others and this property varies in different individuals. The skin is more lightly attached to underlying parts in certain regions, and is here very movable. Its elasticity is well shown under these conditions. If an arm be firmly grasped with the hand it will be found that the skin may move up and down over the underlying muscles as if it were a sleeve. The degree of motility of the skin is appreciated in surgical operations.

FIG. 66.—DIAGRAM SHOWING THE ARRANGEMENT OF THE PRINCIPAL CRISTÆ OF THE THUMB.

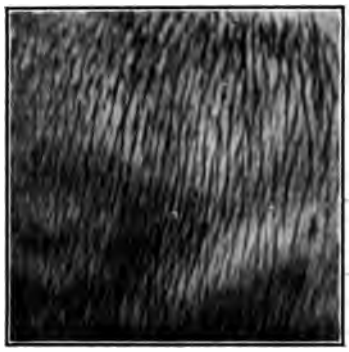


The infinite folds and irregularities on the surface of the skin along with its loose under attachment and elastic nature render it *distensible* to a considerable extent. Roughly speaking, the skin of an individual is sufficiently extensive to cover a body of much larger size. Under certain conditions a leg, for example, may swell to double the usual size but the skin stretches to cover it. The skin over such a swollen part is smoother and more glistening than usual, since the minute folds and patterns are obliterated or smoothed out by the expansion. When increase in size is gradual such as normally occurs during pregnancy the skin area may be stretched to four or five times its previous extent. In these cases the skin is often injured and short parallel, slightly reddish streaks occur which after reduction in size become the silvery white lines, or striæ seen in the abdominal skin of a woman who has borne children.

The surface-area of the skin corresponds approximately to the surface of the body and naturally varies with the size of the individual. It has been variously estimated at from 10,500 to 18,700 sq. cm. for a medium-sized adult male. For the area in children, see p. 23.

Folds and furrows.—The skin presents elevations and depressions due to the fact that it follows more or less closely the contour of the underlying structures, but in addition to this it possesses certain elevations and depressions peculiarly its own. They are found on the skin in various parts of the body. Some are permanent, others only temporary. Large permanent **folds** which include all the layers of the skin are seen, as the prepuce of the penis and the pudendal labia. The most marked depression is the **umbilical fovea.** Other conspicuous folds and furrows are seen in the neighborhood of the lips and eyelids. Certain other less permanent folds and furrows are produced by the action of the joints, **joint-furrows,** and of the muscles of expression of the skin, **'wrinkles.'**

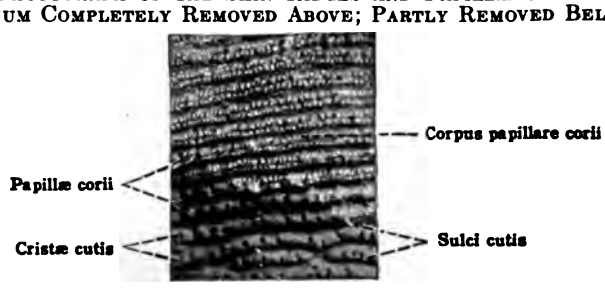
FIG. 67.—FROM A PHOTOGRAPH OF THE SUPERFICIAL FURROWS ON THE BACK OF THE HAND. (× 1.)



Other minute folds and furrows which affect only the epidermis and the superficial layer of the corium are seen in various places. These are represented by the numerous fine superficial creases, unassociated with elevations, forming rhomboidal and triangular figures over almost the whole of the surface of the skin (figs. 65, 66). They are especially numerous on the dorsal surface of the hands (fig. 67). The fine curvilinear ridges [cristæ cutis] with intervening furrows [sulci cutis] arranged in parallel lines in groups on the flexor surface of the hands and feet are also of this type. They form patterns characteristic for each individual and permanent throughout life.

Among the projections are the large permanent folds of skin such as the **labia pudendi,** the **preputium penis,** the **frenula preputii, clitoridis,** and **labiorum pudendi,** and less marked ridges as the median **raphe** of the perineum, scrotum and penis, and the **tuberculum labii superioris.** Of a somewhat different sort are the **touch pads** [toruli tactiles] of the hands and feet. Among

FIG. 68.—FROM A PHOTOGRAPH OF THE SKIN RIDGES AND PAPILLÆ OF THE PALM OF THE HAND. EPITHELIUM COMPLETELY REMOVED ABOVE; PARTLY REMOVED BELOW. (× 5.)



the larger depressions in addition to the **umbilical fovea,** is the **coccygeal foveola,** and a considerable number of well-marked permanent furrows found in various places, such as the **nasolabial** and **mentolabial sulci,** the **philtrum labii superioris,** the **infraorbital sulcus,** and the **infra-** and **supraorbital palpebral sulci.** There are numerous **articular furrows** on both the flexor and extensor surfaces produced by the action of the joints, and associated with intervening folds of skin, particularly on the dorsal surface. They are especially noticeable on the hands. Variations of the palmar joint-sulci are due to variations in opposition of the thumb and the use of the fingers and the relative arrangement of the thumb and fingers and joints. They are of importance as indicating topographically the position of the joints, their relation to which has been made clearer by means of the X-ray.

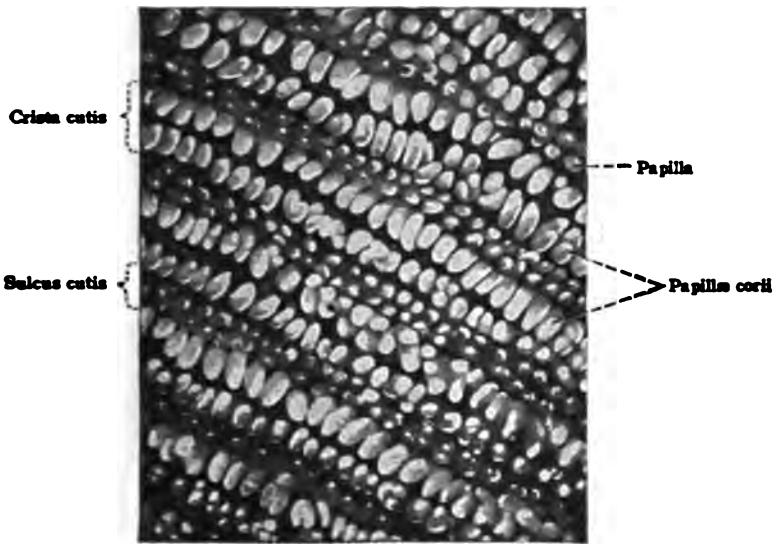
The folds and furrows brought about through the action of the skin muscles run at right angles to the muscle fibers and are more or less transitory at first but become more permanent through repeated or long-continued action. They are represented by the **wrinkles** of the forehead, the lines of expression of the face, the transverse wrinkles of the scrotum and the **radiating** folds around the anus. The more superficial **cristæ cutis** and **sulci cutis** are arranged in groups

within and around the touch pads, on the volar surface of the hands and the plantar surface of the feet (figs. 65, 66). The cristæ of each group are parallel. They correspond to the rows of papillæ of the corium. Since the patterns of the cristæ and sulci are characteristic for the individual, and permanent from youth to old age, they have been classified in a number of types and are important as a means of identification.

There are also a great number of minute depressions which mark the points where the hairs pierce the surface and where the glands open. These are popularly known as **pores.** Under the influence of cold and emotion the hair muscles contract and cause a slight elevation of the skin at the point where the hair emerges. This roughened appearance of the skin is generally known as 'goose-flesh.'

A complex wrinkling of the skin appears in old age, or in the course of exhausting diseases, as a result of loss of elasticity and from absorption of the cutaneous and subcutaneous fat. Rounded depressions called **dimples** are produced by the attachment of muscle-fibers to the deep surface of the skin, as on the chin and cheek, and are made more evident by the contraction of these fibers. Others are produced by the attachment of the skin by fibrous bands to bony eminences, as the elbow, shoulder, vertebræ, and posterior iliac spines. They are best seen when the subcutaneous adipose tissue is well developed.

FIG. 69.—PAPILLÆ OF THE CORIUM AFTER MACERATION. FROM RETOUCHED PHOTOGRAPH EPITHELIUM REMOVED BY MACERATION. (× 25.)



Structure of the corium.—The superficial layer of the corium is of fine, close texture, free from fat, and forms a multitude of eminences called **papillæ corii** (figs. 68, 69) which project into corresponding depressions on the deep surface of the epidermis. For this reason this part of the corium although but indistinctly separated from the deeper layer is called the **corpus papillare.**

Some of the papillæ contain vessels, other nerves, hence they are known as vascular or tactile papillæ. They are very closely set, varying considerably in number in different parts of the body from 36 to 136 to a square millimeter and it has been estimated that there are about 150 million papillæ on the whole surface.

The deeper layer of the corium, the **tunica propria** (stratum reticulare), is composed of coarse loose bands of fibrous tissue intermingled with small fat lobules. The fibrous and elastic tissue is arranged for the most part in intercrossing bundles nearly parallel to the surface of the skin.

The bundles running in some directions are usually more strongly developed and more numerous than those in others, but the direction of the strongly developed bundles varies in different parts of the body. In general those are best developed which have a direction parallel with the usual lines of tension of the skin, hence it results that wounds of the skin tend to gape most at right angles to these lines. The bundles take a direction nearly at right angles to the long axis of the limbs, and on the trunk run obliquely, caudally, and laterally from the spine (figs. 70, 71). On the scalp, forehead, chin, and epigastrium, equally strong bundles cross in all directions, and a round wound, instead of being linear as elsewhere, appears as a ragged or triangular hole. The arrangement of the connective tissue bundles influences the arrangement of the blood-vessels of the skin.

The quantity of *subcutaneous fat* varies considerably in different parts of the body. It is, for instance, entirely absent in the penis, scrotum, and eyelids. When it is abundant, the subcutaneous layer is known as the *panniculus adiposus*.

In some situations, as in the caudal portion of the abdomen and in the perineum, the connective tissue is so arranged that the panniculus may be divided into layers, so that a superficial and a deep layer of the superficial fascia may be recognized. The fat is well developed over the nates, volar surface of the hands and plantar surface of the feet, where it serves as pads or cushions; in the scalp it appears as a single uniform lobulated layer between the corium and the aponeurosis of the epicranial muscle; and on other parts of the surface it is somewhat unequally distributed and shows a tendency to accumulate in apparent disproportion in some localities, as on the abdomen, over the symphysis pubis, about the mammæ in females, etc. Everywhere except on the scalp it may undergo rapid and visible increase or decrease under the influence of change of nutrition.

FIGS. 70 AND 71.—DIAGRAMS SHOWING THE ARRANGEMENT OF THE CONNECTIVE TISSUE BUNDLES OF THE SKIN ON THE ANTERIOR AND POSTERIOR SURFACES OF THE BODY. (After Langer.)

Skin-muscles.—In the subcutaneous tela and the corium muscle fibers are found in larger or smaller groups. These are of two kinds, striated and unstriated (smooth) fibers.

Subcutaneous planes of *striated muscle* are relatively scanty in man when compared with the great panniculus carnosus of the lower mammalia. This is mainly represented by the platysma in the neck which has both its origin and part of its insertion in the skin. Closely associated with this are the muscles of expression of the face and the palmaris brevis muscle which have one end terminating in the deep surface of the skin. The epicranial muscle is also considered by some to belong to this group.

Smooth muscle fibers are scattered through the corium collected into bundles in the neighborhood of the sebaceous glands and the hairs. They are described in connection with these latter (p. 68). In addition to these muscles are found in the scrotum as the dartos, in the perineum, around the anus, and beneath the papilla and areola of the mammary gland.

Bursæ mucosæ subcutaneæ.—In some situations where the integument is exposed to repeated friction over subjacent bones or other hard structures its movements are facilitated by the development of sac-like interspaces in the subcutaneous tissue, the **subcutaneous mucous bursæ.** They are similar to the more deeply placed bursæ which are found in relation with muscle tendons. Their occurrence is quite variable. In some individuals they are numerous, in others very few. They have a considerable practical importance from the fact that they may become greatly swollen.

The most constant subcutaneous mucous bursæ are the following:

Bursa anguli mandibulæ; B. subcutanea prementalis, between the periosteum and soft parts over the tip of the chin; **B. subcutanea prominentiæ laryngeæ** over the ventral prominence of the thyroid cartilage of the larynx (often found in the male); **B. subcutanea acromialis,** between the acromion and the skin; **B. subcutanea olecrani,** beneath the skin on the dorsal surface of the olecranon; **B. subcutanea epicondyli humeri lateralis,** found beneath the skin over the lateral epicondyle of the humerus (occasional); **B. subcutanea epicondyli humeri medialis,** between the skin and the medial epicondyle of the humerus (more frequent); **B. subcutanea metacarpophalangea dorsalis,** between the skin and the dorsal side of the metacarpophalangeal joints (occasional especially the fifth); **B. subcutanea digitorum dorsalis,** beneath the skin over the proximal finger-joints; and rarely over the distal finger-joints; **B. subcutanea trochanterica,** between the skin and the great trochanter of the femur; **B. subcutanea præpatellaris,** beneath the skin covering the caudal half of the patella; **B. subcutanea infrapatellaris,** between the skin and the cephalic end of the ligamentum patellæ; **B. subcutanea tuberositatis tibiæ** ventral to the tibial tuberosity, covered by skin or by skin and crural fascia; **B. subcutanea malleoli lateralis,** between the skin and the point of the lateral malleolus; **B. subcutanea malleoli medialis,** between the skin and medial malleolus; **B. subcutanea calcanea,** in the sole of the foot between the skin and the plantar surface of the calcaneum; **B. subcutanea sacralis,** beneath the skin which covers the lumbodorsal fascia and the region between the sacrum and coccyx.

Blood-vessels of the skin.—The corium and subcutaneous tela are richly supplied with blood-vessels. The cutaneous arteries are as a rule perforating branches from the deeper arteries supplying the muscles and underlying tissue of the region. There are, however, a number of arteries directly supplying the skin, though all of these are small except some of the arteries of the scalp. The skin of the trunk is supplied by branches from the intercostal arteries in a metameric fashion. The areas supplied by certain groups of vessels and the directions which the arteries follow in the skin show much regularity.

The arteries enter the corium from the underlying fascia and there break up into a network of minute vessels supplying the hair-follicles, glands and all cutaneous tissues. The veins of the skin usually accompany the arteries and lead back to the larger underlying vessels. Other veins of considerable size, particularly noticeable on the extremities run in the fascia immediately beneath the skin and independent of the arteries. These large vessels are described in the general section on the veins (p. 701).

Lymphatics of the skin.—The cutaneous lymphatic vessels are found in the skin of all parts of the body but are more abundant in certain places. The lymph-vessels of the skin are developmentally among the first lymph-vessels to appear. The larger vessels and glands of the subcutaneous tela will be found described in connection with the general lymphatic system Section VII. In the corium the lymphatics from the papillæ form a **subpapillary network** which opens into a **subcutaneous plexus** connected with the larger lymph-vessels of the subcutaneous tela. There are no lymph-vessels in the epidermis, but this is supposed to be nourished

by the lymph in the tissue spaces between the cells and these spaces connect indirectly with the lymph-vessels.

The nerves.—The skin has one of the richest nerve supplies of the body. The nerves are in greater proportion in those parts which are most sensitive. The various skin-areas are supplied by specific (segmental) nerves with much greater regularity than in the case of the arteries. The nerves supplying adjoining areas overlap so that there is an intermediate space supplied by both. The variations consist in an extension of one area and a corresponding contraction of an adjoining area. The distribution of the nerves in the skin shows, especially on the trunk and neck, a marked metameric arrangement (see fig. 805).

With the exception of the nerves to the sudoriferous and sebaceous glands, the skin-muscles and blood-vessels, all the cutaneous nerves are sensory. They have diverse modes of termination. Some end in the subcutaneous tela; others, the greater number, terminate in the corium; still others extend to the epidermis. Some of the sensory organs of the skin are shown in fig. 648.

Development of the skin.—The ectoderm of the embryo is at first a single layer of cells but it soon becomes two-layered, the outer layer being very different in form from the uniformly regular underlying cells. This outer layer, *epitrichium or periderm*, is present only in the embryo and fetus and is cast off. The cells of the deeper layer of ectoderm multiply and form a many-celled stratified epithelium. The ectodermal cells also give rise to the hairs, nails, various types of skin-glands, and enamel-organs of the teeth.

The stratified epithelium becomes differentiated into several more or less clearly marked layers due to changes taking place in the cells as they near its outer surface. The lower cells continue to multiply throughout life as the *stratum germinativum*. Cells above this stratum deposit granules in their protoplasm and form the *stratum granulosum*. These cells on reaching a more superficial position become cornified and constitute the *stratum corneum*. This cornified layer is continuously desquamated or thrown off and replaced from the deeper cells. Such is the continuous wear and tear of the outer surface of the body and its means of regeneration.

The *corium* or connective tissue skin is mesodermal in origin and differentiates from the cells of the dermo-muscular plate of mesoderm immediately underlying the embryonic ectoderm. It forms the matrix which received the down-growths from the epidermis, hair-follicles, glands, etc. and serves by means of its rich vascular supply to nourish all the skin organs and parts.

Old age changes.—With advanced age the skin becomes thinner, less elastic and in certain regions the papillæ of the corium almost completely disappear. The cutaneous and subcutaneous fat becomes absorbed and the thin inelastic skin wrinkles over the wasted parts. The epidermis becomes smoother, with finer markings less pronounced, and takes on a sleek, shiny, often scar-like appearance. The hair becomes rough and fails to maintain its general directions. The function of the skin-glands is impaired and scaling often occurs. These changes give to the skin of the aged an entirely different feel and texture from that of the vigorous adult.

THE APPENDAGES OF THE SKIN

The appendages of the skin include: (A) the hairs; (B) the nails; (C) the cutaneous glands; and (D) the mammary glands.

A. THE HAIRS

The **hairs** [pili] are less developed in man than in any other primate. Where well developed they in themselves serve as a protective organ and moreover through their connection with the nervous system they become in a measure organs of special sense. They are strong, flexible, somewhat elastic, and poor conductors of heat. They cover the entire surface of the body with the following exceptions: The flexor surfaces of the hands and feet; the dorsal bends and sides of the fingers and toes; the dorsal surfaces of the distal phalanges of the fingers and toes; the red borders of the lips; the glands and inner surface of the prepuce of the penis and clitoris; the inner surface of the labia majora; the labia minora and the papilla mammæ.

The **size** and **length** of hairs varies greatly not only in different parts of the body but also in different individuals and races. In certain situations the hairs are especially long and large and are designated by special names (such as the capilli, barba, hirci, and pubes).

Strong, well-developed short hairs are found in connection with the organs of sense forming the eyebrows, **supercilia,** the eyelashes, **cilia,** at the entrance to the external acoustic meatus, **tragi,** and at the nares, **vibrissæ.** Upon the extensor surfaces of the extermities, upon the chest, and in other situations in some individuals, especially in adult males, the hairs are also longer and stronger than upon the rest of the body, where they are, as a rule, short, fine and downy. The first hairs appearing in the fetus are very fine, and are called **lanugo.**

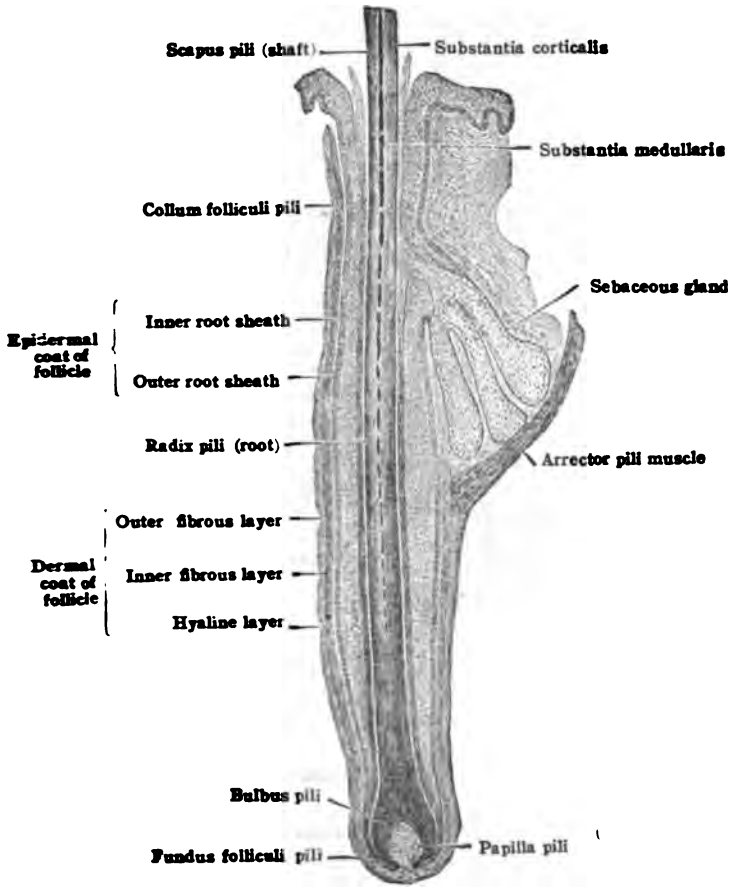
Excess of long hairs, **hypertrichosis,** may involve the whole hairy surface of the body as seen in the exagerated cases of hairy men and bearded women exhibited as freaks. This condi-

tion may be inherited and affect several individuals in the same family. Local areas of long hairs also occur as over nævi and upon the sacrum. Local congestion due to inflammation, irritation, or pressure may cause hypertrichosis. In women, hair upon the upper lip or other parts of the face may be an inherited peculiarity and due to some abnormality of the ovaries. It is also not uncommon after the menopause.

In color the hairs may be either blonde, brown, black, red, or some gradation of these colors. The color varies with the race, and also with the individual, and according to age. It is due to pigment in the cells of the hair but is also influenced by the amount of air between the cells.

Greying and whitening of the hair is due not only to a decrease of pigment but also to an increase in the amount of air between the cells. Sudden blanching of the hair is thought to be due almost entirely to an increase in the quantity of this contained air. Whitening of the hair is

FIG. 73.—LONGITUDINAL SECTION OF A GROWING HAIR OF THE HEAD. (×30.) (From Toldt's Atlas.)



physiological in old age and not infrequent in younger persons. This may be an inherited peculiarity or may follow mental overwork, nervous shock, or prolonged disease. Local blanching is also seen as the result of disease.

The hair may be straight, waved, curled, or frizzled in varying degree. Here also there is not only an individual but also a racial variation, as instanced in the curled or crinkled hair of the African negro and the straight hair of the American Indian. The curliness is caused by the form and manner of implantation in the skin. Straight hairs are round or oval in transection and curled hairs are more flattened. The root of curled hair has been observed in certain instances, as in the negro, to have a curved course in the skin which may account in a measure for its curliness.

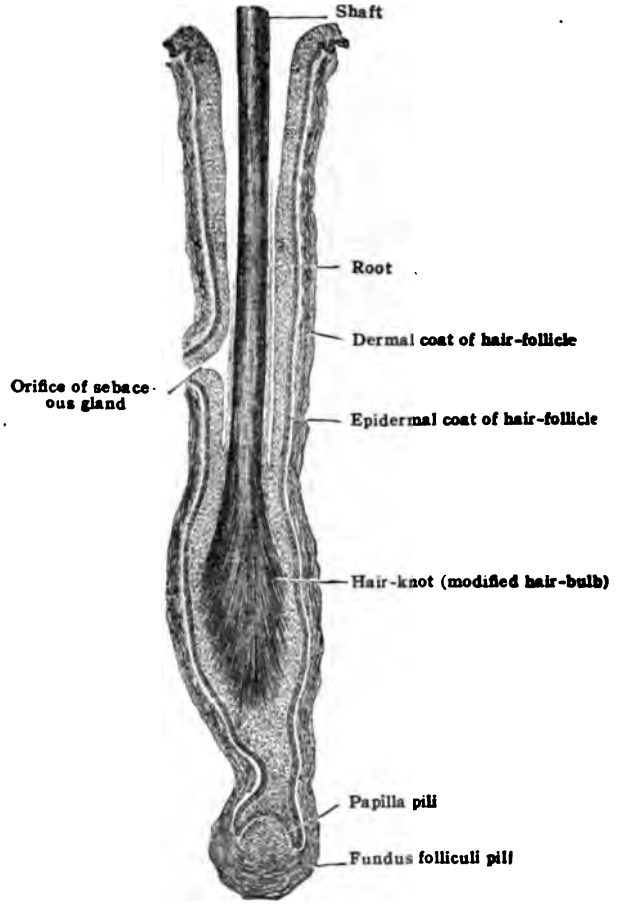
The hairs are *arranged* singly or in groups of from two to five and, except those of the eyelashes, are implanted at oblique angles to the surface of the skin. The directions in which the hairs point are constant throughout life for the same individual. They are arranged in tracts in which the hairs diverge from a center in whorls, the **vortices pilorum.**

These vortices are found constantly in certain definite regions and apportion the whole hairy surface. The centers of vortices are found at the vertex (sometimes double) upon the face, around the external auditory meatus, in the axilla, in the inguinal region, and sometimes on the

lateral surface of the body. These are all paired except as a rule the first. Where adjoining vortices come together the hairs are arranged in lines along which they all point in nearly the same direction, only slightly diverging, forming the **hair streams, flumina pilorum.** In other lines and places the hairs point in coverging directions such as at the umbilicus and over the tip of the coccyx.

The structure of the hair.—Each hair consists of a **shaft** [scapus pili] (fig. 73) projecting from the free surface of the skin to end (unless broken or cut) in a conical tip [apex pili], and of a **root** [radix pili], imbedded in the case of the lanugo hair in the corium and of the larger hairs at various depths in the subcutaneous tela. Surrounding the root is a downgrowth of the skin known as the **follicle** [folliculus pili].

FIG. 74.—LONGITUDINAL SECTION OF A HAIR READY TO FALL OUT, WITH FOLLICLE FOR NEW HAIR. (×30.) (From Toldt's Atlas.)



The root of the hair at its deepest parts swells to from one and one-half to three times the diameter of the shaft forming thus the **bulb** [bulbus pili] (fig. 73). The bulb is hollow and a vascular connective tissue process, the hair **papilla** [papilla pili] (figs. 73, 74) extends from the deepest part of the follicle into the cavity in its base. The follicle consists of an external connective tissue portion, the **theca folliculi,** formed by the corium, and an internal epithelial portion belonging to the epidermis and divided into two portions, the **inner** and **outer root-sheaths** (fig. 73).

At the junction of the outer and middle thirds of the follicle of most of the hairs, the ducts of usually two or more sebaceous glands connect with the space between the hair and its follicle (figs. 73, 75). Immediately beneath this is the narrowest part of the follicle, the **neck** [collum folliculi pili], especially important as the position of the nerve ending of the hair.

Many of the hairs have in connection with their follicle round or flat bundles of unstriped muscle fibers, the **arrectores pilorum** (figs. 73, 75). These are situ-

ated on the side toward which the hairs point, their deep ends being attached to the hair-follicle beneath the sebaceous glands, which they more or less embrace; and their superficial ends connect with the papillary layer of the skin. Contraction of the arrectores not only causes the hairs to become more erect and the skin around them to project somewhat causing 'goose flesh,' but also compresses the sebaceous glands which are situated between the follicle and muscle and helps to empty the glands of their secretion.

The blood supply of the hairs.—The hair-follicles are surrounded by a capillary network of arteries connected with those of the corium and the papillæ are also supplied with loops of arteries.

The **nerves** of the corium supply branches to the hairs. Some of these branches enter the papillæ, others surround the follicle at its neck and are distributed among the cells of the outer root sheath.

Development.—The hairs are developed from the epidermis by thickenings and downgrowths into the corium of plugs of epithelium. The deepest parts of these plugs become swollen to form bulbs and from these the hairs are produced. The central cells of the epithelial downgrowths disintegrate producing the lumen of the follicle. The hairs continue to grow from the deeper cells and protrude from their follicles between the fifth and seventh fetal months. Abnormally they may be scanty at birth and rarely entirely absent, **alopecia.** The lanugo hairs which cover all the hairy parts of the body at birth are soon shed and replaced by new hairs in the old follicles. Throughout life also the hairs are being constantly shed and replaced by

FIG. 75.—VERTICAL SECTION OF THE SKIN FROM SCALP. (×20.)

new ones. This is accompanied by cornification of the bulb and fibrillation of the deep end of the hair (fig. 74). Thinning of the hair and baldness occur when the shed hairs cease to be replaced. This is common in old age and a premature baldness appears to run in certain families. The rate of growth is normally from 1 to 1.5 cm. per month, but is subject to variation.

B. THE NAILS

The **nails** [ungues] are thin, translucent, horny epidermic plates upon the dorsal surfaces of the distal phalanges of the fingers and toes. Through their hardness they serve as protective organs not only by covering the nerve-endings and other delicate structures of the skin; but also by acting as natural weapons. On the fingers they form useful tools. They are four-sided plates presenting a distal free border [margo liber], which overhangs the tips of the fingers, an irregular, sharp proximal edge [margo occultus], and on each side a somewhat thinned border [margo lateralis] (fig. 76).

Each nail is composed of an exposed distal part, the **body** [corpus unguis], and a proximal covered part, the **root** [radix ungius], (figs. 76–78), which ends in the margo occultus. The nail is at a slightly deeper level than the surrounding skin which overhangs the root and the lateral margins in a fold, the **nail-wall** [vallum unguis] (figs. 77, 78). The epidermis of the free edge of the nail-wall, especially proximally, is thickened and often appears as a ragged edge. At a deeper level than the above and extending somewhat more distally is a variably developed thin parchment-like membrane, the **eponychium,** closely attached to the superficial surface of the nail. The groove which is formed between the

vallum and the underlying nail bed is known as the **sulcus matricis unguis.** This lodges the root and lateral margins of the nail and is deepest in the center of the root, becomes shallower toward the lateral margins, and finally disappears entirely toward the free border of the nail (fig. 78).

The **stratum corneum unguis** (fig. 78) which forms the principal thickness of the nail, presents fine longitudinal lines on the free dorsal surface The deeper surface of the nail, the **stratum germinativum unguis,** is a soft epithelial layer. Both these layers are transparent,

FIG. 76.—DORSAL SURFACE OF ISOLATED FINGER-NAIL. (×1.) (From Toldt's Atlas.)

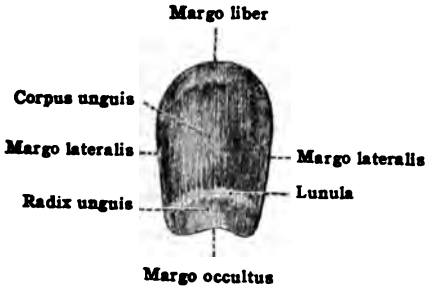


FIG. 77.—FINGER-NAIL AND NAIL BED.

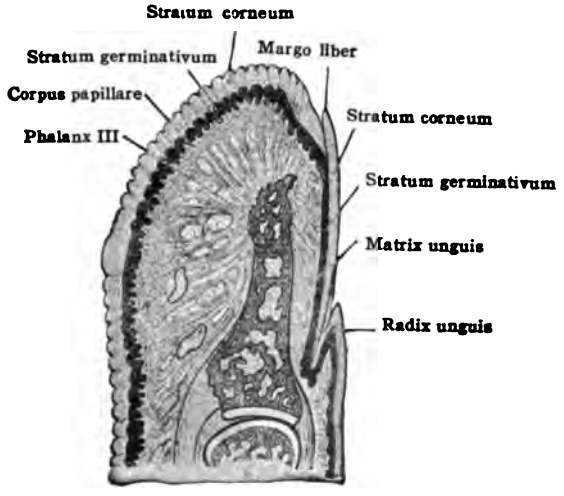
excepting a semilunar area near the root, the **lunula** (figs. 76, 77), which is opaque whitish in color. Beneath the stratum germinativum is the fibrous **nail bed** [matrix unguis], corresponding to the corium and presenting well-marked longitudinal ridges, the **cristæ matricis unguis** (fig. 77).

Blood-supply of the nails.—The **arteries** are numerous in the matrix beneath the body of the nail but fewer beneath the root. They pass from the deep parts of the nail bed toward the surface, running in the main longitudinally and sending anastomosing branches to the papillæ.

The **nerves** beneath the nail are abundant and terminate in free sensory endings and in special end organs of several sorts.

FIG. 78.—LONGITUDINAL SECTION THROUGH THE TIP OF THE MIDDLE FINGER. (×2.) (From Toldt's Atlas.)



Development of the nails.—For an account of the development of the nails, see pp. 57, 70.

Growth of the nails.—The nail grows in length and thickness by multiplication of those cells of the stratum germinativum which are situated between the margo occultus of the root and the distal border of the lunula. The older cells are pushed distally and toward the surface by the deeper cells. As a result the nail becomes gradually thicker from the occult border as far as the distal margin of the lunula. Over the rest of the nail bed no thickening appears to take place. The rate of growth is faster on the fingers than on the toes and varies with age, season, and the individual. When the nail is torn off, or detached through inflammation, it may be regenerated if the cells of the stratum germinativum have not been destroyed.

Congenital hypertrophy of the nails sometimes occurs, but absence or imperfect development is rarely seen. The white spots so frequently seen in the nail are caused by air between the cell layers due usually to injury or impaired development.

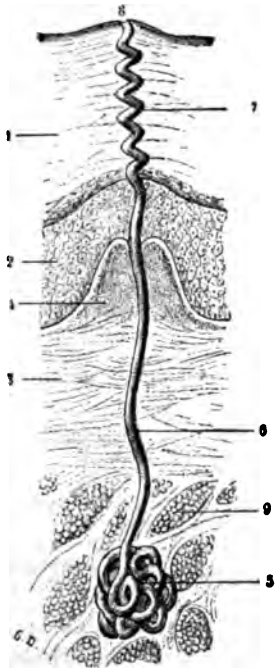
C. THE CUTANEOUS GLANDS

The **glands of the skin** [glandulæ cutis] are of two kinds: **glomiform glands** and **sebaceous glands.** The *glomiform* ('skein-like') glands [glandulæ glomiformes] are of four types: sudoriferous, ciliary, ceruminous and circumanal glands.

The **sudoriferous glands** [glandulæ sudoriferæ] or sweat-glands are modified simple tubular glands which secrete the *sweat* [sudor]. They are found in the skin of all parts of the body except that part of the terminal phalanges covered by the nails, the concave surface of the concha of the ear, the labia minora, and the inferior part of the labia majora in the female and the surface of the prepuce and the glans penis in the male.

FIG. 79.—VERTICAL SECTION OF THE PALMAR SKIN SHOWING AN ISOLATED SUDORIFEROUS GLAND. (Testut.)

1, Stratum corneum; 2, Malpighian layer; 3, corium; 4, papilla; 5, body of sudoriferous gland; and 6, 7, its excretory duct; 8, orifice of duct on surface; 9, subcutaneous fat.



The *number* of sweat glands found in different parts of the body varies greatly. There are very few on the convex surface of the concha and on the eyelid. They are also rather scanty on the dorsal surface of the trunk and neck, more numerous on the ventral surface of these parts and on the extensor surfaces of the extremities, still more numerous on the flexor surfaces and most numerous on the volar surface of the hands and plantar surface of the feet. They vary from less than 57 to more than 370 to the square centimeter.

Each gland (figs. 64, 79) consists of a secretory portion or **body** [corpus gl. sudoriferæ], and an excretory **duct** [ductus sudoriferus], which opens on the surface of the skin by a mouth visible to the unaided eye, the so-called 'pore' [porus sudoriferus]. Occasionally the duct opens into a hair-follicle.

The **bodies** of the glands are irregular or flattened spherical masses, yellowish or yellowish red in color and somewhat transparent. They vary in size from .06 to 4 mm. or more with a mean diameter of .2 to .4 mm., the largest being found in the axilla. They are formed of the irregularly many times coiled terminal part of the gland tube. The bodies of the glands are situated in the deeper part of the corium or in the subcutaneous tela.

The **ducts,** beginning as several coils bound up with those of the bodies, extend often in a straight or slightly wavy course nearly at right angles to the surface as far as the epidermis. This they pierce as spiral canals of from two to sixteen turns, more marked where the epidermis is thickest (fig. 64), and opened on the surface by somewhat widened funnel-shaped mouths. The ducts pass between the papillæ of the corium and open on the summits of the cutaneous cristæ where these are present. The diameter of the ducts is distinctly smaller than that of the secreting part of the glands, and this is true of the lumen also.

The degree of development of the sweat-glands varies with the situation, the individual, and also racially, as instanced by their great development in the negro. In rare cases sweat glands are completely absent from the human skin. The general body-skin of a number of mammals contains no sweat-glands. The glands are smaller in the aged than in the young.

The sudoriferous glands in the axillary region seem to be in some way connected with the sexual function for although a large number persist as small glands, others undergo further development beginning about the ninth year in the female and at puberty in the male. These glands in places form almost a continuous layer and are formed of large partly branched tubules with high secreting cells. The reddish color of the sweat in the axillary and some other regions, especially in certain individuals, is probably derived from the pigment-granules which are found in the glands here. The oil in the secretion lubricates the skin and keeps it soft and supple.

Vessels and nerves.—The sudoriferous glands are supplied from the deep cutaneous plexus by an abundant network of arteries which surround and penetrate between the coils of the gland-tubules. There is an enclosing network of nerve-fibers some of which have been traced to the gland cells.

Development.—The sudoriferous glands are seen first in the fourth or fifth fetal month. The anlages resemble closely those of the hair, but the cells are not so loosely packed. They project down as solid plugs which become long, slender, and tortuous rods. In the seventh fetal month the rods begin to develop a lumen in the deeper parts, which also now begin to coil. A lumen soon develops also in the superficial parts and joins that in the deeper part of the gland. The outer of the two layers of epithelium in the ducts becomes transformed at its transition into the gland proper into the myoepithelial layer.

The **ciliary glands** [gl. ciliares; Molli] are modified sudoriferous glands of the branched tuboalveolar type. They have simpler coils but are larger than ordinary sweat glands. They are situated in the eyelids near their free borders and open into the follicles of the cilia or close to them (see Section IX).

The **circumanal glands** [gl. circumanales] are found in a circular area about 1.5 cm. wide which surrounds the anus, a short distance from it.

These glands are several times the size of the ordinary sweat glands and resemble the glands found in the axilla, their secretion likewise having a strong odor. They are branching tubular glands. The other kinds of glands which are found in this same area are ordinary sweat glands, glands with straight ducts, with saccules and secondary alveoli, and tuboalevolar glands.

Ceruminous gland [gl. ceruminosæ] are glomiform glands somewhat modified from the sudoriferous type. They are branched tuboalveolar glands with relatively large lumina in the coils and narrow short ducts, and occur only in the external acoustic (auditory) meatus.

They are very abundant on the dorsal and superior part of the acoustic meatus in the region of the cartilaginous part, where in the adult most of them open on the surface of the skin close to hairs. Others open into the hair-follicles as they all do in the fetus and child. Their secretion, the **cerumen,** is, when freshly secreted, a fluid or semifluid oily material of a yellowish-brown color, which on exposure to the air becomes solid like wax.

The **sebaceous glands** [gl. sebaceæ] are simple branched or unbranched alveolar glands distributed over nearly the whole surface of the body. Nine-tenths of them are closely associated with the hairs, into the follicles of which they empty (figs. 73, 74), and are therefore absent from certain of the non-hairy parts of the body, as the flexor surfaces of the hands and feet, the dorsal surfaces of the distal phalanges of the fingers and toes. On the other hand, a few are found, usually much modified, opening independent of the hair-follicles, as at the angles of the red margins of the lips, around the nares, around the anus, and the *tarsal* (Meibomian) glands in the eyelids. Modified sebaceous glands are also found upon the mammary papilla and areola in the female, and in some cases upon the superficial surface of the glans and the surface of the prepuce of the penis, here known as **preputial glands;** also a few very small ones may be found upon the labia minora, the glans and prepuce of the clitoris.

The sebaceous glands vary in size in different situations and also in individuals and races. They range from .2 to 2.2 mm. long and nearly as broad. Among the smallest are those of the scalp. The largest are found on the alæ of the nose and on the cheeks where their ducts are visible to the unaided eye. They are also large on the mons pubis, labia majora, scrotum, about the anus and on the mammary areola. Smaller glands are also found associated with these large ones. The size of the glands is independent of the size of the hairs with which they are associated but the number of glands depends upon the size of the hair. On small hairs one or more glands are always found and on large hairs there may be a whole wreath of from four to six separate glands opening into the hair follicle.

The **number** of sebaceous glands has never been exactly estimated, although, it is known that they are less numerous than the su oriferous glands. This is very evident on the extrem-

ities, trunk, and neck, where they bear a relation of 1 to 6 or 8. On the scalp, concha of the ear, and skin of the face they are about equal in number while on the forehead, alæ of the nose, free borders of the eyelids and external genital organs in the female the number of sebaceous glands is greater than the number of sudoriferous glands.

Each sebaceous gland consists of a secretory portion, the **body**, connected with the hair-follicle or the surface of the skin by a wide short **duct**. In the small glands, the body of the gland may consist of a single alveolus but in the larger glands there are from four to twenty of these connected by irregular ducts to a single excretory duct.

The **ducts** open into the hair-follicles near their necks between the inner root-sheath and the hair or upon the surface of the skin. They are always very short, cylindrical, or infundibuliform, and their epithelium is directly connected with that of the outer root-sheath of the hair-follicle or with the epidermis where the hair is wanting.

The glands lie in the superficial layers of the corium and where one or a few are connected to a single hair, they usually open into the hair-follicles on the side toward which the hairs point. Where there are several glands for one hair they may completely surround the hairs like a rosette. The active secretion of the sebaceous glands does not begin before the fifth or sixth year of life. It attains its maximum in the adult and decreases in the aged.

The relation of the arrectores pilorum to the sebaceous glands has been described in connection with the relation of these muscles to the hairs.

Vessels and nerves.—The sebaceous glands are surrounded by a fine capillary plexus of **blood-vessels** closely associated with those of the hairs and skin. Concerning their **lymph-vessels** little is known. The **nerves** of the sebaceous glands are connected with those of the skin and hair but the exact manner of distribution is uncertain.

Development.—The sebaceous glands appear first in the fifth fetal month as single, rarely double, buds on the anlages of the hair-follicles. The distal ends of these enlarged buds become lobulated. In these solid masses of cells lumina for the alveoli and the ducts later are formed, through the fatty degeneration of the central cells. The oily contents of these cells together with the débris and the cast-off surface cells of the epidermis form the **vernix caseosa** on the surface of the fetus.

D. THE MAMMARY GLANDS

The **mammary glands** [mammæ] or breasts are modified cutaneous glands. In the male they remain rudimentary and functionless throughout life, but in the female they are functionally closely associated with the reproductive organs since they secrete the milk for the nourishment of the newborn and are subjected to marked changes at puberty, throughout pregnancy, during and after lactation, and after the menopause.

The two mammæ (fig. 80) are situated on the ventral surface of the thorax one on each side of the sternum. As examined from the surface in a well-developed nulliparous female they appear to extend from the second or third rib to the sixth or seventh costal cartilage and from the lateral border of the sternum to beyond the ventral folds of the axillæ. (For further details on topography and clinical relations, see p. 1366.) Separating the two mammæ there is a median area of variable size, the **sinus mammarum**.

In **shape** they are conical or hemispherical, and in consistency somewhat firm and elastic. The two breasts are seldom equal in size, the left, as a rule being slightly the larger. Each measures from 10 to 13 cm. in diameter being slightly longer in the direction parallel to the lateral border of the pectoralis major muscle. The **weight** of each gland varies from 140 to 200 grams, or more.

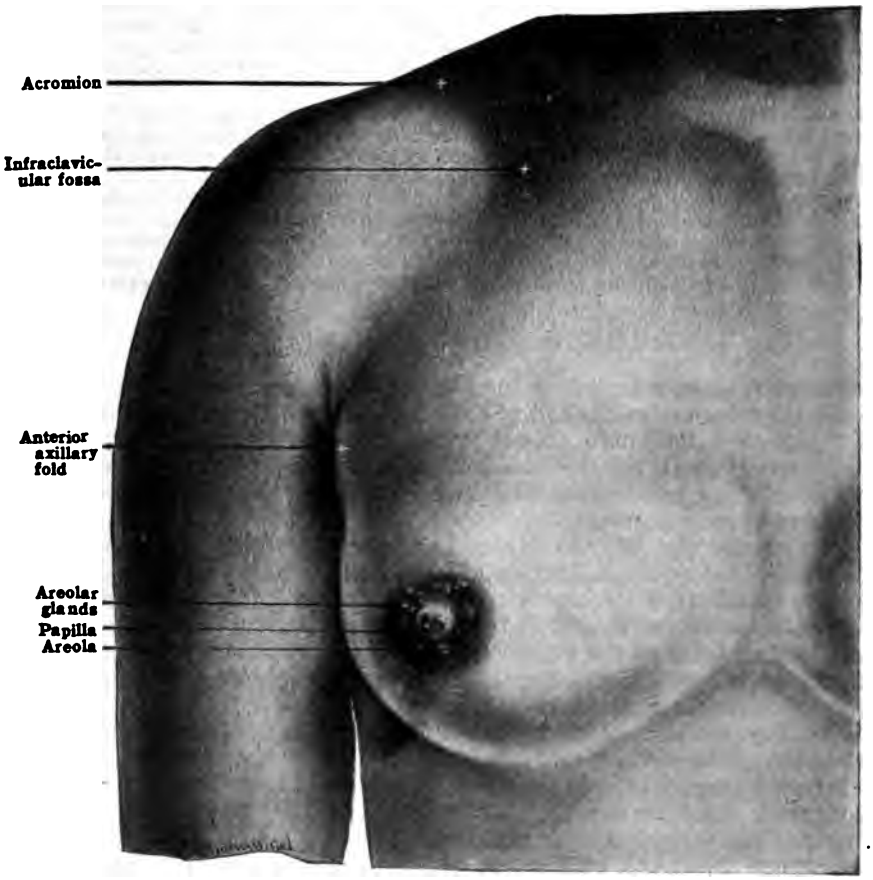
Each mamma presents a ventral surface and a dorsal surface. The **ventral surface** is free, covered by skin, smooth and convex. It is continuous cephalically, without sharp demarcation, with the ventral surface of the thorax but laterally and caudally it is usually sharply defined (figs. 80, 82). It is most prominent slightly mesocaudal to the center and at this point there is a marked pigmented projection, the **nipple** [papilla mammæ] surrounded by a slightly raised area, also pigmented, the **areola mammæ**. These two structures will be described separately later.

The **dorsal surface** of the mammary gland (figs. 82, 83) is attached and concave. It is in relation in its cephalomedial two-thirds with the fascia over the pectoralis major muscle. In its caudolateral third it extends over the base of the axillary fossa, where it is in relation with lymphatic glands and with the serratus anterior muscle, and at its most caudal part, sometimes with the external abdominal oblique muscle.

The usual **number** of breasts in the human species is two; rarely is the number reduced, much more often do we find an increase in this number. Each of these conditions is found in both sexes and may be complete or partial. Complete suppression of both breasts, **amastia**, is

one of the rarest anomalies and is usually associated with other defects. Complete absence of one is less rare. A more frequent condition is arrest of development, **micromastia,** leading to rudimentary but functionless organs. Absence of the nipple, **athelia,** is much commoner and generally affects both breasts. All grades of the imperfection from complete absence to slightly imperfect nipple may be found. When there is an increase this may include the whole breast, **polymastia,** or just the nipple, **polythelia.** The supernumerary structures [mammæ accessoriæ] may be represented only by a pigmented area indicating an areola; or by a nipple with or without an areola: by a gland with a more or less perfect nipple and areola; or with ducts opening without a nipple; or there may be no opening on the surface. The extra mamma is very rarely perfectly developed and functional. Various observers have found the supernumerary breasts or nipples occurring in from 1 to 7 per cent. of the cases examined and somewhat oftener in males than in females. The extra organs are found more frequently on the left side, usually along a line extending from the axilla toward the genitalia. This corresponds to the position in which the mammæ occur in some other mammals and also to the milk-line of the embryo. Although they are occasionally found in other situations, over 90 per cent. of them

FIG. 80.—THE RIGHT MAMMA OF A GIRL 18 YEARS OLD. (Modified from Spalteholz.)



are encountered upon the ventral surface of the thorax along the above-mentioned line caudal and medial to the normal pair of breasts. They are frequently hereditary. It is doubtful whether their possessors are either more fertile or more liable to bear twins.

The **shape** of the breasts varies with the development and functional activity and with the amount of fat. The smooth, somewhat conical breast of the nullipara becomes hemispherical with increase in the amount of fat, while in emaciation it may be reduced to a flattened disk with an irregular surface. After lactation the breasts tend to become more pendulous with marked sulci between them and the thoracic walls, and after repeated pregnancies they may become elongated so as to be almost conical or even have pedunculated bases.

The **size** of the mammary gland in girls remains relatively the same as in the infant up to puberty, when it suddenly increases considerably and continues for a time to enlarge slightly at each menstrual period. There is also a temporary enlargement and soreness at each menstrual period, due perhaps to the increased blood supply. Until the age of puberty the glands measure 8 to 10 mm. in diameter but when they have attained their complete adult development they have in-

creased to 100 to 110 mm. in the cephalomedial, 120 to 130 mm. in the cephalolateral (obliquely from above downward) direction, and 50 to 60 mm. in thickness.

FIG. 81.—THE FEMALE MAMMA DURING LACTATION. (After Luschka.)

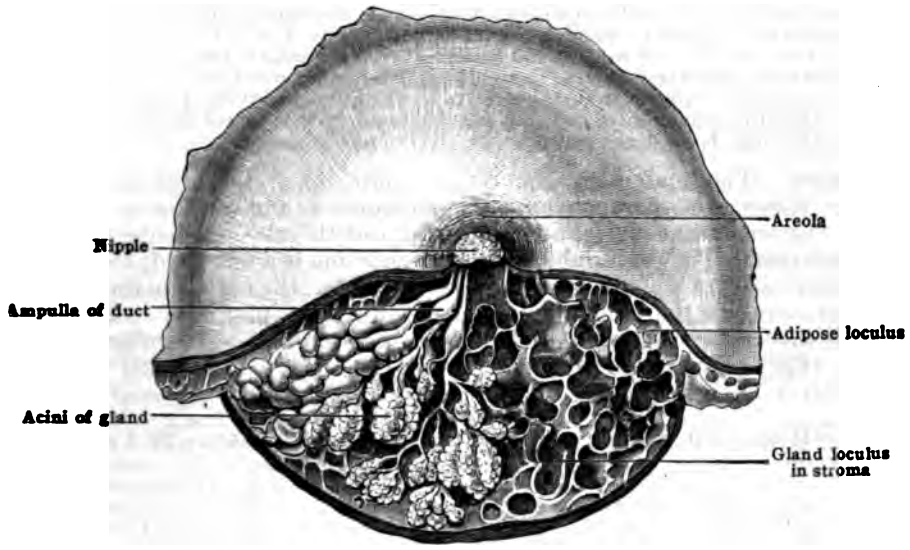


FIG. 82.—SAGITTAL SECTION OF THE RIGHT MAMMA OF A WOMAN TWENTY-TWO YEARS OLD. (Testut.)

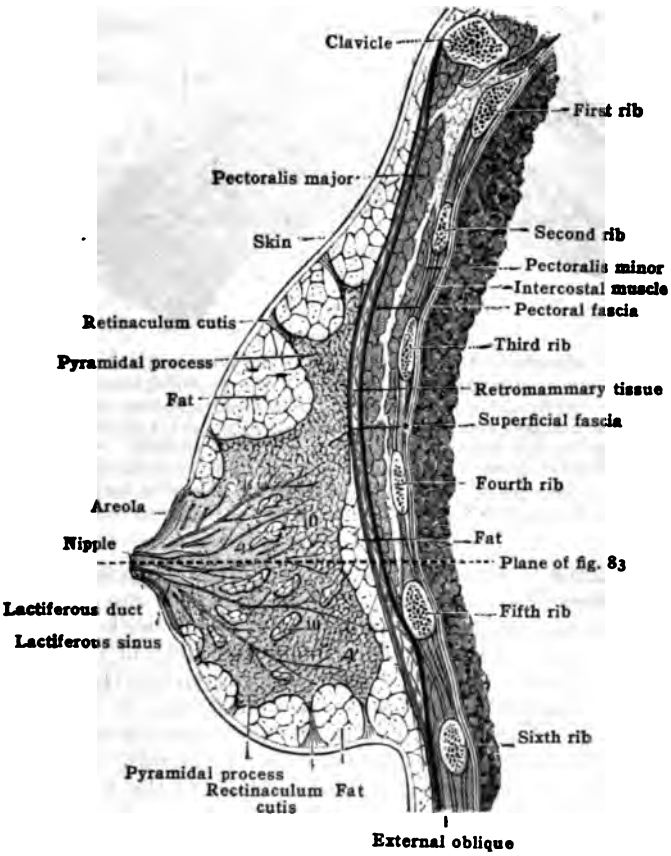


During pregnancy the breasts again increase in size, more especially after the birth of the child. When their full functional activity is established, their volume may be two or three times as great as before pregnancy. After lactation they return again nearly to their former

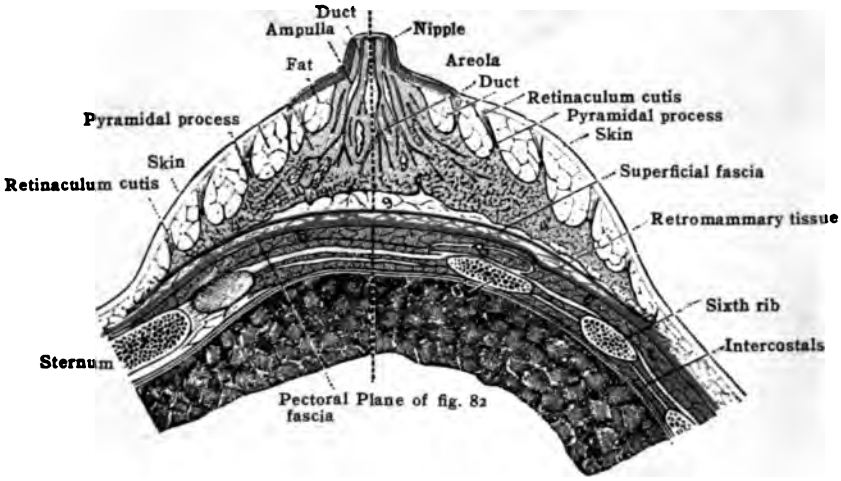
size, which they retain until another pregnancy. After the menopause the useless glands in some cases atrophy and are reduced to small discoidal masses. In others, especially in fat individuals, although the secreting tissue disappears, it is replaced by fat so that there is little or no reduction in size. In addition to the above-mentioned variations in size, the breasts are subject to great individual differences, the cause of which is little understood. Large robust women are sometimes seen with small mammary glands, and small women with large glands.

The *position* of the gland is considered more fully in Section XIV. The level of the mammæ varies with the stature; as a rule, in tall women it is more caudal and in short and broad-chested women it is more cephalic. The tightness of the attachment to the sheath of the pectoralis major muscle is quite variable, but even when quite loose there is some movement of the breast when the arm is raised. The glandular tissue of that part of the breast which overhangs the axilla may be in direct contact with the lymphatic glands.

Structure.—The mammary glands are composed of the essential epithelial glandular tissue, the **parenchyma,** the supporting and enclosing connective tissue of the subcutaneous tela, the **stroma,** and the covering cutaneous layer.

Parenchyma.—The essential part of each mamma is a flattened, circular mass of glandular tissue of a whitish or reddish-white color, the **corpus mammæ.** This is thickest opposite the nipple and thinner toward the periphery. The ventral surface of this mass is convex and made uneven by numerous irregular pyramidal processes (figs. 82, 83) which project toward the skin. The dorsal sufrace, or base, is flat or slightly concave and much less irregular than the ventral surface.

FIG. 83.—HORIZONTAL SECTION OF THE RIGHT MAMMA OF A WOMAN 22 YEARS OLD. (Testut.)



Minute processes of glandular tissue extend from the corpus mammæ into the retromammary tissue, some of them accompanying the septa of the pectoral fascia between the bundles of muscle fibers of the pectoralis major muscle. The circumference of the mamma is thick and well defined, more marked caudally than cephalically, but it presents numerous irregular processes which extend beyond the limits apparent from the surface. One of these especially large and well marked extends cephalolaterally into the axillary fossa, and there are frequently other large but less-marked projections. The glandular tissue in section appears grayish or pinkish in color, and is firm and resistant in consistency. It is thus readily distinguished from the adipose tissue.

The **corpus mammæ** is not a single structure but is composed of from fifteen to twenty separate **lobes** [lobi mammæ] (fig. 81). These are larger and smaller irregular flattened pyramidal groups of glandular tissue, with their apices toward the nipple and their bases radiating toward the periphery of the gland.

Each lobe has a single excretory **duct** [ductus lactiferus] (figs. 81, 82, 83), which opens by a contracted *orifice* (porus lactiferus) in a depression upon the tip of the nipple. When traced from the pore toward the circumference of the gland, the ducts are seen to run first directly dorsally through the nipple, parallel and close to one another. From the base of the nipple they diverge. Each duct is here visible to the unaided eye and measures from 1.5 to 2.5 mm. in diameter. Beneath the areola its diameter increases for a short distance to from 4 to 9 mm., forming thus a reservoir, the ampulla or **sinus lactiferus,** in which the secretion may accumulate for a time. Beyond this dilation the duct continues, gradually decreasing in size as it breaks up into smaller and smaller branches.

There is no anastomosis between the ducts during their course, although at or beneath the pore two or more ducts may join to have a common opening. They possess no valves but when empty their inner surface is thrown into longitudinal plicæ. The ducts have an external coat of white fibrous connective tissue mixed with circular and longitudinal elastic fibers, and an epithelial lining.

Each of the terminal branches of a duct ends in a tubulosaccular, spherical or pyriform **alveolus**. A number of these alveoli which open into a common branch of the duct, when grouped together and bound up with connective tissue, constitute a **lobule** of the gland (lobulus mammæ). A lobe is made up of all the lobules whose ducts join one common excretory duct.

Stroma.—The lobes, lobules, and alveoli are completely covered by a connective tissue sheath too delicate to constitute a distinct capsule. Outside of this the whole gland is embedded in the subcutaneous tela which forms for it a sheath, **capsula adiposa mammæ**. This is particularly well developed on the ventral surface where the fat fills in between the irregularities caused by the lobes and lobules and gives to the surface of the gland its smooth appearance. Within the corpus mammæ there is little fat between the lobules in nulliparæ but much more fat is found here in the stroma in multiparæ. When the fat is absorbed, as it is during lactation and in emaciation, the lobules stand out much more distinctly. There is however, no fat immediately beneath the areola and nipple. The connective tissue is here loosely arranged and allows free motility of the nipple and also permits the more easy distention of the ducts and sinuses during lactation. The connective tissue strands, **retinacula mammæ**, which extend from the apices of the glandular processes on the ventral surface of the mamma are connected to the corium and correspond to the retinacula cutis found in other situations. These are sometimes particularly well developed over the cephalic part of the mamma and have been called the *suspensory ligament of Cooper*.

The dorsal surface of the mamma is bound to the pectoral fascia by loose connective tissue containing, as a rule, only a small amount of retromammary fat (figs. 82, 83). The attachment to the sheath of the pectoralis major muscle is at times so loose that the spaces between the connective tissue appear to form serous sinuses, the **retromammary bursæ**.

In addition to the axillary process or 'tail' of the gland, a projection is sometimes seen extending toward the sternum and another caudolaterally; also processes extending toward the clavicle and caudomedially have been described. Besides these large projections there are numerous branched interlacing processes which combine into larger and smaller masses on the ventral surface and exist as minute extensions on the dorsal surface. In thin women, the parenchyma at the apex of these triangular processes reaches nearly to the surface.

A mammary gland may be made up of a larger amount of stroma and a smaller amount of glandular tissue, or the reverse, and therefore a small breast may furnish more milk than a large one. There is also a variation in different parts of the same breast, one lobe or section may have well-developed lobules while in another they remain almost as at puberty, merely branching ducts.

The **skin** covering the ventral surface of the mamma is covered with lanugo hairs associated with sebaceous glands, and contains many sweat glands of the ordinary type. It is so thin that the subjacent veins are readily seen through it. It is closely adherent to the subjacent fatty layer but its flexibility, elasticity, and motility over the deeper glandular tissue permit much stretching during the enlargement which occurs at the time of lactation. In spite of this, **lineæ albicantes** are often produced especially when the breasts have been unusually large. Aside from the above-mentioned particulars it does not differ from the skin of the adjacent part of the thorax, except over the center of the breast where it forms the areola and nipple.

The **areola mammæ** (figs. 80 to 83) is covered by a thin, delicate, pigmented skin. The *color* in young nulliparæ is reddish, the shade varying with the complexion. During pregnancy the color darkens, slightly in blondes, but so as to become almost black in marked brunettes.

This pigmentation serves as one of the signs of gestation. After lactation the color fades, but little pigmentation remaining in blondes, considerable in brunettes. During pregnancy there is sometimes seen extending more or less beyond the areola a less deeply and less uniformly pigmented ring, the **secondary areola**. In size, the areola is subject to considerable individual variation and is increased in pregnancy.

The **surface** of the areola is roughened by a number of slight elevations irregularly arranged. These are due to underlying large sebaceous and rudimentary milk-glands [gl. areolares: Montgomerii], tubercles or *glands of Montgomery*. Projections caused by sebaceous glands are also found in the secondary areola. All of these tubercles enlarge greatly during pregnancy and the glands produce a slight secretion which is discharged through ducts that open on their summits. The sweat glands are few but large, and in addition to the lanugo hairs there are usually several well-developed hairs.

The *corium* of the areola is devoid of fat but contains a well-developed layer of smooth muscle-fibers, the fascicles of which intercross in various directions but may be seen to be mainly of two orders, circular and radial. They are continuous with those of the nipple. The circular fibers are most numerous adjacent to the nipple, where they may form a layer nearly 2 mm. in thickness.

The areola varies greatly in size, measuring from 15 to 60 mm. in diameter. There is some confusion in regard to the areolar glands and the tubercles of Montgomery. Some consider

the tubercles to be caused by the areolar glands, others consider them caused by the sebaceous glands. Sebaceous glands undoubtedly cause the projections in the secondary areola. The sudoriferous glands of the areola are large and compound tubular glands with a complicated glomerulus and are considered as transitions between sweat and mammary glands. The sebaceous glands are even more numerous than the sudoriferous and are composed of several lobes. They also have been considered by some as intermediate stages in the formation of mammary glands, but this is improbable. There are ten to fifteen very small areolar glands (though Pinard found an average of but four to each breast), whose structure is essentially identical with that of the principal mammary glands. They have dilations on their ducts and they open on the areola at times in common with a sebaceous gland.

The **nipple** [papilla mammæ] (figs. 80 to 83) in well-developed nulliparæ is situated slightly mesocaudal to the center of the breast and on a level with the fourth rib or fourth intercostal space about 12 cm. from the median line. But its position in reference to the thoracic wall varies greatly with age, individual, and the present and past activity of the gland. The nipple is usually somewhat conical or cylindrical with a rounded fissured tip marked by fifteen to twenty minute depressions into which the lactiferous ducts empty. The average length of the nipple is 10 mm. to 12 mm. The skin is thin, wrinkled, and pigmented like the areola, except over the tip of the nipple where there is no pigment.

The **corium** of the nipple has many large vascular and nervous papillæ and there is no fat in it. Hairs and sudoriferous glands are absent, but sebaceous glands are present in great numbers. Their secretion here and over the areola serves to keep the skin soft and to protect it from the saliva of the nursing infant. In the deeper layers of the corium smooth muscle-fibers form a loose stratum continuous with that of the areola. This is made up principally of an external circular layer and to a slight extent by an internal layer whose bundles of fibers are parallel with the milk-ducts. Numerous interlacing muscle-fibers connected with these layers and mixed with loose connective tissue, and elastic fibers, but no fat, surround the lactiferous ducts as they pass through the axis of the nipple.

The nipple usually does not project from the surface until the third year. It soon becomes conical but does not attain its full size until shortly after puberty. The size of the nipple is variable, ordinarily in proportion to the size of the gland, but large nipples are sometimes found on small breasts and small nipples on large breasts. During pregnancy the nipple increases in size and becomes more sensitive and more easily erectile. The shape of the nipple in addition to conical or cylindrical may be hemispherical, flattened, discoidal, or slightly pedunculated. Its end may be invaginated or the entire nipple retracted beneath the surface of the gland and projecting only in response to stimuli.

The circular muscle-fibers of the nipple act like those at its base in the areola. By intermittent, rhythmic contractions they tend to empty the lactiferous ducts; by continuous and tight contraction they act as a sphincter. When contracted they also narrow the nipple, make it harder, erect, and more projecting. When the vertical fibers contract they depress the tip of the nipple or they may retract the whole nipple beneath the surface. The muscle of the areola when stimulated puckers the skin toward the nipple causing circular, concentric folds in the skin of the areola.

The **male mammary gland** [mamma virilis]. This develops exactly as in the female. From birth to puberty the glands in the two sexes have a parallel growth and development, but from this time on the glands in the male grow but slightly and reach their full development about the twentieth year.

The corpus mammæ in the adult male measures from 1.5 to 2.5 cm. in diameter and .3 to .5 cm. in thickness. It is whitish in color, tough, and stringy. It is composed of the same number of lobes as in the female but these consist of little more than short ducts with no true acini and may be reduced to mere epithelial or connective tissue strands. The areola and nipple are present and pigmented, but the nipple averages only 2 to 5 mm. in height. The areola has a diameter of 2 to 3 cm. and is covered with hairs. The areolar tubercles may be recognized and the areolar muscle is present. The position of the nipple in relation to the chest-wall is more constant than in the female as the breast is less movable. It is seldom beyond the limits of the fourth intercostal space or the two adjacent ribs, and averages 12 cm. from the median line. Occasionally the male breast may hypertrophy on one or both sides (**gynecomastia**).

Blood-supply.—The main arterial supply to the mammary gland is from mammary rami of perforating branches of the internal mammary artery (p. 607). Usually that from the second or third intercostal space is especially large. Small branches, external mammary rami, are also supplied to the caudal and lateral segments of the breast by the lateral thoracic artery (p. 611). Some rami from the thoracoacromial or supreme thoracic arteries may reach the cephalo-lateral segment of the breast and small twigs, lateral mammary rami, from the anterior branches of the lateral cutaneous rami of the aortic intercostal arteries (p. 627) supply its deep surface. The veins from a superficial plexus communicating with deeper veins corresponding to the arteries.

The lymphatics.—The lymphatics of the mammæ are extremely numerous, forming rich plexuses and free anastomoses. There is a rich plexus in the skin of the areola and nipple which empties mainly into a subareolar plexus. Deep lymphatics arise in the spaces around the alveoli in all parts of the gland, and most of these converge toward the nipple where they join the subareolar plexuses. They anastomose freely with the cutaneous lymphatics and many of

them empty into the subareolar plexus through large lymph-vessel swhich run parallel with the lacteal ducts. From the subareolar plexus usually two large lymph-vessels arise and pass toward the axilla to empty into the axillary lymph-glands. Other lymphatic vessels of the mammary gland follow the course of the various blood-vessels. For further details on the lymphatics, see p. 756.

The nerves.—The gland proper receives its nerves laterally from the lateral mammary rami of the anterior rami of the lateral cutaneous branches of the fourth to sixth intercostal nerves and medially from the medial mammary rami of the anterior cutaneous branches of the second to the fourth intercostal nerves. The skin over the breast receives in addition to branches from the above nerves, branches from the supraclavicular nerves of the cervical plexus. Sympathetic fibers reach the gland but by what course is not yet clear. The nerves are distributed in part to the skin, in part to the plain muscle of the areola and nipple, some to the blood-vessels, and others to the glandular tissue. The secretion is, however, not entirely controlled by nerves as it is influenced also by hormones from other organs brought to it by the blood.

Development.—In very early embryos the epithelium over an area on the side of the body extending from the forelimb to the hindlimb (or beyond these limits) is seen to be deeper and more cubical, the mammary streak. In this area there is produced by multiplication of cells a ridge, the *mammary line or ridge*. In spots along this line, corresponding to the relative position of the mammary glands in some mammals and the supernumerary mammæ in man, the epithelium thickens. The intervening parts of the line disappear as the spots enlarge to form transient *mammary hillocks*. In man development ordinarily proceeds in but one of these hillocks on each side. The deep surface of the hillock projects into the corium as the superficial surface flattens out and the mesodermic cells of the corium condense around the ingrowth producing the *nipple zone*. Rapid proliferation of the deeper cells produces a *club-shaped stage* from the deeper surface of which small bud-like masses of epithelial cells sprout and extend as solid plugs into the corium. These are the anlages of the true secreting part of the gland and the number of buds corresponds to the number of lobes of the future gland. The sprouts extend beyond and beneath the nipple zone and are supported by closely packed connective tissue cells forming the *stroma zone*. The epithelial buds continue to grow and branch and a lumen is finally produced in the originally solid plugs. The primary epithelial ingrowth degenerates and ultimately disappears. A cavity is produced in it which later connects with the lumina of the gland ducts. The depressed nipple zone becomes elevated above the surface soon after birth.

SECTION III

OSTEOLOGY

REVISED FOR THE SIXTH EDITION

BY ROBERT J. TERRY, A.B., M.D.

PROFESSOR OF ANATOMY IN WASHINGTON UNIVERSITY

THE SKELETON

THE skeleton forms the solid framework of the body, and is composed of bones, and in certain parts, of pieces of cartilage. The various bones and cartilages are united by means of ligaments, and are so arranged as to give the body definite shape, protect from injury the more important delicate organs, and afford attachment to the muscles by which the various movements are accomplished.

In its widest acceptance, the term **skeleton** includes all parts of the framework, whether internal or external, and as in many of the lower animals there are, in addition to the deeper osseous parts, hardened structures associated with the integument, it is convenient to refer to the two groups as **endoskeleton** and **exoskeleton** or **dermal skeleton,** respectively. All vertebrate animals possess an endoskeleton, and many of them a well-developed exoskeleton also; but in mammals, the external skeleton, when it exists, plays a relatively subordinate part. In most of the invertebrates the endoskeleton is absent and the dermal skeleton alone is found. The exoskeleton is phylogenetically the older and the endoskeleton the more recent form; transition between the two is presented by the ganoid fishes.

Bones are divisible in regard to form into four classes:—**long, short, flat, and irregular.** The **long bones,** found in the limbs, sustain the weight of the trunk and form a system of levers which, with the muscles attached to them, provide the means of prehension and locomotion. The **short bones,** illustrated by those of the carpus and tarsus, are found mainly where compactness, elasticity, and limited motion are the principal requirements. **Flat bones** confer protection or provide broad surfaces for muscular attachment, as in the case of the cranial bones and the shoulder-blade. Lastly, the **irregular** or **mixed bones** constitute a group of peculiar form, often very complex, which cannot be included under either of the preceding heads. These are the vertebræ, sacrum, coccyx, and many of the bones of the skull.

The **surface contour** of a bone presents inequalities in the shape of eminences and depressions. Ridges, spines, tubercles and grooves are directly related to the origin and insertion of muscles; other grooves of crooked and branched form, canals and foramina are adapted to blood-vessels; smooth surfaces, cartilage-covered and of various forms (heads, condyles, trochlear surfaces) enter into the formation of joints. The surfaces of a bone with the exception of cartilage-covered articular surfaces are closely invested with a tough, fibrous vascular **periosteum** intimately connected with the tendons and ligaments which find attachment on the bone. All bones present a superficial layer of **compact osseous substance** which varies in thickness. Within the denser covering there exists a sponge-structure of bony plates and tubes known as **cancellous bone** which is most abundant in the short and irregular forms: in long bones it is limited almost entirely to the enlarged extremities. The cancellous bone contains the **red marrow.** The plates of cancellous bone correspond to the lines of pressure and tension to which most bones are subjected. The shaft of a long bone contains a spacious **medullary cavity** occupied by the fatty marrow; into this space a constant artery (the medullary or nutrient) enters by the so-called **nutrient foramen** of the shaft. The flat bones of the cranial vault have very dense outer and inner tables of compact substance; the intermediate layer of cancellous bone, channeled for large veins, is known as the **diploë.** In certain parts of the skull the spongy substance is replaced by the air-filled **paranasal sinuses.**

Vessels and nerves.—It is a characteristic of the vascular system of the skeleton that the bones are poor in capillary nets but are furnished with an abundance of fine arterioles. Arteries enter the flat bones at various points. Veins run at first with the arteries, then enter separate bony-walled canals. In the long bones, arteries supply (1) the spongy structure of the extremities, by twigs coming from the articular arteries which branch in the periosteum; (2) the compact bone of the shaft, by vessels of the periosteum; (3) the walls of the medullary cavity and the medulla by the **nutrient artery.** The latter divides on entering the medullary cavity into proximal and distal branches which at the extremities anastomose with the articular arteries supplying the red marrow and cancellous bone. The nutrient artery is accompanied

by two **veins**; most of the venous blood of the medulla and spongy bone is returned by large and numerous veins which leave the bone by foramina at the extremities. **Lymph vessels** are abundant in the periosteum and perivascular lymphatics are present in the Haversian canals. Very little is known concerning the **nerves** which accompany the arteries into bone.

Among the **physical properties** of bone of special interest is that of *elasticity*, which declines in old age, the bones becoming brittle and liable to fracture.

The *strength* of bone has been determined in various ways with pressure in the direction of its long axis. The femur broke at 263–400 kg.; the humerus at 174–276 kg., (Messerer.)

In regard to *hardness*, there is not a great deal of variation generally throughout the skeleton; the petrous portion of the temporal bone is exceptionally hard. The *specific gravity* of bone ranges from 1.87 to 1.97.

The *color* of bones in the living is white tinged very slightly with pink and yellow.

Burning a bone in the air reduces its weight one-third and the residue consists of earthy salts chiefly phosphate of lime. The mineral matter may be removed from a bone by treating it with an acid; there remains a tough, elastic substance, retaining the form of the original bone and which on boiling yields gelatine.

Like other systems, the osseous framework is subject to **variation.** The bones are among the last organs to assume their definitive shapes and are directly or indirectly under the environmental influences of all the soft structures. Skeletal variations may or may not represent heritable characters. In the following discussion of the bones, only a few of the more typical and important variations are noted.

The number of bones in the skeleton varies at different ages (see p. 26), some, which are originally quite independent, becoming united as age advances. They are arranged in an **axial set,** which includes the vertebral column, the skull, the ribs, and the sternum, and an **appendicular set,** belonging to the limbs. The following table shows the number of bones usually distinct in middle life, excluding the auditory ossicles:—

		Bones
Axial Skeleton	The vertebral column	26
	The skull	23
	The ribs and sternum	25
Appendicular Skeleton	The upper limbs	64
	The lower limbs	62
	Total	200

Several of the skull-bones are **compound,** i. e., in the immature skeleton they consist of separate elements which ultimately unite to form a single bone. In order to comprehend the nature of such bones it is advantageous to study them in the various stages through which they pass in the process of development in the fetus and the child.

It follows, therefore, that to appreciate the **morphology** of the skeleton the **osteogenesis** or mode of development of the bones must be studied, as well as their topography or position.

Some bones arise by **ossification** in **membrane,** others in **cartilage.** In the embryo, many portions of the skeleton are represented by cartilage which may become infiltrated by lime-salts—**calcification.** This earthy material is taken up and redeposited in a regular manner—**ossification.** Portions of the original cartilage persist at the articular ends of bones, and, in young bones, at the **epiphysial** lines, i. e., the lines of junction of the main part of a bone with the extremities or epiphyses. Long bones increase in length at the **epiphysial cartilages,** and increase in thickness by ossification of the deeper layers of the investing membrane or **periosteum.** These processes—intracartilaginous and intramembranous ossification—proceed concurrently in the limb-bones of a young and growing mammal.

There is no bone in the human skeleton which, though preformed in cartilage, is perfected in this tissue. The ossification is completed in membrane. On the other hand, there are numerous instances in the skull, of bones the ossification of which begins in, and is perfected by, the intramembranous method. Ossification in a few instances commences in membrane, but later invades tracts of cartilage; occasionally the process begins in the **perichondrium** and remains restricted to it, never invading the underlying cartilage, which gradually disappears (vomer and nasal bones are examples). Further details of development and ossification are included in the description of each bone. (For early development, see p. 25.)

The **limb-bones** differ in several important particulars from those of the skull. Some of the long bones have many centers of ossification, but these have not the same significance as those of the skull. It is convenient to group the centers into two sets, **primary** and **secondary.** The **primary** nucleus of a long bone appears quite early in fetal life, and the main part (shaft) thus formed is called the **diaphysis.** In only three instances does a **secondary** center appear before birth, e. g., the lower end of the femur, the head of the tibia, and occasionally the head of the humerus. Many **primary** ossific nuclei appear after birth. When a bone possesses one or more secondary centers, the primary nucleus, as a rule, appears early.

Secondary centers which remain for a time distinct from the main portion of a bone are termed **epiphyses** (fig. 84). An epiphysis may arise from a single nucleus, as is the case at the lower end of the femur, or from several, as at the upper end of the humerus. Prominences about the ends of long bones may be capped by separate epiphyses.

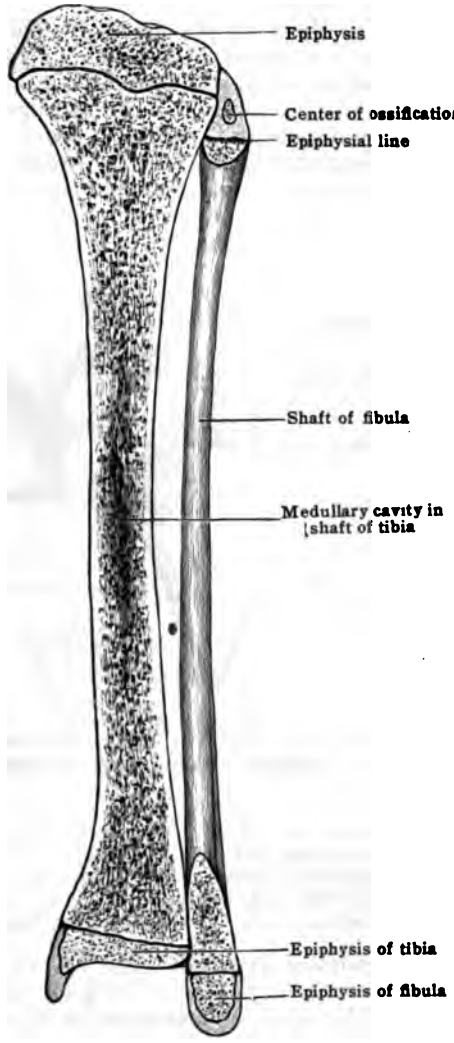
According to Parsons, there are at least three kinds of epiphyses:—(1) Those which appear at the articular ends of long bones, which, since they transmit the weight of the body from bone

to bone, may be termed *pressure* epiphyses. (2) Those which appear as knob-like processes, where important muscles are attached to bones; and as these are concerned with the pull of muscles, they may be described as *traction* epiphyses. (3) The third kind includes those epiphyses which represent parts of the skeleton at one time of functional importance but which, having lost their function, have now become fused with neighboring bones and only appear as separate ossifications in early life. These may be termed *atavistic* epiphyses and include such epiphyses as the tuberosity of the ischium, the representative of the hypoischium of reptiles.

The epiphyses of bones seem to follow certain rules, thus:—

1. Those epiphyses whose centers of ossification appear last are the first to unite with the shaft. There is one exception, however, to this statement, viz., the upper end of the fibula, which is the last to unite with the shaft, although its center appears two years after that for the lower end. This may perhaps be accounted for by the rudimentary nature of the proximal end of the fibula in man and many other mammals.

FIG. 84.—THE TIBIA AND FIBULA IN SECTION TO SHOW THE EPIPHYSES.



2. The epiphysis toward which the nutrient artery is directed is the first to be united with the shaft. It is also found that while the increase in length of the long bones takes place at the epiphysial cartilages, the growth takes place more rapidly and is continued for a longer period at the end where the epiphysis is the last to unite. The shifting of the investing periosteum, which apparently results from these two factors, leads to obliquity of the vascular canal by drawing the proximal portion of the nutrient artery toward the more rapidly growing end. Moreover, when a bone has only one epiphysis, the nutrient artery will be directed toward the extremity which has no epiphysis.

3. The centers of ossification appear earliest in those epiphyses which bear the largest relative proportion to the shafts of the bones to which they belong.

4. When an epiphysis ossifies from more than one center, the various nuclei coalesce before the shaft and epiphysis consolidate, e. g., the upper end of the humerus.

I. THE AXIAL SKELETON

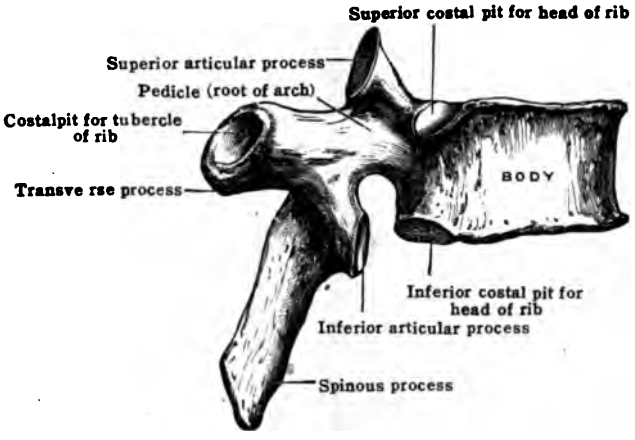
A. THE VERTEBRAL COLUMN

The **vertebral column** [columna vertebralis] (fig. 100) functions as a pillar for the support of the trunk and a case for the protection of the spinal cord and nerve roots. It consists of a series of bones called **vertebræ,** closely connected by means of fibrous and elastic structures, which allow of a small amount of motion between any two adjacent members of the series, but which give to the column as a whole a high degree of flexibility.

Stability of the vertebral column is secured partly through the form of the individual vertebræ and the form of the entire pillar, but also to a large extent by means of muscular control.

In the young subject the vertebræ are thirty-three in number. Of these, the upper twenty-four remain separate throughout life, and are distinguished as **movable** or **true vertebræ.** The succeeding five vertebræ become consolidated in the adult to form one mass, called the **sacrum,** and at the terminal part of the column are four rudimentary vertebræ, which also tend to become united as age advances, to form the **coccyx.** The lower nine vertebræ thus lose their mobility as individual bones, and are accordingly known as the **fixed** or **false**

FIG. 85.—A THORACIC VERTEBRA. (Side View.)



vertebræ. Of the true vertebræ, the first seven are called **cervical** [cervicales], the succeeding twelve **thoracic** [thoracales] or **dorsal,** and the remaining five **lumbar** [lumbales].

Although the vertebræ of the different regions of the column differ markedly in many respects, each vertebra is constructed on a common plan, which is more or less modified in different regions to meet special requirements. The essential characters are well seen in the vertebræ near the middle of the thoracic region, and it will be advantageous to commence the study of the vertebral structures with one selected from this region.

Description of a thoracic vertebra (figs. 85, 86).—The vertebra consists of two essential parts—a body in front and an arch behind.

The **body** [corpus vertebræ] or **centrum** functions in supporting the weight of the trunk. It is a solid disk of bone, somewhat heart-shaped, deeper behind than in front, slightly concave on its superior and inferior surfaces, and wider transversely than anteroposteriorly. The upper and lower surfaces are rough for the intervertebral disks which are interposed between the bodies of the vertebræ, and the margins are slightly lipped. The circumference of the body is concave from above downward in front, convex from side to side, and perforated by numerous vascular foramina. Posteriorly it is concave from side to side and presents one or two large foramina for the exit of veins from the cancellous tissue. On each side of the body, at the place where it joins the arch, are two **costal pits** (superior and inferior) [fovea costalis superior; inferior] placed at the upper and lower borders, and when two vertebræ are superimposed, the adjacent

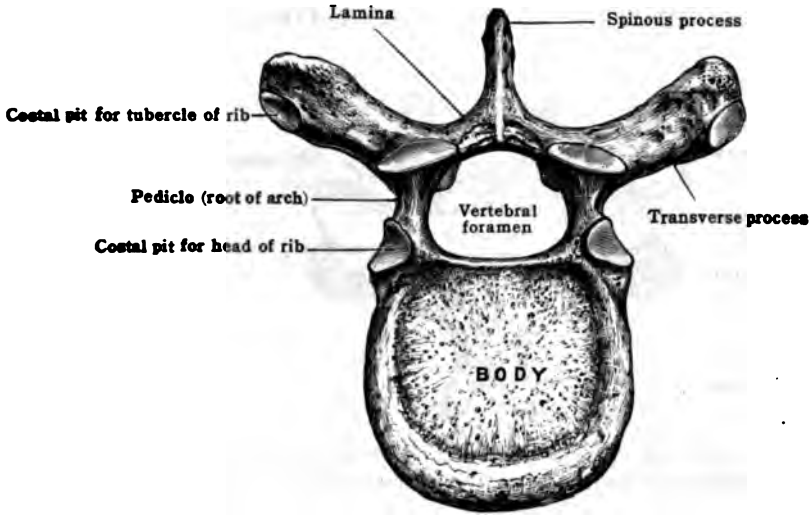
costal pits form a complete articular pit for the head of a rib. The superior and inferior costal pits were formerly designated as 'demifacets.'

The **arch** [arcus vertebræ] serves to protect the spinal cord and the roots of the spinal nerves. It is formed by two pedicles and two laminæ, and supports seven processes—one spinous, two transverse, and four articular. The pedicles or **roots** of the vertebral arch [radices arcus vertebræ] are two short, constricted columns of bone, projecting horizontally backward from the posterior surface of the body. The concavities on the upper and lower borders of each pedicle, of which the lower is much the deeper, are named **vertebral notches** [incisuræ], and when two vertbræ are in position, the notches are converted into **intervertebral foramina** for the transmission of the spinal nerves and blood-vessels. The **laminæ** are two broad plates of bone which connect the spinous process with the roots (pedicles) and complete the arch posteriorly.

The superior border and the lower part of the anterior surface of each lamina are rough for the attachment of the ligamenta flava which bind together the adjacent vertebræ. The upper part of the anterior surface is smooth, where it forms the posterior boundary of the vertebral canal. When articulated, the laminæ in the thoracic region are imbricated or sloped, one pair over the other, somewhat like tiles on a roof.

The **spinous process** [processus spinosus], serves mainly for muscular attachment. It is long and three-sided, projects backward and downward from the

FIG. 86.—A THORACIC VERTEBRA. (From Above.)



center of the arch and terminates in a slight tubercle. It gives attachment by its prominent borders to the interspinous ligaments and by its free extremity to the supraspinous ligament.

The **transverse processes** [processus transversus] are two in number and extend laterally from the arch at the junction of the pedicles and laminæ. They are long, thick, backwardly directed columns of bone terminating in clubbed extremities, on each of which is a costal pit [fovea costalis transversalis] for articulation with the tubercle of a rib. The transverse processes, in addition to supporting the ribs, afford attachment to and powerful leverage for muscles.

The **articular processes,** two superior and two inferior, project upward and downward opposite the attachments of the transverse processes and form joints between successive vertebræ. The superior are flat and bear facets or surfaces [facies articulares superiores] which are directed upward, backward, and laterally, and are situated a little in advance of the inferior, the facets of which [facies articulares inferiores] are oval, concave, and directed downward, forward, and medially.

The **vertebral foramen** is bounded anteriorly by the body, posteriorly and on each side by the arch. It is nearly circular, and is smaller than in the cervical or the lumbar region. When the vertebræ are articulated, the series of rings constitute the **spinal** or **vertebral canal** [canalis vertebralis], in which is lodged the spinal cord and its membranes.

THE CERVICAL VERTEBRÆ

The segment of the vertebral column which forms the axial skeleton of the neck is posessed of a high degree of flexibility, resulting from the peculiar conformation of its constituent vertebræ and from the special characteristics of the articulations between the individual bones. For **muscular attachments,** see figs. 90 and 91; also section on MUSCULATURE.

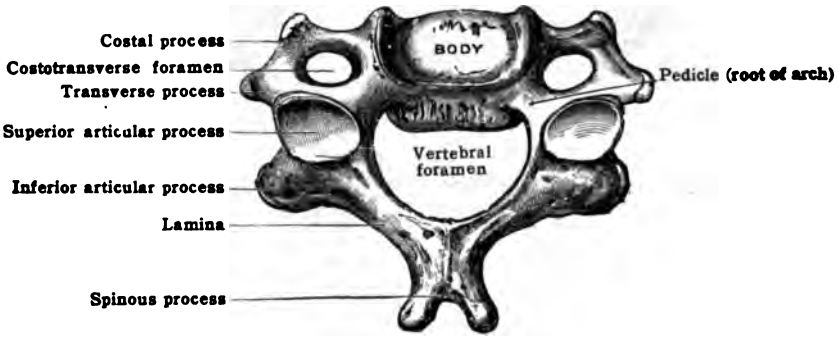
A typical cervical vertebra (from the third to the sixth inclusive) presents the following characteristics (fig. 87):—The **body** is smaller than in other regions of the column and is of oval shape with the long axis transverse.

The lateral margins of the upper surface are raised into prominent lips, so that the surface is concave from side to side; it is also sloped downward in front. The inferior surface, on the contrary, projects downward in front and is rounded off at the sides to receive the corresponding lips of the adjacent vertebra. It is concave antero-posteriorly and convex in an opposite direction. The partial interlocking of the adjacent bodies increases the stability of the intervertebral articulations.

The **roots** (pedicles) are directed laterally and backward and spring from the body about midway between the upper and lower borders. The superior and inferior notches are nearly equal in depth, but the inferior are usually somewhat deeper. The **laminæ** are long, narrow, and slender. The **spinous process** is short and bifid at the free extremity.

Articular processes.—Both the superior and inferior articular processes are situated at the junction of the root with the lamina and they form the upper and

FIG. 87.—A CERVICAL VERTEBRA.



lower extremities of a small column of bone. The articular surfaces are oblique and nearly flat, the superior looking backward and upward, and the inferior forward and downward.

The **transverse process** presents near its base a round **costotransverse foramen** [foramen transversarium] for the transmission of the vertebral artery, vein, and a plexus of sympathetic nerves. Moreover, each process is deeply grooved above for a spinal nerve, and is bifid at its free extremity, terminating in two tubercles—anterior and posterior.

The **costotransverse foramen** is very characteristic of a cervical vertebra. It is bounded medially by the pedicle, posteriorly by the transverse process (which corresponds to the transverse process of a thoracic vertebra), anteriorly by the **costal process** (which corresponds to the rib in the thoracic region), and laterally by the costotransverse lamella. The latter is a bar of bone joining the two processes and directed obliquely upward and forward in the upper vertebræ and horizontally in the lower.

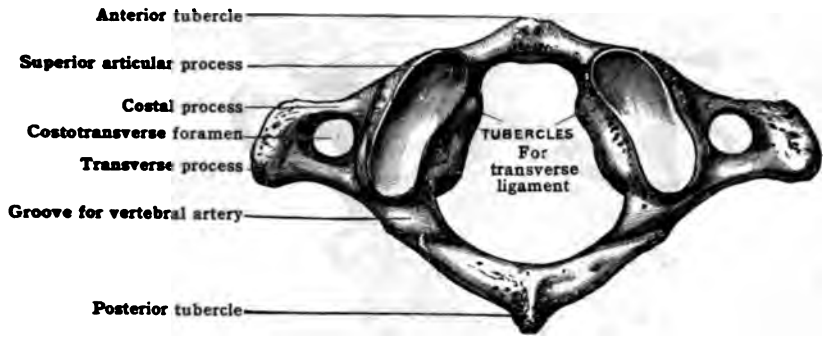
The **vertebral foramen** is triangular with rounded angles; it is larger than in the thoracic or lumbar vertebræ, in adaption to the cervical enlargement of the spinal cord and the greater mobility of the cervical region of the column.

Peculiar cervical vertebræ.—The various cervical vertebræ possess distinguishing features, though, with the exception of the first, second, and seventh, which are so different as to necessitate separate descriptions, these are largely confined to the direction of the costotransverse lamella, and the size and level of the anterior and posterior tubercles. In the third the anterior tubercle is higher than the posterior and the costotransverse lamella is oblique; in the fourth the anterior tubercle is elongated vertically, so that its lower end is nearly on a level with the posterior, though the lamella still remains oblique. In the fifth and sixth they are nearly on the same level, but in the latter the anterior tubercle is markedly developed to form the **carotid tubercle.**

The Atlas or First Cervical Vertebra

The atlas (fig. 88) is remarkable in that it has neither body nor spinous process. It has the form of an irregular ring, and consists of two thick portions, the **lateral masses,** united in front and behind by bony arches. The **anterior arch** joins the lateral masses in front and constitutes about one-fifth of the entire circumference of the ring. On its anterior surface it presents a **tubercle** for the attachment of the *longus colli* muscle and the anterior longitudinal ligament, and its posterior surface a circular facet [fovea dentis] for articulation with the odontoid process [dens] of the epistropheus. The upper and lower borders serve for the attachment of ligaments uniting the atlas to the occipital bone and epistropheus respectively.

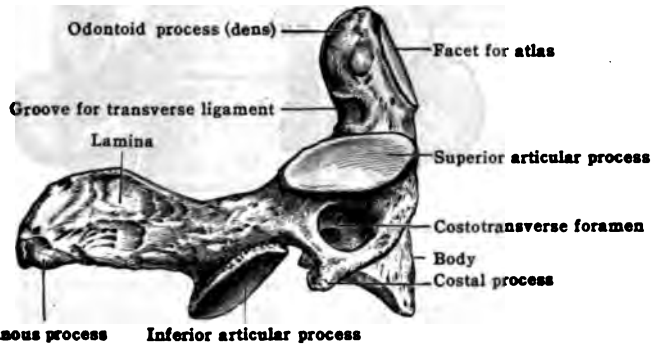
Fig. 88.—The First Cervical Vertebra or Atlas.



The **lateral masses** are thick and strong, supporting the articular processes above and below and extending laterally into the transverse processes. The superior articular surfaces are elongated, deeply concave, and converge in front. Directed upward and medially they receive the condyles of the occipital bone, and occasionally each presents two oval facets united by an isthmus. The inferior articular surfaces are circular and almost flat; they are directed downward and medially and articulate with the epistropheus. The articular processes, like the superior articular processes of the epistropheus, differ from those of other vertebræ in being situated in front of the places of exit of the spinal nerves.

Between the upper and lower articular surfaces on the inside of the ring are two smooth rounded **tubercles,** one on each side, to which the transverse ligament is attached. This liga-

Fig. 89.—The Epistropheus or Axis.



ment divides the interior of the ring into a smaller anterior part for the dens of the epistropheus, and a larger posterior part, corresponding to the foramina of other vertebræ, for the spinal cord and its membranes.

The **transverse processes** are large and extend farther outward than those of the vertebræ immediately below. They are flattened from above downward and each is perforated by a large **costotransverse** foramen; the extremity is not bifid, but, on the contrary, is broad and rough for the attachment of numerous muscles. The **posterior arch** unites the lateral masses behind and forms about two-fifths of the entire circumference. It presents in the middle line a rough elevation or tubercle representing a rudimentary spinous process. At its junction with the lateral mass on the superior surface is a deep **groove,** the **sulcus arteriæ vertebralis,** which lodges the vertebral artery and the suboccipital (first spinal) nerve. The groove corresponds to the superior notches of other vertebræ and occasionally it is converted into a foramen by a bony arch—the ossified oblique ligament of the atlas. A similar but much shallower notch is present on the inferior surface of the posterior arch, and, with a corresponding notch on the

axis, forms an intervertebral foramen for the exit of the second spinal nerve. The upper and lower surfaces of the arch afford attachment to ligaments uniting the atlas to the occipital bone and the axis. For **muscular attachments,** see figs. 90 and 91.

THE EPISTROPHEUS (AXIS)

The **epistropheus** (axis)(fig. 89) is the thickest and strongest of the cervical vertebræ, and is so named from forming a pivot on which the atlas rotates, carrying the head. It is easily recognized by the rounded **dens** (odontoid process) which surmounts the upper surface of the **body.** This process, which represents the displaced body of the atlas, is large, blunt, and tooth-like, and bears on its anterior surface an oval facet for articulation with the anterior arch of the atlas;

The upper oblique portion of longus colli and insertion of inferior oblique portion
Origin of vertical portion of the longus colli; its insertion is into the second, third, and fourth vertebræ

posteriorly it presents a smooth groove which receives the transverse ligament. To the apex a thin narrow fibrous band (the apical dental ligament) is attached, and on each side of the apex is a rough surface for the attachment of the alar ligaments which connect it with the occipital bone. The enlarged part of the process is sometimes termed the **head,** and the constricted basal part the **neck.**

The inferior surface of the body resembles that of the succeeding vertebræ and is concave from front to back and slightly convex from side to side. Its anterior surface is marked by a median ridge separating two lateral depressions for the insertion of the *longus colli.*

The roots (pedicles), are stout and broad; the **laminæ** are thick and prismatic: the **spinous process** is large and strong, deeply concave on its under surface, and markedly bifid; the **transverse processes** are small, not bifurcated and not grooved. The costotransverse foramen is directed very obliquely upward and laterally and the costal process is larger than the transverse.

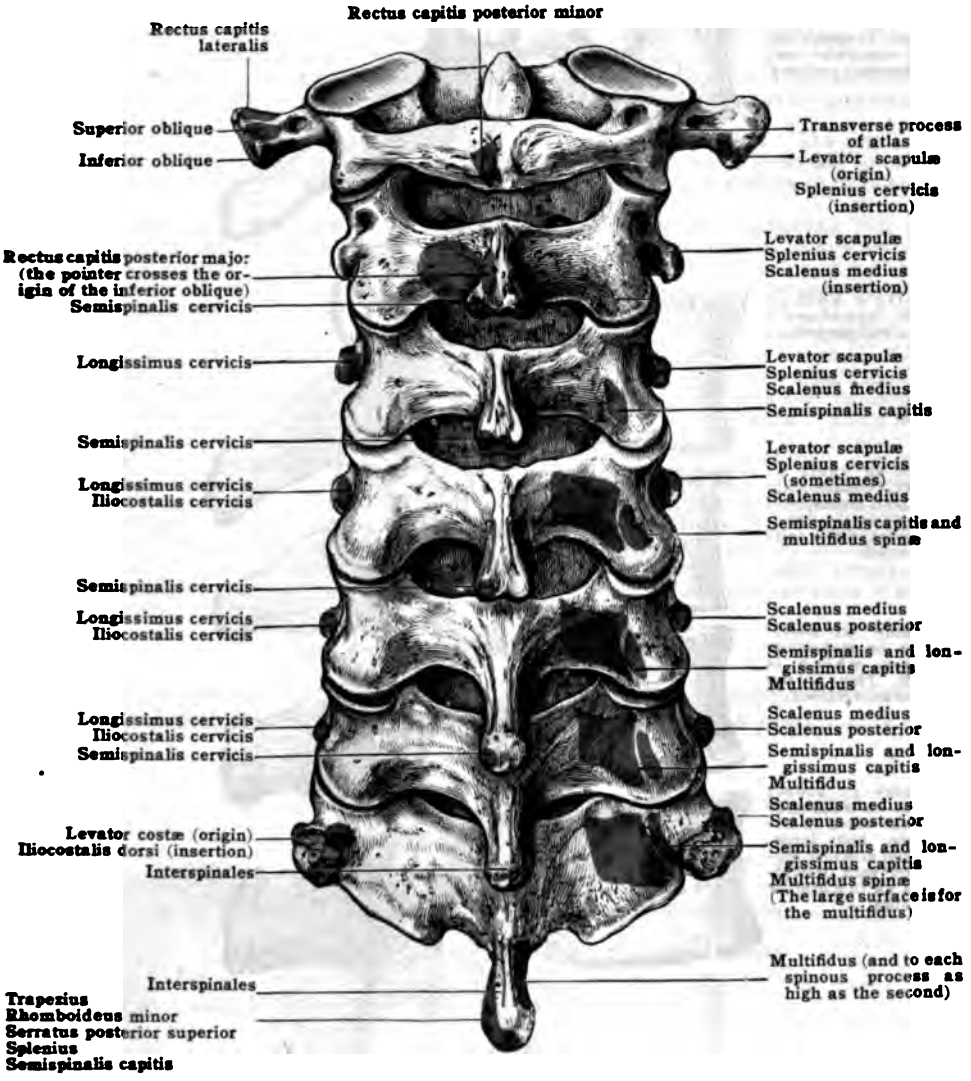
The **superior articular surfaces** are oval, and directed upward and laterally for articulation with the atlas. They are remarkable in being supported partly by the body, and partly by the pedicles, and in being situated in front of the superior notches. The **inferior articular surfaces** are similar in form and position to those of the succeeding vertebræ. For **muscular attachments** see figs. 90 and 91.

The Seventh Cervical Vertebra

Situated at the junction of the cervical and thoracic regions of the vertebral column, the seventh cervical vertebra (figs. 90, 91) may be described as a transitional vertebra—i. e., possessing certain features characteristic of both regions.

The **spinous process** is longer than that of any of the other cervical vertebræ. It is not bifurcated, but ends in a broad tubercle projecting beneath the skin, whence the name **vertebra prominens** has been applied to this bone. The **trans-**

Fig. 91.—The Cervical Vertebræ. (Posterior View.)



verse process is massive; the costal element of the process is very small, but, on the other hand, the posterior or vertebral part of the process is large and becoming more like the transverse process of a thoracic vertebra.

The costotransverse foramen is the smallest of the series and may be absent. It does not, as a rule, transmit the vertebral artery, but frequently gives passage to a vein. Occasionally the costal process is segmented off and constitutes a cervical rib. The body sometimes bears on each side near the lower border a costal pit for the head of the first rib. When this is present, there is usually a well-developed cervical rib. For **muscular attachments,** see figs. 90 and 91.

Variations.—The cervical vertebræ exhibit great variation in regard to the extremities of their spinous processes. As a rule among Europeans, the second, third, fourth, and fifth vertebræ possess bifid spines. The sixth and seventh exhibit a tendency to bifurcate, their tips presenting two small lateral tubercles; sometimes the sixth has a bifid spine, and more

rarely the seventh presents the same condition. Occasionally all the cervical spines, with the exception of the second, are non-bifid, and even in the axis the bifurcation is not extensive. In the lower races of men the cervical spines are relatively shorter and more stunted than in Europeans generally and, as a rule, are simple. The only cervical vertebra which presents a bifid spine in all races is the epistropheus; even this may be non-bifid in the Negro, and occasionally in the European. (Owen, Turner, Cunningham.) The laminæ of the lower cervical vertebræ frequently present posteriorly distinct tubercles from which fasciculi of the *multifidus* muscle

XII

arise. They are usually confined to the sixth and seventh vertebræ, but are fairly frequent on the fifth, and are occasionally seen on the fourth.

The occurrence of *cervical ribs* was mentioned above in connection with the seventh cervical vertebra. They occur normally in birds and reptiles. For their clinical significance in man, see p. 1365.

The dens epistrophei may form a separate *os odontoideum*, the apex of which may correspond to a vestigial body of the atlas. In the atlas, ossification of the anterior or posterior arch may be incomplete The groove for the vertebral artery is not rarely converted into a foramen (typical for mammals). Fusion, partial or complete, of the atlas with the occipital frequently occurs.

THE THORACIC VERTEBRÆ

The general characters of the thoracic (or dorsal) vertebræ have already been considered (p. 84). Their most distinguishing features are the pits on

the **transverse processes** and sides of the **bodies** articulating with the **tubercles** and **heads of the ribs** respectively.

Peculiar thoracic vertebræ.—Several vertebræ in this series differ from the typical example. The exceptional ones are—the **first, ninth, tenth, eleventh,** and **twelfth** (fig. 92).

The **first** thoracic vertebra is a transitional vertebra. The **body** in its general conformation approaches very closely the seventh cervical, in that the greatest diameter is transverse, and its upper surface is concave from side to side. On each side is an entire pit, close to the upper border, for the head of the first rib, and a very small pit (inferior costal pit) below for the head of the second rib. The **spinous process** is thick, strong, almost horizontal and usually more prominent than that of the seventh cervical, an important point to remember when counting the spines in the living subject.

The **ninth** has superior costal pits, and usually no inferior; when the inferior pits are present, this vertebra is not exceptional.

The **tenth** usually has an entire costal pit at its upper margin, on each side, but occasionally only a superior costal pit. It has no lower pits and the pits on the transverse processes are usually small.

The **eleventh** has a large body resembling that of a lumbar vertebra. The pits are on the pedicles and they are complete and of large size. The transverse processes are short, show evidence of subdivision into three parts, and have no pits for the tubercles of the eleventh pair of ribs.

In many mammals, the spines of the anterior vertebræ are directed backward, and those of the posterior directed forward, whilst in the center of the column there is usually one spine vertical. The latter is called the *anticlinal vertebra*, and indicates the point at which the thoracic begin to assume the characters of lumbar vertebræ. In man the eleventh thoracic is the anticlinal vertebra.

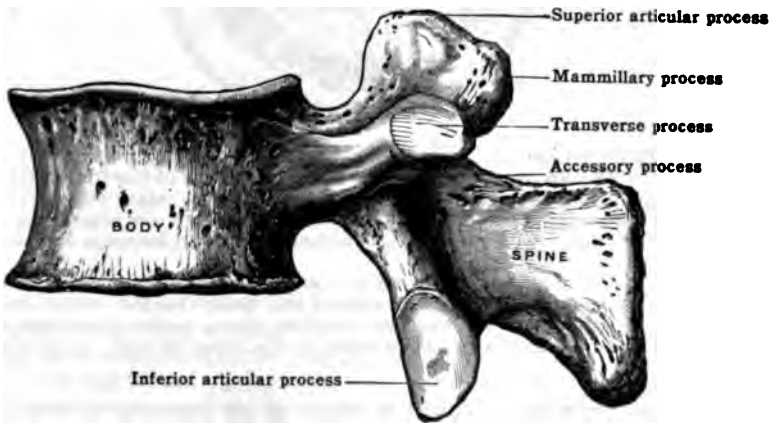
The **twelfth** resembles in general characters the eleventh, but may be distinguished from it by the articular surfaces on the inferior articular processes being convex and turned laterally as in the lumbar vertebræ. The transverse process is rudimentary and tripartite, presenting for examination three tubercles, *superior*, *inferior*, and *lateral*, which correspond respectively to the mammillary, accessory, and transverse processes of a lumbar vertebræ. There is one complete pit on the root (pedicle) for the head of the twelfth rib.

Variations.—The twelfth thoracic, in the absence of the twelfth pair of ribs, commonly conforms to the type of a lumbar vertebra. The transverse process of the tenth occasionally lacks the facet for costal articulation. The lumbar form of transverse process may be present in the eleventh thoracic vertebra. A peculiarity, more frequent in the thoracic and lumbar than in the cervical and sacral regions of the column, is the existence of a half-vertebra (fig. 101). Such specimens have a wedge-shaped half-centrum, to which are attached a lamina, a transverse, superior, and inferior articular, and half a spinous process. As a rule, a half-vertebra is ankylosed to the vertebræ above and below.

THE LUMBAR VERTEBRÆ

The lumbar segment of the vertebral column is massive to support the weight of the head, thorax and upper limbs, yet sufficiently flexible to permit of a con-

FIG. 93.—A LUMBAR VERTEBRA. (Side view.)



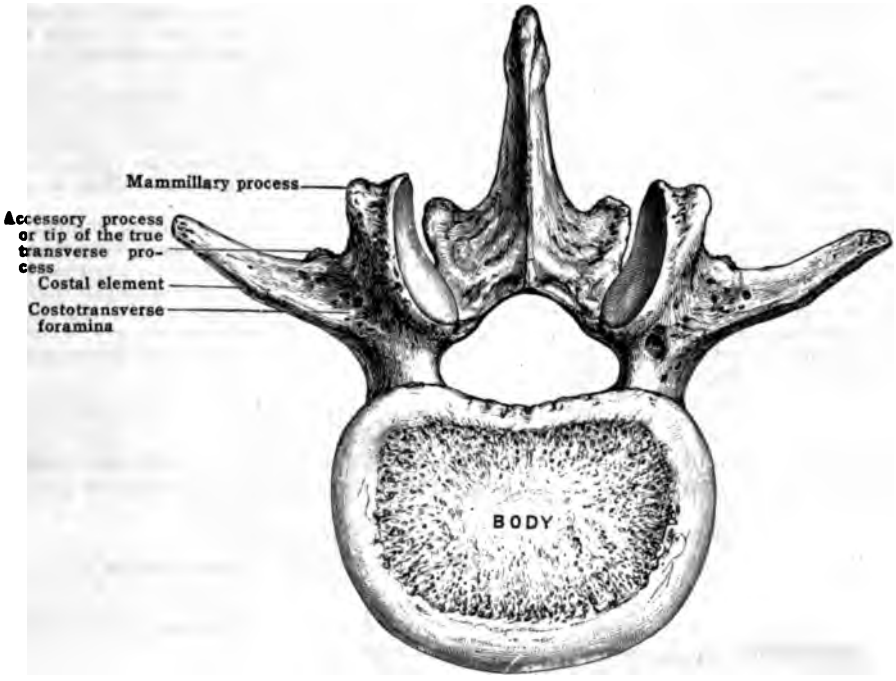
siderable range of movement. The **lumbar vertebræ** (figs. 93, 94) are distinguished from the cervical and thoracic vertebræ by their large size and by the absence of costal articular surfaces.

The **body** is somewhat reniform, with the greatest diameter transverse, flat above and below, and generally slightly deeper in front than behind. The **roots** (pedicles) are strong and directed straight backward, and the lower vertebral

notches are deep and large. The **laminæ** are shorter and thicker than those of the thoracic or cervical vertebræ, and the **vertebral foramen** is triangular, wider than in the thoracic, but smaller than in the cervical region. The vertebral canal of the lumbar region contains the termination of the spinal cord and its membranes, and the cauda equina. The **spinous process,** thick, broad, and somewhat quadrilateral, projects horizontally backward. The **articular processes** are thick and strong. The superior articular surface is concave and directed backward and medially; the inferior is convex and looks forward and laterally. The superior pair are more widely separated than the inferior pair and embrace the inferior articular processes of the vertebra above.

The posterior margin of each superior articular process is surmounted by the **mammillary process** or tubercle (metapophysis) which corresponds to the superior tubercle of the **transverse process** of the last thoracic vertebra. In man the mammillary tubercles are rudimentary, but in some animals they attain large proportions, as in the kangaroo and armadillo. The **transverse processes** are long, slender, somewhat spatula-shaped, compressed from before backward, and directed laterally and a little backward. They are longest in the third vertebra

FIG. 94.—A LUMBAR VERTEBRA.
(Showing the compound nature of the transverse process. Upper view.)



and diminish in the fourth, second, and fifth, in this order, to the first, in which they are shortest of all. Their extremities are in series with the lateral tubercles of the transverse processes of the twelfth thoracic vertebra and also with the ribs. With the latter the so-called transverse processes in the lumbar region are homologous, and hence they are sometimes called the **costal processes**. Occasionally the costal element differentiates and becomes a well-developed lumbar rib.

Behind the base of each transverse or costal process is a small eminence, directed downward, which corresponds with the inferior tubercle of the lower thoracic transverse process, and with the transverse processes of the thoracic vertebræ above, and is named the **accessory process** (anapophysis). It is well developed in some of the lower animals, as in the dog and cat.

The **fifth lumbar vertebra** deviates in some of its features widely from the other members of the series. It is massive, and the **body** is much thicker in front than behind; it forms with the sacrum the *sacrovertebral angle*. The **transverse processes** are short, thick, conical, and spring from the body as well as from the roots of the arch. They afford the attachment to the iliolumbar ligaments. The **spinous process** is smaller than that of any of the other lumbar vertebræ; the **laminæ** project into the vertebral foramen on each side; and the **roots** are stout and flattened from above downward. The **inferior articular**

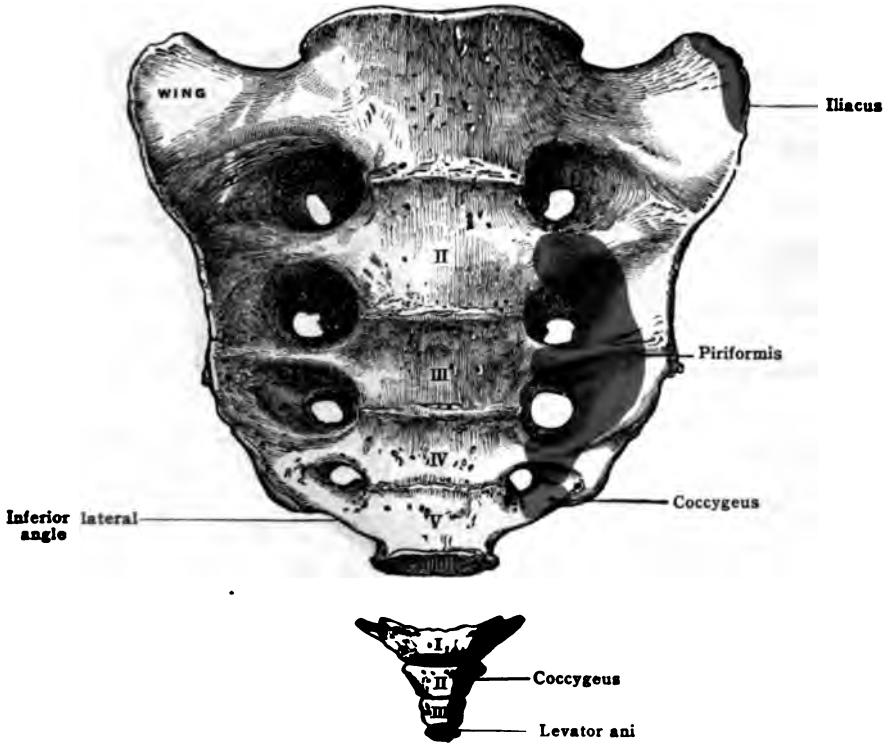
processes are separated to such a degree as to be wider apart than the superior, and they articulate with the first sacral vertebra.

Variations.—The roots of the arch in this vertebra are liable to a remarkable deviation from the conditions found in other parts of the spine. The peculiarity consists of a complete solution in the continuity of the arch immediately behind the superior articular processes. In such specimens the anterior part consists of the body carrying the roots, transverse and superior articular processes; while the posterior segment is composed of the laminæ, spine, and inferior articular processes. The posterior segment of the ring of this vertebra may even consist of two pieces. There is reason to believe that this abnormality of the fifth lumbar vertebra occurs in five per cent. of all subjects examined. Sir William Turner found seven examples among thirty skeletons examined. The skeletons in which this occured were;—a Malay, an Andamanese, a Chinese, two Bushmen, an Eskimo, and a Negro. A similar condition is occasionally met with either unilaterally or bilaterally in the thoracic vertebræ. The fifth lumbar may show a tendency to conform to the type of upper sacral vertebræ, with which it may even become fused.

THE SACRUM

The five sacral vertebræ (figs. 95, 96) are united in the adult to form the **os sacrum,** a large, curved, triangular bone, forming the base of the vertebral column and lying between and firmly connected with the hip bones. Together with the coccyx, it completes the posterior boundary of the minor pelvis. Of

FIG. 95.—THE SACRUM AND COCCYX. (Anterior view.)



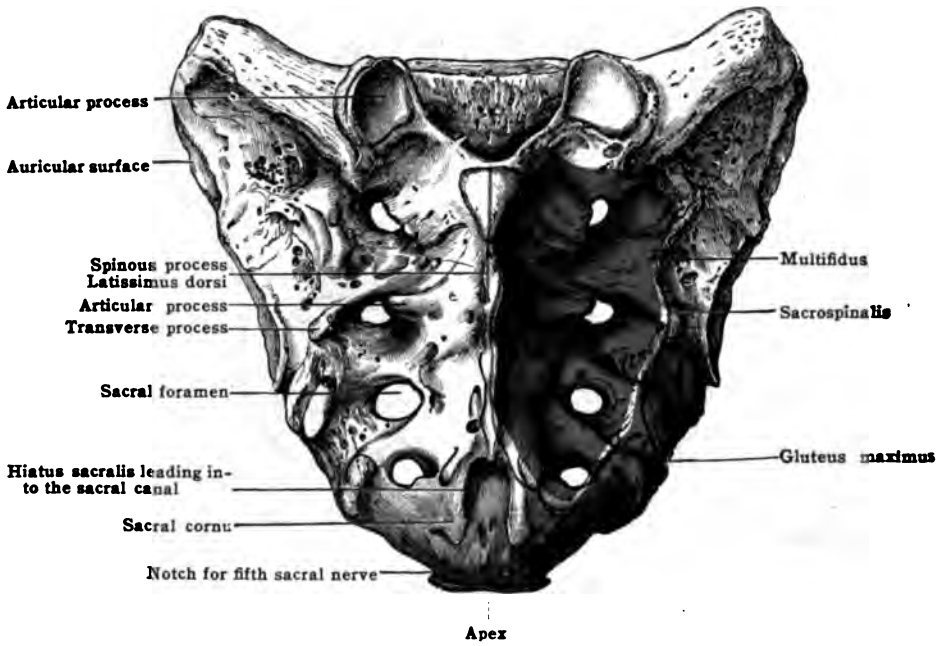
the five vertebræ which compose the sacrum the uppermost is the largest, the succeeding ones become rapidly smaller, and the fifth is quite rudimentary. In the erect posture the sacrum lies obliquely, being directed from above downward and backward, and forms with the last lumbar vertebra an anterior projection known as the sacrovertebral angle or **promontory**.

Surfaces.—The **pelvic surface,** [facies pelvina] directed downward and forward, is smooth, concave from above downward and slightly from side to side. It is crossed in the middle by four transverse ridges [lineæ transversæ] which mark the positions of the intervertebral disks and separate the bodies of the five sacral vertebræ. Of the bodies, the first and second are nearly equal in size and are larger than the third, fourth, and fifth, which, in vertical depth, are also nearly equal to each other. At the extremities of the transverse ridges on each side

are four openings, called the **anterior sacral foramina,** which transmit the anterior divisions of the first four sacral nerves; they are also traversed by branches of the lateral sacral arteries. The foramina are separated by wide processes, representing the costal processes of the vertebræ, which unite laterally to form the **lateral portion** (or mass) [pars lateralis]. The latter presents grooves occupied by the sacral nerves, and is rough opposite the second, third, and fourth sacral vertebræ, where the *piriformis* muscle takes origin. The lateral part of the fifth sacral vertebra gives insertion to the *coccygeus.*

The **dorsal surface** [facies dorsalis] is strongly convex and rough giving origin to the powerful sacrospinalis muscle. The midline is occupied by four eminences representing the somewhat suppressed **spinous processes.** Of these the first is the largest, the second and third may be confluent, and the fourth is often absent. The processes are united to form an irregular ridge or crest [crista sacralis media]. The bone on each side of the spines is slightly hollowed and is formed by the united **laminæ.** In the fourth sometimes, but always in the fifth, the laminæ fail to meet in the middle line, leaving a gap, the **hiatus sacralis,** at the termination of the spinal canal, the lateral margins of which are prolonged downward as the **sacral cornua.**

FIG. 96.—THE SACRUM. (Posterior View.)



The cornua represent the lower articular processes of the fifth sacral vertebra and give attachment to the posterior sacrococcygeal ligaments. Lateral to the laminæ is a second series of small eminences which represent the **articular** and **mammillary processes** of the vertebræ above. The first pair are large for the last lumbar vertebra, the second and third are small, and the fourth and fifth are inconspicuous. Together they form a pair of irregular ridges [cristæ sacrales articulares].

Immediately lateral to the articular processes are the **posterior sacral foramina,** four on each side; they are smaller than the anterior, and give exit to the posterior primary divisions of the first four sacral nerves. Lateral to the foramina on each side are five elevations representing the **transverse processes.** The first pair, situated at the junction of the posterior surface with the base, are large and conspicuous; all serve for the attachment of ligaments and muscles.

Together they form on each side of the sacrum an irregular ridge, **crista sacralis lateralis.** The space between the spinous and transverse processes presents a shallow concavity known as the **sacral groove,** continuous above with the vertebral groove of the upper part of the column, and, like it, lodging the *multifidus* muscle. Bridging across the groove and attached to the sacral spines medially, and to the lower and back part of the sacrum laterally, is the **flat tendon** of origin of the *sacrospinalis* (*erector spinæ*). The *gluteus maximus* takes origin from the back of the lower two pieces of the sacrum.

The base [basis ossis sacri] or upper surface of the sacrum (fig. 98) bears considerable resemblance to the upper surface of the fifth lumbar vertebra. It presents in the middle the body, of a reniform shape, posterior to which is the upper end of the sacral canal bounded by two laminæ. On each side of the canal are two articular processes bearing well-marked mammillary tubercles. The conjoined transverse and costal processes form on each side a broad surface, the wing or **ala** of the sacrum, continuous with the iliac fossa of the hip-bone, and giving attachment to a few fibers of the iliacus.

The lateral margins (fig. 97).—It has already been noted that the lateral portion of the sacrum is the part lateral to the foramina. It is broad and thick above, where it forms the ala, but narrowed below. The lateral aspect of the upper part presents in front a broad irregular surface, covered in the recent state with fibrocartilage, which articulates with the ilium and is known as the **auricular**

FIG. 97.—LEFT LATERAL VIEW OF SACRUM AND COCCYX.

surface [facies auricularis]. The position is somewhat variable, but in most instances corresponds to the sides of the first, second and third sacral bones. The general direction of the auricular surface approaches an anteroposterior plane. It is bounded posteriorly by some rough depressions for the attachment of the posterior sacroiliac ligaments.

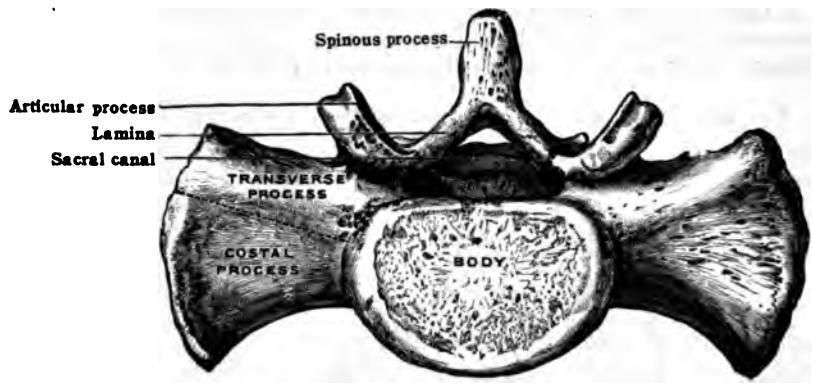
Below the auricular surface, the lateral margin is rough for the sacrotuberous and sacrospinous (greater and lesser sacrosciatic) ligaments, and terminates in the projection known as the **inferior lateral angle.** Immediately below the angle is a notch, converted into a foramen by the transverse process of the first coccygeal vertebra, and a ligament connecting this with the inferior lateral angle of the sacrum. Through this foramen passes the anterior branch of the fifth sacral nerve.

The apex [apex ossis sacri] is directed downward and forward and is formed by the inferior aspect of the body of the fifth sacral vertebra. It is transversely oval and articulates by means of an intervertebral disk with the coccyx. In advanced life the apex of the sacrum becomes united to the coccyx by bone.

The **sacral canal** is the continuation of the spinal canal through the sacrum. Like the bone, it is curved, triangular in section at the base and flattened toward the apex. It terminates at the hiatus sacralis between the sacral cornua, where the laminæ of the fourth and fifth sacral vertebræ are incomplete. The canal opens on the surface by the anterior and posterior sacral foramina and lodges the lower branches of the cauda equina, the filum terminale, and the lower portion of the dura and arachnoid. The subdural and subarachnoid spaces extend downward within the canal as far as the body of the second sacral vertebra.

Differences in the two sexes.—The sacrum of the female is usually broader in proportion to its length, much less curved, and directed more obliquely backward than that of the male. The curvature of the female sacrum belongs chiefly to the lower part of the bone, whereas in the

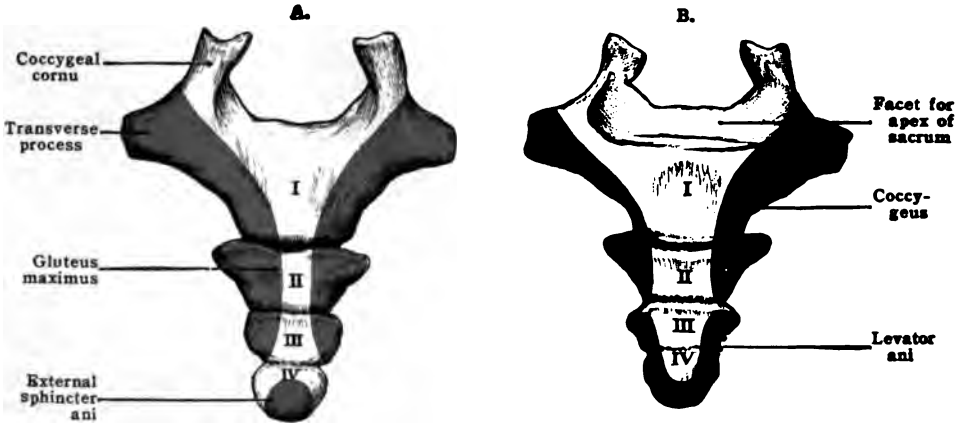
FIG. 98.—BASE OF SACRUM.



male it is equally distributed over its whole length; but the curvature is subject to considerable variation in different skeletons.

Racial differences.—The human sacrum is characterized by its great breadth in comparison with its length, though in the lower races it is relatively longer than in the higher. The proportion is expressed by the *sacral index* $= \frac{\text{breadth} \times 100}{\text{length}}$. The average sacral index in the British male is 112, in the female 116. Sacra in which the index is above 100 are *platyhieric*, as in Europeans; those under 100 are *dolichohieric*, as in most of the black races (Sir W. Turner).

FIG. 99.—THE COCCYX. A. Posterior view; B. Anterior view.



THE COCCYGEAL VERTEBRÆ

The four coccygeal vertebræ are united in the adult to form the **coccyx** [os coccygis] (fig. 99). While four is the usual number of these rudimentary vertebræ, occasionally there are five, and rarely three. In middle life the first piece is usually separate, and the original division of the remaining portion of the coccyx into three parts is indicated by transverse grooves. In advanced life the pieces of the coccyx, having previously united to form one bone, may also become joined to the sacrum.

The **first** piece of the coccyx is much broader than the others. It consists of a body, transverse processes, and rudiments of a neural arch. The body presents on its upper surface an oval facet for articulation with the apex of the sacrum. On each side of the body a **transverse**

process projects laterally and is joined either by ligament or bone to the inferior lateral angle of the sacrum, forming a foramen for the anterior division of the fifth sacral nerve. From the posterior surface of the body two long **coccygeal cornua** project upward and are connected to the sacral cornua by the posterior sacrococcygeal ligaments, enclosing on each side an aperture —the last intervertebral foramen—for the exit of the fifth sacral nerve. The coccygeal cornua represent the roots and superior articular processes of the first coccygeal vertebra. The **second** piece of the coccyx is much smaller than the first, and consists of a body, traces of transverse processes, and a neural arch, in the form of slight tubercles at the sides and on the posterior aspect of the body. The **third** and **fourth** pieces of the coccyx, smaller than the second piece, are mere nodules of bone, corresponding solely to vertebral bodies.

The **anterior surface** of the coccyx gives attachment to the anterior sacrococcygeal ligament and near the tip to the *levator ani;* it is in relation with the posterior surface of the rectum. The **posterior surface** of the coccyx is convex, and the upper three pieces afford attachment to the *gluteus maximus* on each side, and the last piece to the coccygeal portion of the *sphincter ani externus*. The **lateral margins** are thin, and receive parts of the sacrosciatic ligaments, of the *coccygei* muscles, and of the *levatores ani*.

Variations of the sacrum and coccyx.—The number of sacral vertebræ may be increased to six, resulting from the fusion of the first coccygeal or, less often, of the last lumbar. The number may be reduced to four. The junction between the lumbar and sacral parts of the column is occasionally made by an element presenting the characteristics of a lumbar vertebra on one side and of a sacral on the opposite. The auricular surface may extend beyond the general level of the base of the sacrum or be displaced downward to reach the fourth sacral vertebra. The sacral canal may be open posteriorly to a greater degree than is normally the case. Coalescence of the coccyx and sacrum takes place less often and later in life in the female than in the male.

THE VERTEBRAL COLUMN AS A WHOLE

The vertebral column (fig. 100) is the central axis of the skeleton and is situated in the median line at the posterior aspect of the trunk. Superiorly it supports the skull; laterally it gives attachment to the ribs, through which (in part) it receives the weight of the upper limbs, and inferiorly it is supported by the hip-bones, by which the weight of the trunk is transmitted to the lower limbs. Its length varies in different skeletons, but on an average it measures about 70 cm. (28 in.) in the male and about 2.5 cm. (1 in.) less in the female. To the entire length the cervical region contributes about one-sixth, the thoracic about one-third, the lumbar about one-fourth, and the sacrococcygeal portion the remaining about one-sixth. About one-fourth of the length of the presacral spine is made up of intervertebral disks.

Curvatures.—The vertebral column presents a series of curvatures, four when viewed in profile and one when viewed from the front or back. The former are directed alternately forward and backward, and are named, from the regions of the column in which they occur, **cervical, thoracic, lumbar,** and **sacral**. The fifth curve is **lateral,** being in most cases directed toward the right side. The cervical, thoracic and lumbar curvatures pass imperceptibly into one another, but at the junction of the last lumbar vertebra with the sacrum a well-marked angle occurs, known as the **sacrovertebral** or **lumbosacral** angle, with the result that the promontory of the sacrum overhangs the cavity of the minor pelvis and forms a portion of its superior aperture.

The thoracic and sacral curves have their concavities directed forward and are developed during intrauterine life (fig. 25). They are in obvious relation to two great cavities of the trunk, thoracic and pelvic, and may be regarded as **primary** or **accommodation** curves, for the thoracic and pelvic viscera. The thoracic curve extends from the second to the twelfth thoracic vertebra and the sacral curve coincides with the sacrum and coccyx.

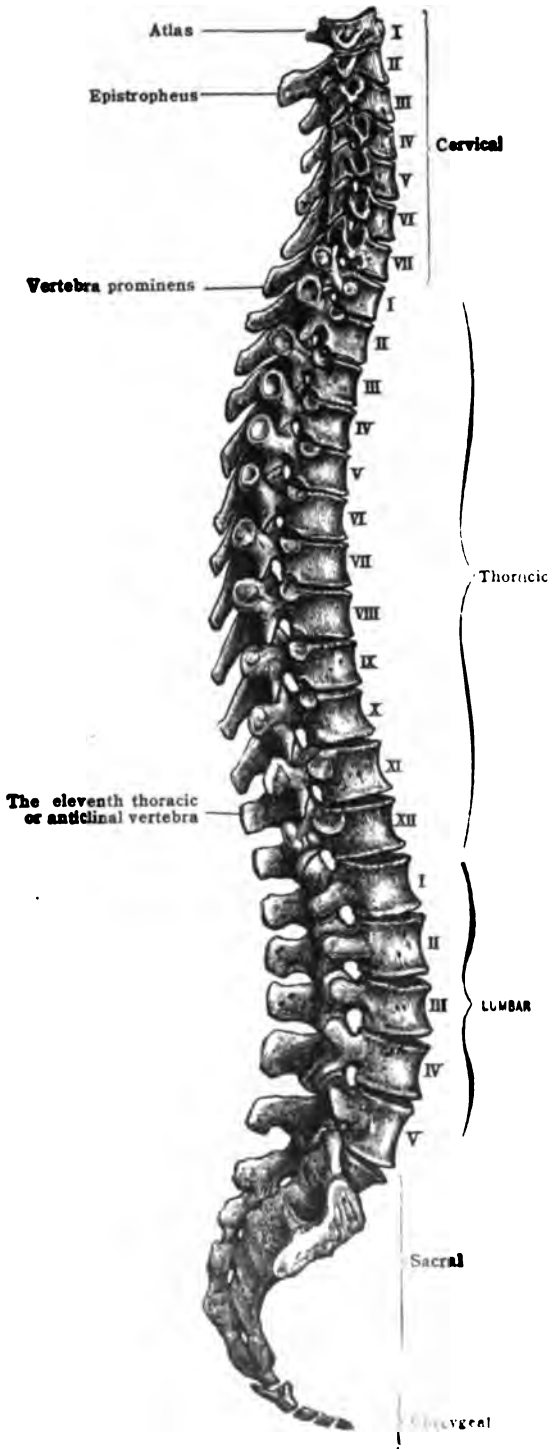
The cervical and lumbar curves have their convexities directed forward, and are developed during the first year after birth (see p. 27). They are essentially curves of **compensation,** necessary for the maintenance of the upright posture, and are brought about mainly by modifications in the shape of the intervertebral disks. The cervical curve is formed about the third month, or at the time when the infant can sit upright. The great peculiarity of the curve is that it is never consolidated, being present when the body is placed in the erect position and obliterated by bending the head down upon the chest. The lumbar curve is developed about the end of the first year or when the child begins to walk, but is not consolidated until adult life. (Symington.) The cervical curve extends from the atlas to the second thoracic vertebra, and the lumbar curve from the twelfth thoracic to the promontory of the sacrum.

The lateral curve is situated in the upper thoracic region, usually presenting the convexity to the right, is probably associated with the greater use made of the right hand. This curve, however, is particularly liable to modification in different occupations and in different races. The *aortic impression* normally present consists of a variable flattening of the left side of the thoracic vertebræ in the middle of the series.

Viewed from the front, the vertebral column presents a series of **pyramids** due to the successive increase and decrease in size of the bodies. These become broader from the axis to the first thoracic vertebra and then decrease to the fourth thoracic. The first pyramid therefore includes all the cervical vertebræ except the atlas, and has the apex directed upward and its base downward, whilst the second is inverted and formed by the first four thoracic vertebræ. The third pyramid, much the longest, is the result of the increase in size from the fourth thoracic to the fifth lumbar vertebra, and the fourth, which is inverted, is produced by the rapid contraction of the sacral and coccygeal vertebræ.

Viewed from behind, the spinous processes project in the midline, and the transverse processes as two lateral rows. Of the spines, those of the epistropheus, seventh cervical, first thoracic, and the lumbar vertebræ appear most prominent. On each side is the **vertebral groove,** the floor of which is formed in the cervical and lumbar regions by the laminæ and articu-

FIG. 100.—VERTEBRAL COLUMN. (Lateral view.)



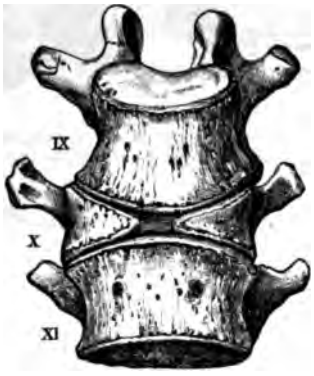
lar processes, and in the thoracic region, by the laminæ and transverse processes. The transverse processes project laterally for a considerable distance in the atlas, first thoracic, and the middle of the lumbar series; they are shortest in the third cervical and the twelfth thoracic.

In the lateral view, the intervertebral foramina appear oval in shape, and are small in the cervical, larger in the thoracic, and largest in the lumbar region.

Numerical variation.—Addition to the total number of vertebræ by intercalation of an element probably does not occur. Addition to a group is rather frequently observed and has been accounted for by reduction in number of the elements in an adjacent group, the total number of vertebræ in the column remaining unaltered. In this fluctuation, the vertebra added is intermediate in form between the types of the two groups concerned.

Structure of a vertebra.—The bodies of the vertebræ are largely composed of cancellous tissue, with a thin outer covering of compact tissue. In a vertical section through the centrum the fibers of the cancellous tissue are seen to be arranged vertically and horizontally, the vertical

FIG. 101.—A DIVIDED THORACIC VERTEBRA. (After Turner.)



fibers being curved with their concavities directed toward the center of the bone (fig. 102). The horizontal fibers are slightly curved parallel with the upper and lower surfaces, and have their convexities toward the center of the bone. They are not so well defined as the vertical set. (Wagstaffe.)

Ossification.—The vertebræ in general.—The ossification of each vertebra (see p. 27) takes place in cartilage from three primary and five secondary centers. The three primary centers appear, one in the body and two in the arch, about the seventh week of intrauterine life. In the thoracic region the nucleus for the body appears first, but in the cervical region it is preceded by the centers for the arch. The nucleus for the body soon becomes bilobed, and this condition is sometimes so pronounced as to give rise to the appearance of two distinct nuclei. Indeed, the nucleus is very rarely double and the two parts of the body may remain separate throughout life (fig. 101). The bilateral character of the nucleus is further emphasized by the occasional formation of half-vertebræ. The lateral centers are deposited near the bases of the superior articular processes and give rise to the roots, laminæ, articular, and the greater parts of the transverse and spinous processes.

FIG. 102.—A VERTEBRAL CENTRUM IN SECTION TO SHOW THE PRESSURE CURVES.

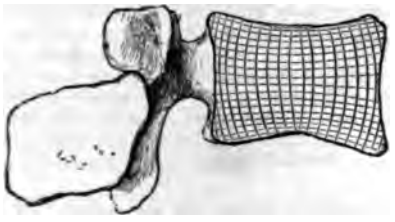


FIG. 103.—A VERTEBRA AT BIRTH.

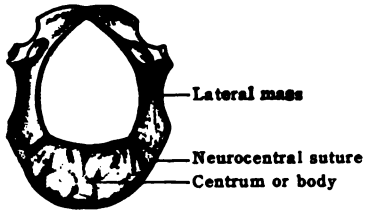
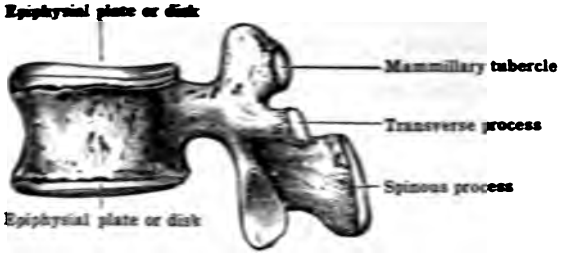


At birth a typical vertebra (fig. 103) consists of three osseous pieces—a body and two lateral masses, which constitute the arch, the parts being joined together by hyaline cartilage. The line of union of the lateral portion with the body is known as the *neurocentral suture*, and is not actually obliterated for several years after birth. In the thoracic region the central ossification does not pass beyond the point with which the head of the rib articulates, and leaves a portion of the body on each side formed from the lateral ossification. A thoracic vertebra at the fifth year shows that the pits for the heads of the ribs are situated behind the neurocentral suture, which is directed obliquely backward and medially. The laminæ unite during the first year after birth; and by the gradual extension of ossification into the various processes, the vertebræ have attained almost their full size by the time of puberty. Subsequently the secondary centers appear in the cartilaginous extremities of the spinous and transverse processes (fig. 104), and in the cartilage on the upper and lower surfaces of the bodies, forming in each vertebra two annular plates, thickest at the circumference and gradually thinning toward the central deficiency (figs. 104, 105). The epiphyses appear from the fifteenth to the twentieth year and join with the vertebra by the twenty-fifth year.

In several vertebræ the mode of ossification differs from the account given above—in some cases considerably—and necessitates separate consideration.

Atlas (fig. 104).—The lateral portions and posterior arch are formed from two centers of ossification, which correspond to the lateral centers of other vertebræ and appear about the seventh week. The anterior arch is ossified from one center, which, however, does not appear until a few months after birth. Union of the lateral parts occurs posteriorly in the third year,

FIG. 104.—LUMBAR VERTEBRA AT THE EIGHTEENTH YEAR WITH SECONDARY CENTERS.

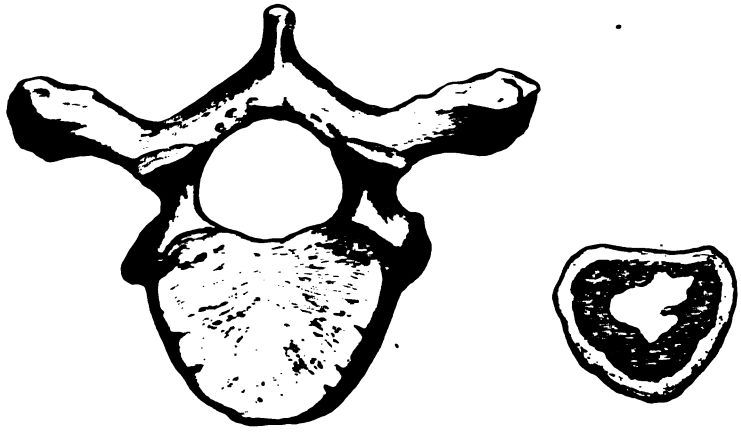


being sometimes preceded by the appearance of a secondary center of ossification in the intervening cartilage and the union of the lateral parts with the anterior arch occurs about the seventh year.

Epistropheus (figs. 105–107).—The arch, and the processes associated with it, are formed from two lateral centers which appear, like those in the other vertebræ, about the seventh

FIG. 105.—UPPER THORACIC VERTEBRA WITH AN EPIPHYSIAL PLATE REMOVED AND DRAWN AT THE SIDE.

The plate shows the characteristic deficiency in the center. ×1.



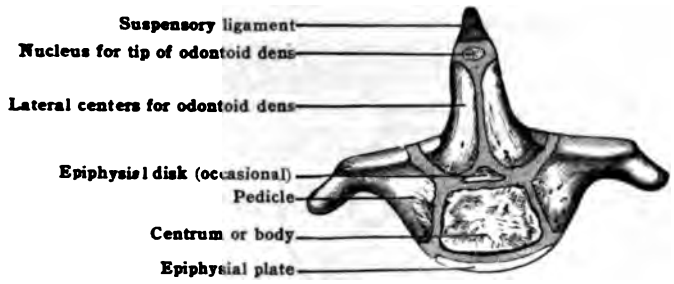
week. The common piece of cartilage which precedes the body and dens is ossified from four or five centers, one (or two) for the body of the epistropheus, in the fourth month, two, sometimes three, for the dens, a few weeks later, and one, for the apex of the dens, in the second year. The two collateral centers for the main part of the dens soon coalesce, so that at birth the epistropheus consists of four osseous pieces—two lateral portions which constitute the arch, the body, and the dens, surmounted by a piece of cartilage. During the third or

FIG. 106.—IMMATURE ATLAS. (Third Year.)

fourth year the dens joins with the body, the line of union being indicated even in advanced life by a small disk of cartilage, and the arch unites in front and behind about the same time or a little later. The apical nucleus of the dens, which represents an epiphysis, joins the main part about the twelfth year and in the seventeenth year an epiphysial plate appears for the lower surface of the body. There are also rudiments, adjoining the cartilaginous disk, of the upper plate of the body.

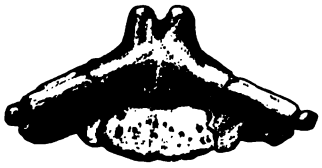
Cervical vertebræ (fig. 110).—In the cervical vertebræ the lateral centers form a larger share of the body than in the vertebræ of other regions, and the neurocentral suture runs almost in a sagittal direction. The sixth, seventh, and even the fifth have additional centers which ap-

FIG. 107.—DEVELOPMENT OF THE EPISTROPHEUS (AXIS).



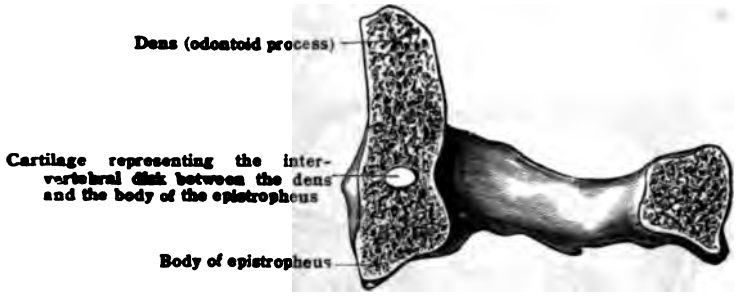
pear before birth for the anterior or costal divisions of the transverse processes. In the other cervical vertebræ the costal processes are ossified by extension of the lateral nuclei. The costal processes of the seventh cervical sometimes remain separate, constituting cervical ribs.

FIG. 108.—THE EPISTROPHEUS AT FOUR YEARS OF AGE, SHOWING THE SIZE AND EXTENT OF THE DENS. (Natural size.)



Lumbar vertebræ (fig. 111).—In the lumbar vertebræ the neurocentral suture is almost transverse, and to the usual number of centers of ossification, two other epiphyses for the mammillary tubercles are added, the centers appearing about puberty. The transverse process of the first lumbar vertebra is occasionally developed from an independent center.

FIG. 109.—THE EPISTROPHEUS (FROM AN ADULT) IN SAGITTAL SECTION.



Dens (odontoid process)
Cartilage representing the intervertebral disk between the dens and the body of the epistropheus
Body of epistropheus

The fifth lumbar exhibits in some cases a special mode of ossification in the arch. Instead of two centers, there are four—one on each side for the root, transverse process, and supe-

FIG. 110.—AN IMMATURE CERVICAL VERTEBRA.

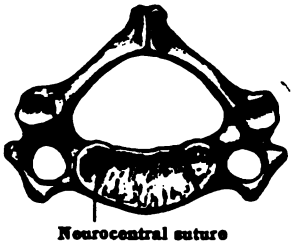


FIG. 111.—OSSIFICATION OF THE FIFTH LUMBAR VERTEBRA.

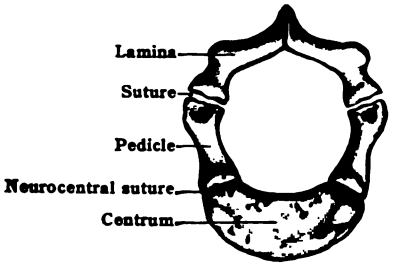
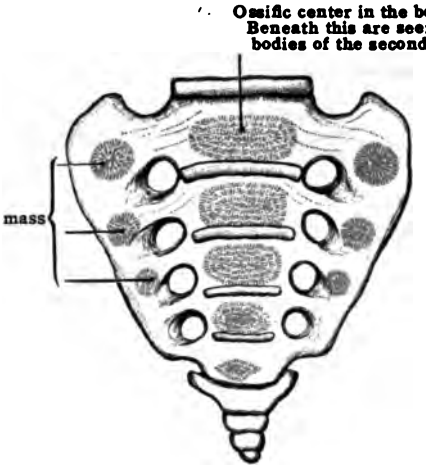


rior articular process, and another on each side for the lamina, inferior articular process, and the lateral half of the spinous process (fig. 111). There may be failure of union of roots with the laminæ or of the laminæ with one another.

Sacral vertebræ (figs. 112–114).—The sacrum ossifies from thirty-five centers, which may be classified as follows:—In each of the five vertebræ there are three primary nuclei—one for the body and two for the arch; in each of the first three the costal element of the lateral mass on each side is formed from a separate nucleus; associated with each body are two epiphysial plates; and on each lateral margin are two irregular epiphyses, one for the auricular surface and another

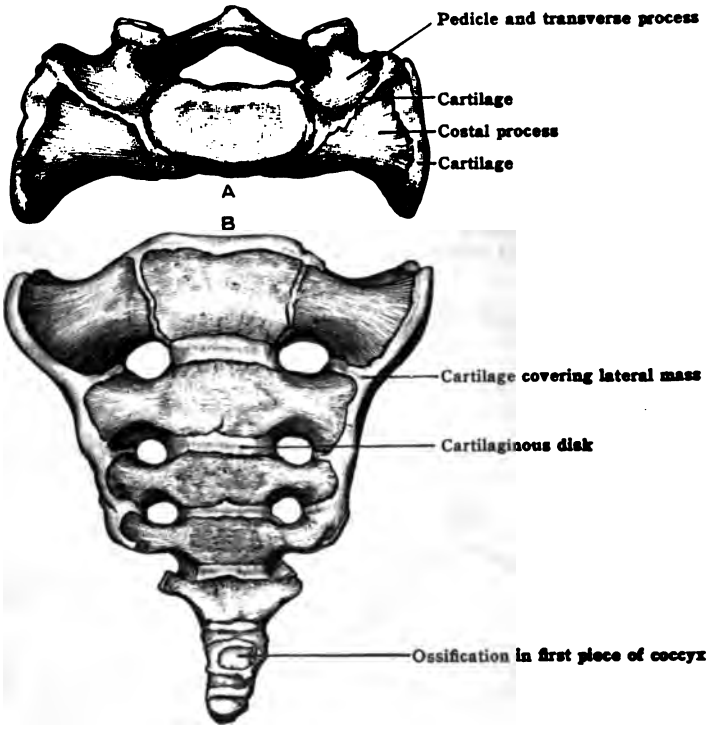
FIG. 112.—SACRUM AT BIRTH TO SHOW CENTERS OF OSSIFICATION. (Enlarged one-third.)



Ossific center in the body of first sacral vertebra. Beneath this are seen in succession the centers in the bodies of the second, third, fourth, and fifth vertebræ
Ossific centers in the lateral mass

for the rough edge below. The centers for the bodies appear about the eighth or ninth week and for the vertebral arches from the third to the fifth month. The arches join the bodies at different times in the different vertebræ, ranging from the second year below, to the fifth or sixth year above, and union of the laminæ takes place behind some years later, from about the ninth to the fifteenth year.

FIG. 113.—THE SACRUM AT FOUR YEARS OF AGE (B). THE FIGURE AT THE TOP (A) SHOWS THE BASE DRAWN FROM ABOVE. ($\times\frac{3}{4}$.)



The centers for the costal elements appear outside the anterior sacral foramina, from the fifth to the seventh month, and these unite with the bodies somewhat later than the arches.

The centers for the epiphysial plates appear about the fifteenth year, and for the auricular epiphyses and the edges below, from the eighteenth to the twentieth year.

Consolidation begins soon after puberty by fusion of the costal processes, and this is followed by ossification from below upward in the intervertebral disks, resulting in the union of the adjacent bodies and the epiphysial plates, the ossific union of the first and second being completed by the twenty-fifth year or a little later. The marginal epiphyses are also united to the sacrum by the twenty-fifth year. Even in advanced life intervertebral disks persist in the more central parts of the bone and can be well seen in sections.

Coccygeal vertebræ.—The coccygeal vertebræ are cartilaginous at birth and each is usually ossified from a single center, though there may be two for the first piece. Ossification begins soon after birth in the first segment, and in the second from the fifth to the tenth year. The centers for the third and fourth segments appear just before, and after, puberty respectively. As age advances the various pieces become united with each other, the three lower uniting before middle life and the upper somewhat later. In advanced life the coccyx may join with the sacrum, the union occurring earlier and more frequently in the male than in the female.

FIG. 114.—SACRUM AT ABOUT TWENTY-TWO YEARS. (×⅜.)

The Serial Morphology of the Vertebræ

Although at first sight many of the vertebræ exhibit peculiarities, nevertheless a study of the mode by which they develop, and their variations, indicates the serial homology of the constituent parts of the vertebræ in each region of the column.

The body (centrum) of the vertebra is that part which immediately surrounds the notochord. This part is present in all the vertebræ of man, but the centrum of the atlas is dissociated from its arch, and ankylosed (as the dens) to the body of the epistropheus.

The *arches* and *spinous processes* are easily recognized throughout the various parts of the column in which complete vertebræ are present. The *articular processes* or *zygapophyses* are of no morphological interest.

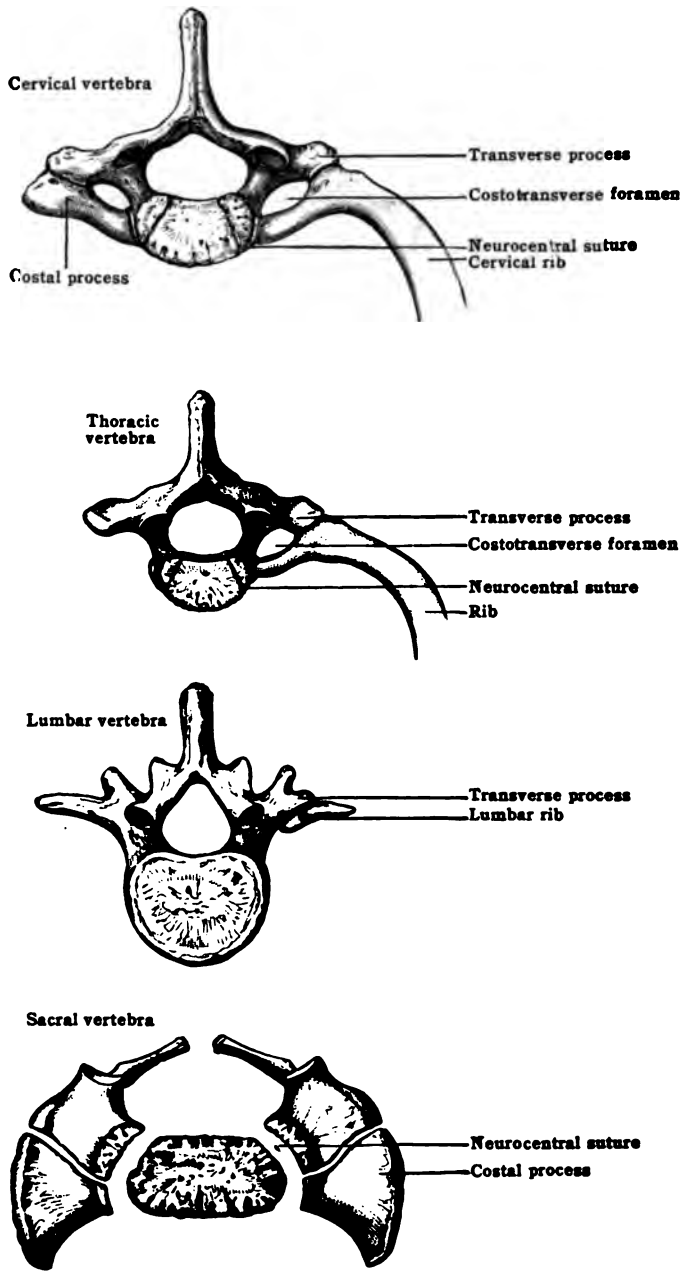
The *transverse processes* (fig. 115) offer more difficulty. They occur in the simplest form in the thoracic series. Here they articulate with the tubercles of the ribs, whence the term *tubercular processes* or *diapophyses* has been given them (the place of articulation of the head of the rib with the vertebra is the *capitular process* or *parapophysis*), and the transverse process and the neck of the rib enclose an arterial foramen named the costotransverse foramen. In the cervical region the costal element (*pleurapophysis*) and the transverse process are fused together, and the conjoint process thus formed is pierced by the costotransverse foramen. The compound nature of the process is indicated by the fact that the anterior or costal processes in the lower cervical vertebræ arise from additional centers and occasionally retain their independence as cervical ribs, and in Sauropsida (birds and reptiles) these processes are represented by free ribs. In the lumbar region, the compound nature of the transverse process is further marked. The true transverse process is greatly suppressed, and its extremity is indicated by the accessory tubercle. Anterior to this in the adult vertebræ a group of holes represents the costotransverse foramen, and the portion in front of this is the costal element. Occasionally it persists as an independent ossicle, the lumbar rib.

In the sacral series the costal elements are coalesced in the first three vertebræ to form the greater part of the lateral portion for articulation with the ilium, the costotransverse foramina being completely obscured. In rare instances the first sacral vertebra will articulate with the ilium on one side, but remain free on the other, and under such conditions the free process exactly resembles the elongated transverse process of a lumbar vertebra. The first three sacral vertebræ which develop costal processes for articulation with the ilium are termed *true sacral* vertebræ, while the fourth and fifth are termed *pseudosacral*. A glance at fig. 115 will show the homology of the various parts of a vertebra from the cervical, thoracic, lumbar, and sacral regions.

B. THE CRANIUM OR SKULL

The bony framework of the head, termed the cranium or skull, presents the most complex structure of the skeleton. This condition is the result mainly of the presence and close association in the head of the brain and group of sense organs on the one hand and, on the other, the highly specialized entrance to the

FIG. 115.—MORPHOLOGY OF THE TRANSVERSE AND ARTICULAR PROCESSES.



digestive and respiratory systems, the mouth and nasal cavities. In adaptation to the huge, rounded brain of man a bony capsule, the *cerebral cranium*, has been formed, consisting mostly of flat bones rigidly united by special joints called sutures. (For structure of cranial wall, see p. 81.) The cerebral cranium is directly supported by the vertebral column, and where the two come together a certain degree of transition of form of adjacent parts can be distinguished. The

erebral cranium passes without sharp line of demarcation into the *visceral ranium*, or facial skeleton, which includes the jaws and the bony support of the ongue, the hyoid bone.

Both subdivisions of the cranium in this zone of contact are concerned in providing the keletal support for the nose, the eyes and ears. Many individual bones, some singly, but nost of them in pairs, go to make up the skull; and whereas some of those entering into the erebral division are confined entirely to that division and some of the bones constituting the isceral skeleton are purely visceral in relation and function, other elements are both cerebral nd visceral in position and use. It follows that a sharp distinction of cerebral and visceral imits can hardly be made and that attempts to range all cranial bones in one of two categories nust lead in some instances to arbitrary choice. The term cranium is frequently restricted to he cerebral cranium, the visceral cranium being then designated as the facial skeleton.

THE SKULL AS A WHOLE

The skull, consisting of the cerebral and visceral crania, may first be considered s a whole. Taking a general view, it is spheroidal in shape, smooth above, ompressed from side to side, flattened and uneven below, and divisible into six egions: a superior region or vertex, a posterior or occipital region, an anterior or rontal region, an inferior region or base, and two lateral regions.

(1) The Superior Region

Viewed from above (*norma verticalis*) the skull presents an oval outline with he broader end behind, and includes the **frontal,** the two **parietal,** and the inter- arietal portion of the **occipital bones.** The lateral limits of the superior region nay be set at the **temporal lines** which pass through the **parietal eminences.** The surface is smooth and rounded and covered by the scalp. In a skull of verage width the zygomatic arches are visible, but in very broad skulls they are bscured.

The **sutures** of the vertex are the following:

The **metopic,** which is, in most skulls, merely a median fissure in the frontal bone just bove the **glabella;** occasionally it involves the whole length of the bone. It is due to the per- istence of the fissure normally separating the two halves of the bone in the infant.

The **sagittal** is situated between the two parietals, and extends from the bregma to the ambda. The single or paired **parietal foramen** lies close to the sagittal suture a short distance nterior to the bregma.

The **coronal** lies between the frontal and parietals, and extends from pterion to pterion.

The **lambdoid** is formed by the parietals and interparietal portion of the occipital. It xtends from asterion to asterion.

The **occipital** suture is only present when the interparietal bone exists as a separate element fig. 135).

The more important anthropometric points are:—

The **bregma,** which indicates the situation of the frontal (greater) fontanelle, and marks he confluence of the coronal, the sagittal, and, when present, the metopic sutures.

The **lambda,** where the sagittal enters the lambdoid suture; it marks the situation of the ccipital (lesser) fontanelle.

The **obelion,** a little anterior to the lambda, is usually indicated by a flat area between the aired parietal foramina.

(2) The Posterior Region

Viewed from behind (*norma occipitalis*) the skull is somewhat pentagonal in orm. Of the five angles, the superior or median is situated in the line of the agittal suture; the two upper lateral angles coincide with the parietal eminences nd the two lower with the mastoid processes of the temporal bones. Of the ides, four are somewhat rounded, and one, forming the basal line, running etween the mastoid processes, is flattened.

The center is occupied by the lambda, and radiating from this point are three sutures, he **sagittal,** and the two parts of the **lambdoid.** Each half of the lambdoid suture bifurcates t the mastoid portion of the temporal bone, the two divisions constituting the **parietomastoid** nd **occipitomastoid** sutures; the point of bifurcation is known as the **asterion.**

In the lower part of the view is seen the **external occipital protuberance** (inion), the **occipital rest,** and the three pairs of **nuchal lines,** which give it a rough and uneven appearance. The **ccipital point** is the point of the occiput furthest from the glabella in the median plane. It s situated above the external occipital protuberance.

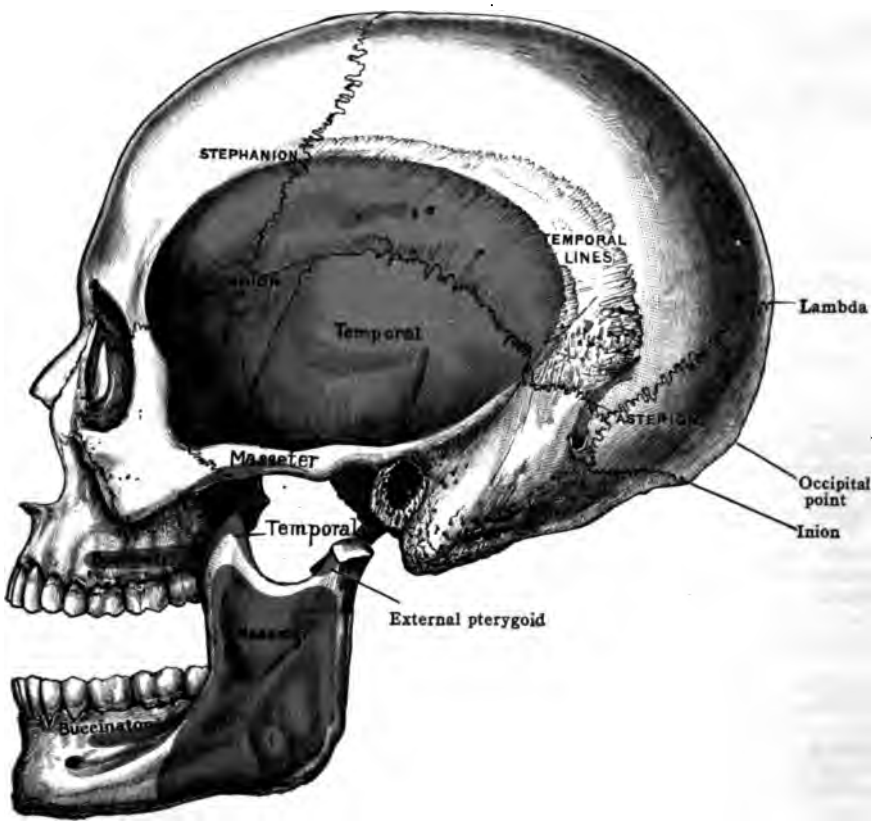
(3) The Lateral Region

The **lateral region** (*norma lateralis*) (fig. 116) may be divided into a cerebral and a visceral (facial) portion by a line extended between the root of the nose and the tip of the mastoid process. The cerebral portion presents two regions: that of the **temporal fossa** and that of the **external auditory meatus.**

The **temporal fossa** is occupied in the recent state by the body of the **temporal** muscle to which it is adapted. It is somewhat semilunar in shape, is bounded *above* and *behind* by the **temporal lines** in *front* by the frontal and zygomatic bones, and great wing of sphenoid, and *laterally* by the zygomatic arch, by which it is separated superficially from the infratemporal fossa; more deeply the infratemporal ridge of the sphenoid separates the two fossæ.

The fossa is formed by parts of five bones, the zygomatic, temporal, parietal, frontal, great wing of sphenoid, and is traversed by six sutures, coronal, sphenozygomatic, sphenosquamosal, sphenoparietal, squamosal, and sphenofrontal. The temporal lines, two in number, run a somewhat parallel course, separated by a narrow smooth tract of bone. The lower line

Fig. 116.—The Skull. Norma lateralis.



begins at the temporal crest of the frontal bone, passes onto the parietal and terminates by joining the *supramastoid crest* of the temporal bone; it marks the limit of the *temporal* muscle above and behind. The point where the lower temporal line is crossed by the coronal suture is the **stephanion,** and the region where the frontal, sphenoid, temporal, and parietal bones meet is the **pterion.** The latter is sometimes occupied in the adult by the **epipteric bone.**

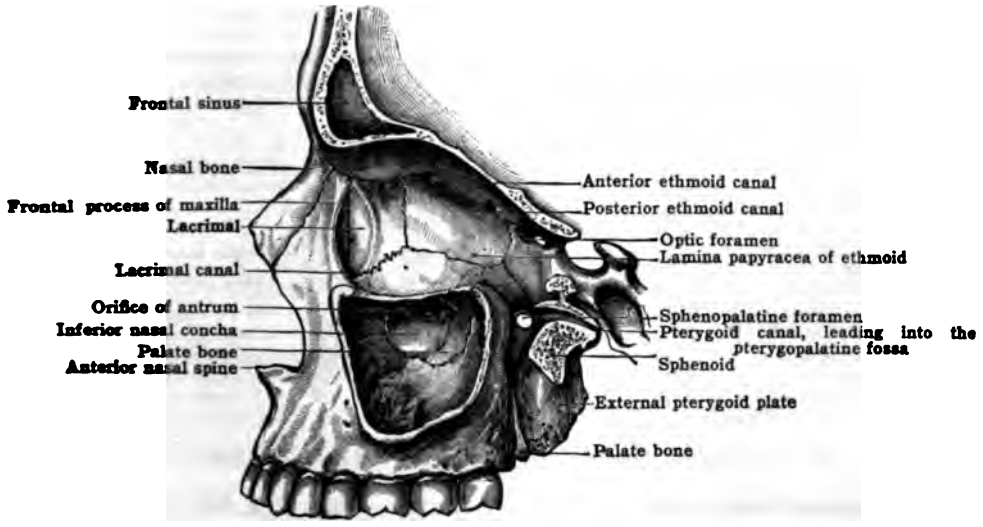
The **external auditory meatus** [meatus acusticus externus] is a short canal in the lateral region of the skull confined to the temporal bone and leading to the tympanic cavity. Its walls are formed for the most part by the tympanic portion of the temporal bone, above to some extent by the squamous portion. The entrance to the canal [porus acusticus externus] is bounded by the roughened, free margin of the tympanic, known as the *external auditory process,* to which is fixed the cartilaginous auricle. At the bottom of the meatus, a slight groove [*sulcus tympanicus*] can be seen which receives the inferior part of the circumference of the tympanic membrane Anterior to the external auditory meatus and separated from it by the tympanic is a deep concavity, the **mandibular fossa,** the anterior portion of which, made by the squamous portion of the temporal, is adapted to the articulation of the lower jaw; the posterior part, contributed by the tympanic, lodges an extension of the parotid gland. These two portions are separated by the *petrotympanic* (*Glaserian*) *fissure,* a narrow gap separating the squamous from the tympanic. Regarding the latter, it is further to be observed that it is quite thin in its middle, sometimes perforated; and that it presents medially a free irregular margin [*vagina processus styloidei*] in relation to the base of the styloid process.

Behind the external auditory meatus is the *mastoid portion* of the temporal bone, projecting downward in the conical *mastoid process*. Its surface is rough, affording attachment to muscles. A *mastoid foramen*, at or near the posterior margin of this portion, gives passage to a vein from the transverse sinus. The mastoid portion is demarcated from the temporal fossa by the supramastoid crest which continues forward over the entrance to the external auditory meatus and into the posterior root of the zygoma.

The *visceral (facial) portion of the lateral region* is concerned with mastication and includes the articulation of the mandible and the surfaces and processes to which are attached the masticatory muscles. It is directly continuous above with the temporal fossa, which, as has been pointed out, gives origin to the *temporal* muscle, and presents the form of a deep hollow the **infratemporal fossa.**

The infratemporal fossa (zygomatic fossa), irregular in shape, is situated below and to the medial side of the zygoma, covered in part by the ramus of the mandible. It is bounded *in front* by the lower part of the medial surface of the zygomatic, and by the infratemporal surface of the maxilla, on which are seen the orifices of the posterior superior alveolar canals; *behind* by the posterior border of the lateral pterygoid plate, the spine of the sphenoid, and the articular tubercle; *above* by the infratemporal ridge, a small part of the squamous portion of the temporal, the great wing of the sphenoid perforated by the foramen ovale and foramen spinosum; *below* by the alveolar border of the maxilla; *laterally* by the ramus of the mandible and the zygoma formed by zygomatic and temporal; *medially* by the lateral pterygoid plate, a line from which to the spine of the sphenoid separates the infratemporal fossa from the base of

FIG. 117.—A SECTION OF THE SKULL SHOWING THE MEDIAL WALL OF THE ORBIT, THE MEDIAL WALL OF THE ANTRUM, AND THE PTERYGOPALATINE FOSSA.



the skull. It contains the lower part of the *temporal* muscle and the coronoid process of the mandible, the *external* and *internal pterygoid muscles*, the internal maxillary vessels, and the mandibular division of the trigeminal nerve with numerous branches. At the upper and medial part of the infratemporal fossa are seen the inferior orbital and pterygopalatine fissures.

The zygomatic arch (zygoma) functions chiefly as the origin of the *masseter* muscle and in the articulation of the mandible. It is formed by the broad, zygomatic process of the zygomatic bone articulating with the slender zygomatic process of the temporal bone. Beneath the zygomatic arch, between it and the wall of the cranium, is a wide opening leading from the temporal into the infratemporal fossa which accommodates the lower portion of the *temporal* muscle and the coronoid process of the mandible into which it is inserted.

The ramus of the mandible is adapted in form for articulation with the base of the cranium and for the insertion of the masticatory muscles. This stout, flat plate stands up from the body of the mandible, and ends above in two processes separated by the broad mandibular notch. The posterior process, condyloid, is articular; the anterior, coronoid, slender and pointed. For detailed description of the mandible see p. 163.

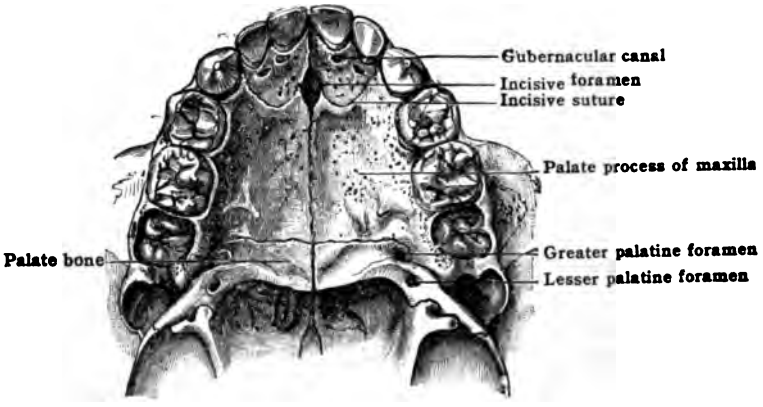
The inferior orbital (or sphenomaxillary) **fissure** is horizontal in position, and lies between the maxilla and the great wing of the sphenoid; laterally it is usually completed by the zygomatic, though in some cases the sphenoid joins the maxilla, and in this way excludes the zygomatic bone from the fissure; medially it is terminated by the infratemporal surface of the orbital process of the palate bone. Through this fissure the orbit communicates with the pterygopalatine (sphenomaxillary), infratemporal, and temporal fossæ. It transmits the infraorbital nerve and vessels, the zygomatic nerve, ascending branches from the sphenopalatine ganglion to the orbit, and a communicating vein from the ophthalmic to the pterygoid plexus.

The pterygopalatine (pterygomaxillary) **fissure** forms a right angle with the inferior orbital fissure and is situated between the maxilla and the anterior border of the pterygoid process of

the sphenoid. At its lower angle, where the two lips of the fissure approximate, the lateral pterygoid plate occasionally articulates with the maxilla, but they are usually separated by a thin portion of the pyramidal process of the palate. The pterygopalatine fissure, which serves to connect the infratemporal fossa with the pterygopalatine fossa, is bounded medially by the perpendicular part of the palate; it transmits branches of the internal maxillary artery, and the corresponding veins, to and from the pterygopalatine fossa.

The **pterygopalatine** (sphenomaxillary) **fossa** (fig. 117) is a small space, of the form of an inverted pyramid, situated at the angle of junction of the inferior orbital (sphenomaxillary) with the pterygopalatine (pterygomaxillary) fissure, below the apex of the orbit. It is bounded *in front* by the infratemporal surface of the maxilla; *behind*, by the base of the pterygoid process and the lower part of the anterior surface of the great wing of the sphenoid; medially by the perpendicular part of the palate with its orbital and sphenoidal processes; *above* by the lower surface of the body of the sphenoid. Three fissures terminate in it—viz., the superior orbital, pterygopalatine, and inferior orbital; through the superior orbital fissure it communicates with the cranium, through the pterygopalatine fissure with the infratemporal fossa, through the inferior orbital fissure with the orbit, and through the sphenopalatine foramen on the medial wall it communicates with the upper and back part of the nasal fossa. Including the **sphenopalatine** foramen six foramina open into the fossa. Of these, three are on the posterior wall: enumerated from without inward, and from above downward, they are the **foramen rotundum,** the **pterygoid (Vidian) canal,** and the **pharyngeal** (pterygopalatine) **canal.** The apex of the pyramid leads below into the **pterygopalatine canal** and the **accessory palatine canals** which branch from it; and anteriorly is the orifice of the **infraorbital canal.** The fossa contains the sphenopalatine ganglion, the maxillary nerve, and the terminal part of the internal maxillary artery, and the various foramina and canals in relation with the fossa serve for the transmission of the numerous branches which these vessels and nerves give off.

FIG. 118.—HARD PALATE OF A CHILD FIVE YEARS OLD.



(4) INFERIOR REGION OR EXTERNAL BASE OF SKULL

The **external base** of the skull (*norma basilaris*) (figs. 119, 120) extends from the incisor teeth to the occipital protuberance, and is bounded on each side by the alveolar arch, zygomatic bone, zygoma, temporal bone, and the superior nuchal line of the occipital bone. It may be divided into three portions: (a) anterior or visceral, (b) middle or subcerebral, and (c) posterior or suboccipital.

(a) The **anterior portion** includes portions of the mandible, the maxilla and the hyoid bone. (For description of the hyoid, see p. 167.)

Mandible.—The inferior margin and medial surface of the body of the mandible can be seen in an examination of the inferior aspect of the cranium. The two halves of the body extending from the ramus forward in a parabolic curve meet at the *symphysis of the chin.* Their rounded, thick, inferior edges are subcutaneous. At the back of the symphysis, the *mental tubercles* give attachment to muscles of the tongue and hyoid bone. Lateral to the midplane, a shallow depression, *digastric fossa*, marks the origin of the anterior belly of the *digastric* muscle. The oblique *mylohyoid line* indicates the origin of the *mylohyoid* muscle, which enters into the formation of the floor of the mouth. The region of the medial surface of the jaw above this line is related to the mouth cavity: the sublingual salivary gland lies in this region, its place near the symphysis being marked by a shallow fossa. The region below the mylohyoid line is in relation to structures of the neck: a fossa posteriorly indicates the position of the submaxillary salivary gland and opposite it the inferior margin of the body of the bone is often slightly grooved where the external maxillary artery passes from the neck onto the face. The posterior portion of the mylohyoid line stands at the level of the transition between the mouth and pharynx, giving attachment to the *superior constrictor* muscle of the pharynx and the pterygomandibular ligament.

The teeth and alveolar processes of the mandible are best studied from the anterior aspect of the skull. The *alveolar processes* of the *maxillæ* together form an elliptic curve. They pre-

he dental *alveoli* adapted to the form of the roots of the eight pairs of permanent teeth
e adult. Between the processes of the two sides extends the **hard palate** [palatum durum]
separates the mouth and nasal cavity. It is composed of the palatine processes of the
la and palate bones meeting their fellows in a median suture. A transverse suture con-
the palate process of the maxilla with that of the palate bone behind it. The roughened
e of the hard palate denotes the presence of many glands in the mucosa which covers it,
he grooves and foramina are adapted to the passage of palatine vessels and nerves. A
median foramen anteriorly (*incisive foramen*) communicates with the nasal fossæ on each
y the *incisive canals*. The large opening of the pterygopalatine canal between the palate
naxilla and the lower openings of the canals in the palate bone itself (greater and lesser
ne foramina) give passage to nerves and vessels. The soft palate is fixed to the posterior
margin of the hard palate, which is extended backward in the midline to form the *posterior spine*.

The middle or subcerebral portion of the external base of the skull presents
ntral region adapted largely to the nasopharynx and lateral areas traversed
ne cerebral vessels and nerves entering and leaving the cranial cavity. When
ed in profile the subcerebral portion appears as a deep fossa sunk between
nore elevated anterior and posterior portions.

he *central region* presents the stout basilar part of the occipital bone, continuous anteriorly
the body of the sphenoid, the pterygoid processes of the latter, and the apices of the
sal parts of the temporal bones. This region communicates with the nasal fossæ by the
d openings (choanæ), limited by palate processes of the palate bones below, by the vaginal
sses of the pterygoids and alæ of the vomer above, laterally by the medial pterygoid
æ and medially by the vomer (see fig. 126). With the exception of the vomer, these also
support to the upper part of the pharynx. A *notch* in the upper part of the free margin of
nedial pterygoid plate is adapted to the cartilaginous portion of the auditory tube which
nearby in the lateral wall of the nasopharynx and leads to the adjacent *groove* [semicanalis
auditivæ] in the angle between the petrosal part of the temporal and the great wing
e sphenoid. The pharyngeal aponeurosis (see p. 1159) is attached to the external cranial
in this region. The *pharyngeal tubercle* of the pars basilaris, the free edge of the medial
goid plate and its *hamulus* give origin to the *superior constrictor* muscle of the pharynx.
eas the lateral plate of the pterygoid process is adapted to the origin of masticatory
les, the medial lamina is related to pharyngeal structures. From its base in the *scaphoid*
arises the tensor veli palatini muscle whose tendon is deflected by the hamulus. Bran-
of the sphenopalatine artery and sphenopalatine ganglion reach the roof of the nasopharynx
ne *pharyngeal canal*, running beneath the vaginal process of the medial pterygoid plate.
intimately connected with the pharynx is the pterygoid (Vidian) nerve which occupies
terygoid canal directed forward through the base of the pterygoid process. This canal
s anteriorly into the pterygopalatine fossa and posteriorly into the *foramen lacerum*, the
given to the space (occupied by the basal fibrocartilage) with jagged margins between
ars basilaris of the occipital and the great wing of the sphenoid on the one hand and the
mity of the pars petrosa of the temporal on the other.
he central region of the subcerebral division, close to the occipital foramen, gives insertion
scles of the vertebral column and, under cover of the occipital condyles, passage by way of
ypoglossal canals to the hypoglossal nerves.
he *paired lateral areas* of the subcerebral region intervene between the infratemporal fossæ
nandibular fossæ laterally and the nasopharyngeal region medially. These areas present
nber of foramina for the passage of vessels and nerves. Most anteriorly the *foramen ovale*
s the great wing of the sphenoid behind the base of the pterygoid process. It transmits
andibular division of the trigeminal nerve. The middle meningeal branch of the internal
llary artery enters the cranium by the *foramen spinosum*, which perforates the posterior
of the sphenoid between the foramen ovale and the *spina angularis* (for the sphenoman-
ar ligament). The orifice of the *carotid canal*, occupied by the internal carotid artery
ars on the inferior surface of the pars petrosa of the temporal bone. Behind this orifice
large *jugular foramen* in which the internal jugular vein is formed and through which
the glossopharyngeal, vagus and accessory nerves. The anterior wall of the foramen,
by the petrous portion of the temporal bone, presents two fossæ; a larger oval one, the
ar fossa occupied by the superior bulb of the internal jugular vein, and a smaller notch-like
ssion, *canaliculus cochleæ*, medial to the jugular fossa, transmitting a vein from the cochlea
e internal jugular. Upon the lateral wall of the jugular fossa, a minute foramen leads to
astoid canaliculus, transmitting the auricular branch of the vagus. On the ridge between
gular fossa and orifice of the carotid canal is the *fossula petrosa*, in the bottom of which
he opening of the *tympanic canaliculus* carrying the tympanic branch of the glossopharyn-
nerve. At the side of the jugular foramen and behind the base of the styloid process is
tylomastoid foramen, the inferior opening of the facial canal, the passageway through the
al wall for the facial nerve. The slender *styloid process*, ensheathed at its base by the
al process, springs from the temporal bone, beneath the tympanic cavity.

The posterior portion of the external cranial base presents the joint for
ulation with the neck and the great areas for the attachment of the muscles
h move the head and neck. The foramen magnum lies within this region.
he paired *occipital condyles*, oval in form and elevated above the general
lie upon either side of the foramen magnum chiefly in the *lateral parts* of the
ital bone. They articulate with the atlas; a tubercle on the margin gives

FIG. 119.—THE SKULL. Norma basilaris. (To show muscular attachments.)

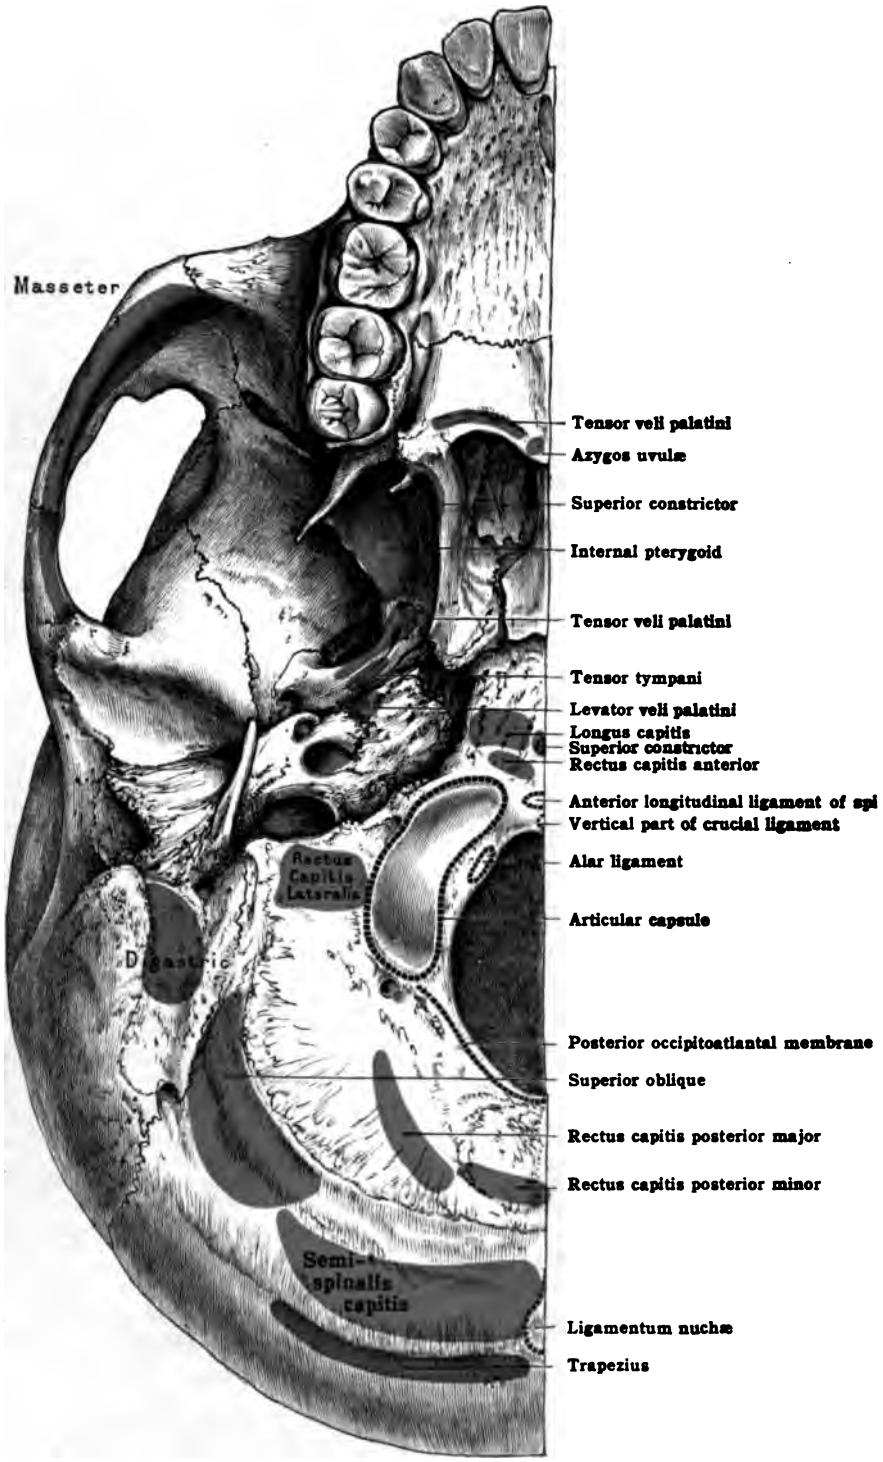


FIG. 120.—THE SKULL. Norma basilaris. Bones colored.

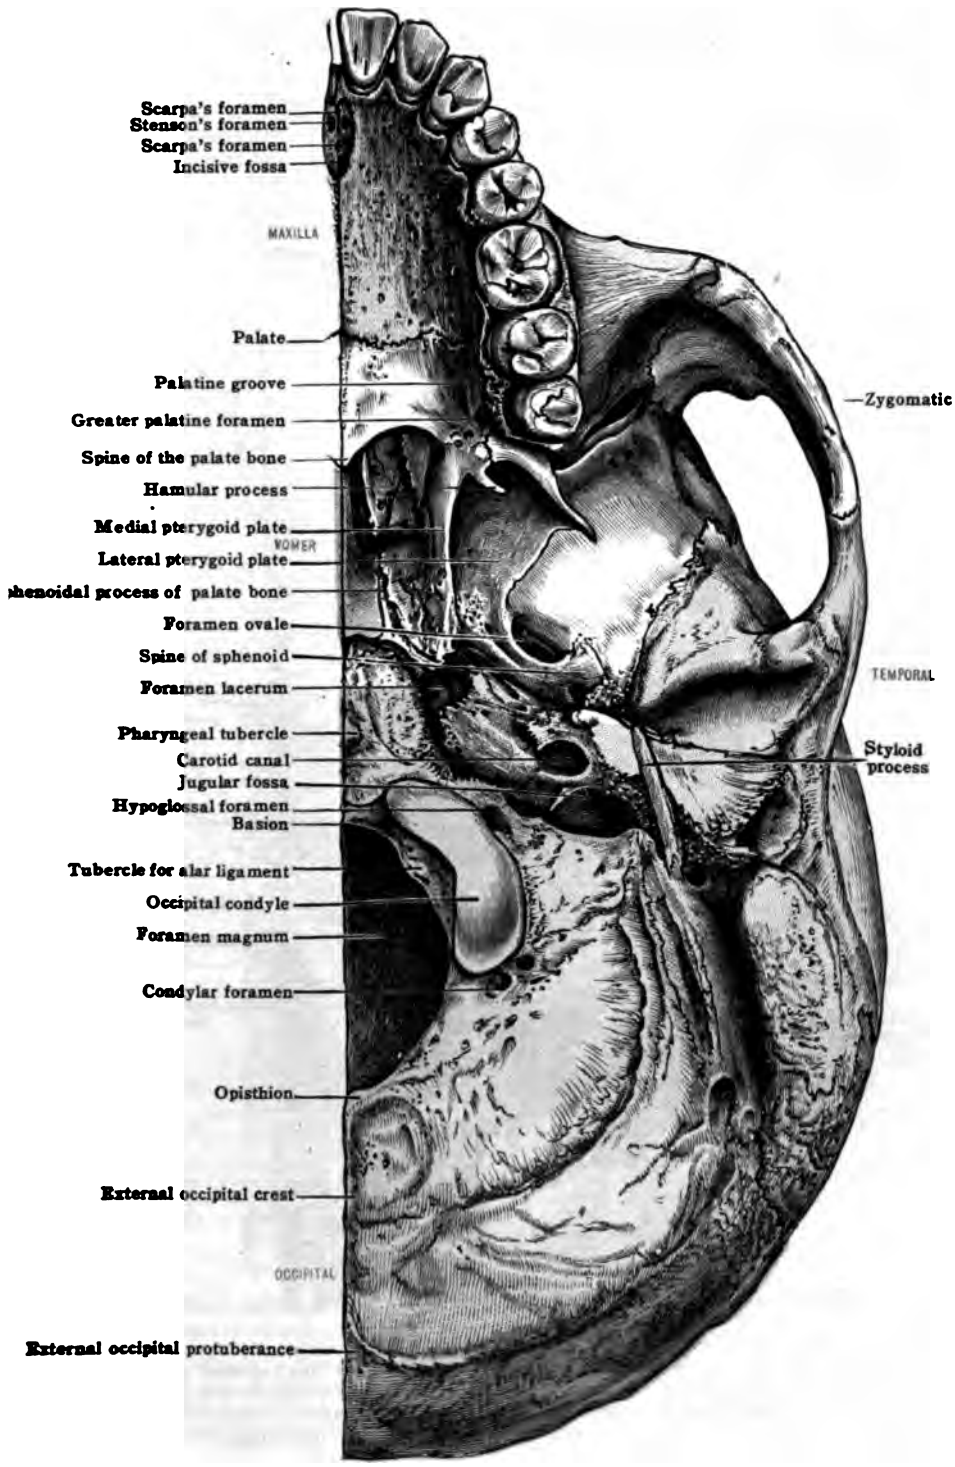
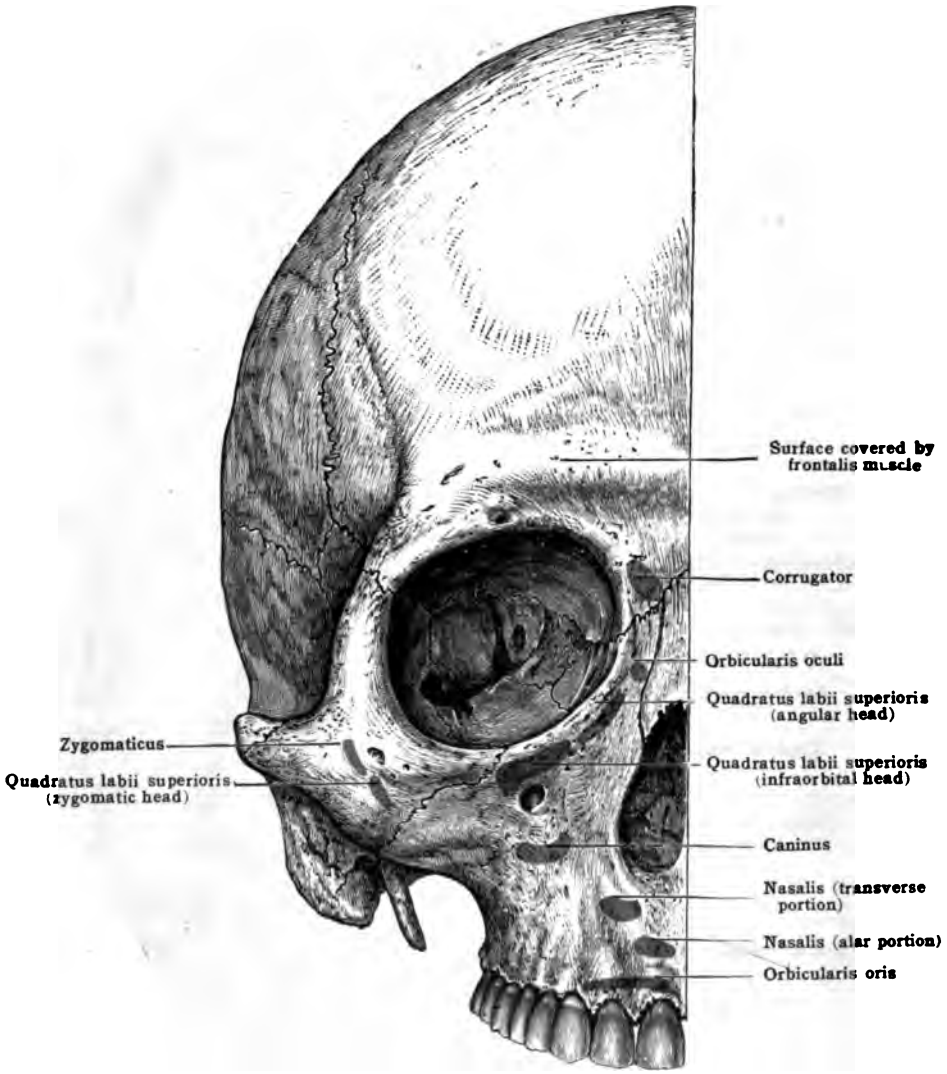


attachment to the alar ligament. Lateral to the condyle, the rough surface of the *jugular process* gives insertion to the *rectus capitis lateralis* muscle. This process articulates laterally with the pars mastoidea of the temporal; in front it enters into the boundary of the jugular foramen. Behind the jugular process and condyle is the *condylar fossa*, adapted to receive the edge of the superior articular process of the atlas.

Regarding the areas for the attachment of muscles: the posterior belly of the *digastric* arises from the *digastric fossa* of the mastoid portion medial to the mastoid process. The *squamous part* (squama occipitalis), behind the foramen magnum and lateral parts, convex and rough, is mapped out by ridges indicating the limits of muscular insertion and sites of ligament-

FIG. 121.—THE SKULL. Norma facialis. To show origin of muscles.



ous attachment. The *external occipital crest*, in the midline from the external occipital protuberance to the foramen magnum, gives attachment to the ligamentum nuchæ. From the external *occipital protuberance*, the *superior nuchal line* reaches to the lateral angle of the occipital bone; from the middle of the crest, the *inferior nuchal line* arches toward the jugular process. The names of the muscles inserted here will be found in the description of the occipital bone (p. 122).

Within this region of the external base, openings for the passage of so-called emissary veins are present: the *mastoid foramen* near the posterior margin of the pars mastoidea, communicating with the transverse sinus; a *condylar canal* often found in the bottom of the condylar fossa opening into the terminal part of the same sinus. The occipital artery occupies the *occipital groove* of the pars mastoidea medial to the digastric fossa.

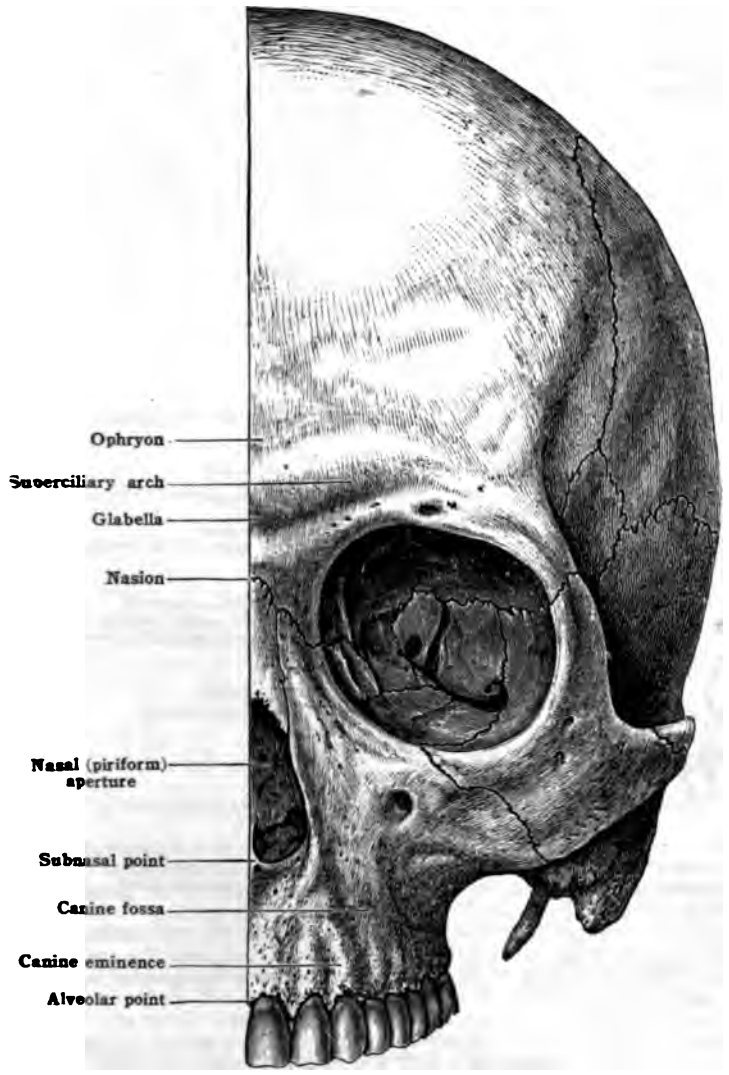
For description of the *foramen occipitale magnum*, see p. 125.

(5) The Anterior Region

The **anterior region** (*norma facialis*) (figs. 121, 122) comprises the anterior end of the cerebral cranium, or forehead, and the skeleton of the face. The configuration of this region is determined by the presence of the nose, eyes and mouth, the **nasal skeleton, orbits** and **jaws** giving support to these organs.

The upper part or forehead, narrowest between the temporal crests about half an inch above the zygomatic processes of the frontal, presents at this level

Fig. 122.—The Skull. Norma facialis.



the two **transverse sulci,** above which are the **frontal eminences** corresponding to the anterior poles of the frontal lobes of the brain.

The **bones** entering into formation of the *norma facialis* are:—the frontal, nasals, lacrimals, orbital surfaces of the small and the great wings, and a portion of the body of the sphenoid, the laminæ papyraceæ of the ethmoids, the orbital processes of the palate bones, the zygomatics, maxillæ, inferior nasal conchæ, and the mandible.

THE ORBITS

Below the forehead are the openings of the **orbits** [orbitæ] (figs. 122, 123) two cavities of pyramidal shape, with their bases directed forward and laterally and their apices backward and medially. Each cavity forms primarily a socket

for the eyeball and the muscles, nerves, and vessels associated with it, but also contains vessels and nerves not directly related to the eye, but which pass through to other regions.

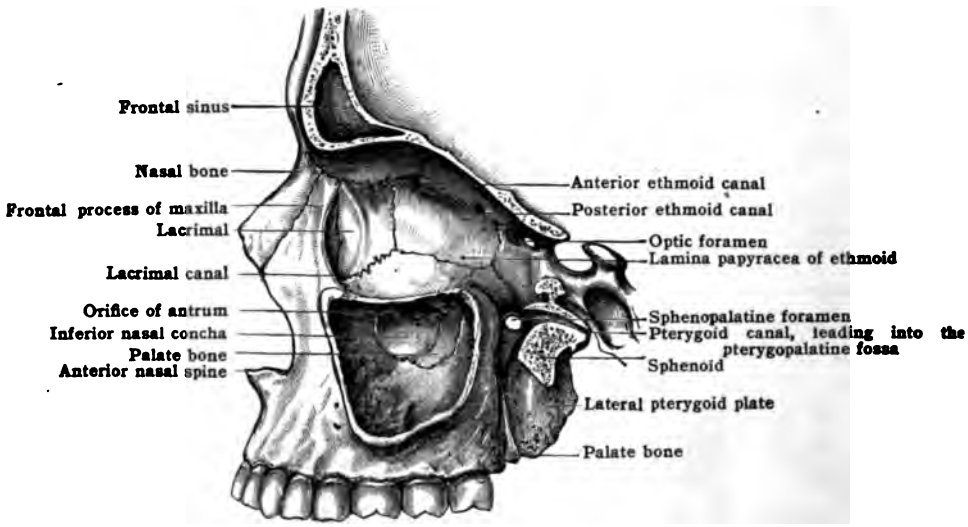
Seven bones enter into formation of its walls, viz., the frontal, zygomatic, sphenoid, ethmoid, lacrimal, palate, and maxilla; but as three of these—the frontal, sphenoid, and ethmoid—are single median bones which form parts of each cavity, there are only eleven bones represented in the two orbits. Each orbit presents four walls, a circumference or base, and an apex.

The **apex** of each orbit corresponds to the **optic foramen**, a circular orifice between the two roots of the lesser wing of the sphenoid bone, which transmits the optic nerve and ophthalmic artery. From the circumference of the optic foramen the straight muscles (*recti*) of the eyeball arise.

The **superior wall** or **roof**, vaulted and smooth, is formed mainly by the orbital plate of the frontal and is completed posteriorly by the small wing of the sphenoid. At the lateral angle it presents the **fossa of the lacrimal gland**, and at the medial angle a depression [fovea trochlearis] or a spine for the pulley of the *superior oblique* muscle of the eye.

The **inferior wall** or **floor** is directed upward and laterally and is not so large as the roof. It is formed by the orbital plate of the maxilla, the orbital process of the zygomatic, and the orbital process of the palate bone. At its medial angle it presents the *nasolacrimal canal*, occupied by the nasolacrimal duct between the orbit and nasal fossa; and near this, a depression for the origin of the *inferior oblique* muscle. It is marked near the middle by a furrow for the

FIG. 123.—THE MEDIAL WALL OF THE ORBIT.



infraorbital artery and the maxillary nerve, terminating anteriorly in the *infraorbital canal*, through which the nerve and artery emerge on the face. Near the commencement of the canal a narrow passage, the anterior alveolar canal, runs forward and downward in the anterior wall of the antrum, transmitting nerves and vessels to the incisor and canine teeth.

The **lateral wall**, directed forward and medially, is formed by the orbital surface of the great wing of the sphenoid, and the zygomatic. Between it and the roof, near the apex, is the **superior orbital** (sphenoidal) **fissure**, a narrow gap intervening between the greater and lesser wings of the sphenoid, and connecting the orbit and cranial cavity. It transmits several structures, including the ophthalmic, oculomotor, trochlear and abducent nerves and the ophthalmic vein or veins; it also transmits some filaments from the cavernous plexus of the sympathetic, the orbital branch of the middle meningeal artery and recurrent branches of the lacrimal artery. The lower margin of the fissure presents near the middle a small tubercle, from which the inferior head of the *lateral rectus* muscle arises. Between the lateral wall and the floor, near the apex, is the **inferior orbital** (sphenomaxillary) **fissure**, through which pass the maxillary nerve and its zygomatic branch, and the infraorbital vessels from the pterygopalatine fossa. A connection is established through the fissure between the orbital veins and the pterygoid plexus in the infratemporal fossa. The great wing of the sphenoid forms the posterior margin of the fissure, the orbital plate of the maxilla its anterior edge, and the zygomatic its lateral boundary. On the latter bone are seen the zygomatico-orbital orifices of the zygomaticotemporal and zygomaticofacial canals, which traverse the zygomatic bone, transmitting the nerves of the same name to the temporal fossa and cheek. The commencement of the zygomaticotemporal canal is sometimes seen in the sphenozygomatic suture.

The **medial wall**, narrow and nearly vertical, is formed from before backward by the frontal process of the maxilla, the lacrimal, the lamina papyracea of the ethmoid, and the body of the sphenoid. It is traversed by three vertical sutures:—one between the frontal process of the maxilla and the lacrimal, a second between lacrimal and lamina papyracea, and a third between

the **lamina papyracea** and the sphenoid. Occasionally the sphenoidal concha appears in the orbit between the ethmoid and the body of the sphenoid. Anteriorly is the **fossa of the lacrimal sac,** hollowed out of the lacrimal bone and frontal process of the maxilla; behind this the **posterior lacrimal crest,** from which the *lacrimal part of the orbicularis oculi* muscle arises. At the junction of the medial wall with the roof, and in the suture between the ethmoid and frontal, are seen the orifices of the **anterior** and **posterior ethmoidal canals,** the anterior, transmitting the anterior ethmoidal vessels and nerve; and the posterior, the posterior vessels and nerve.

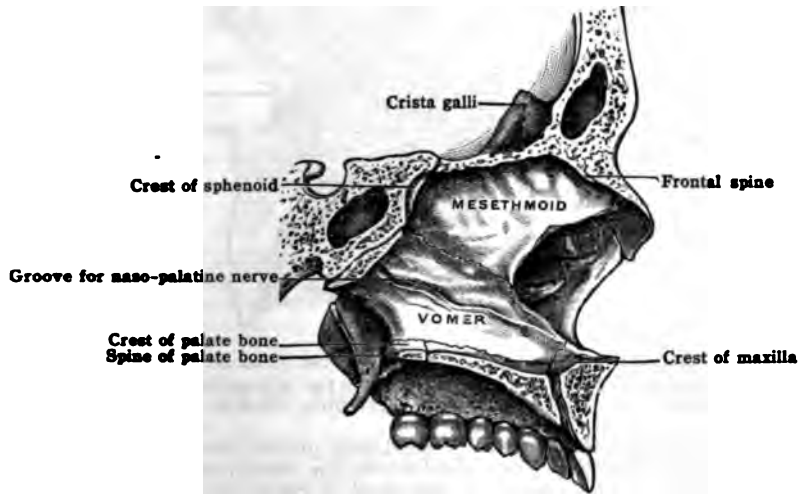
The **base** or circumference is quadrilateral in form and corresponds to the **aditus orbitæ.** It is bounded by the frontal bone above, presenting the sharp **supraorbital margin,** broken by the **supraorbital notch** (sometimes a foramen) giving passage to the supraorbital branch of the ophthalmic nerve and the supraorbital artery. Above the margin the **superciliary arch** extends medially into the prominence of the **glabella.** The frontal process of the maxilla and the medial angular process of the frontal are on the medial side, the zygomatic bone and the zygomatic process of the frontal on the lateral side of the aditus orbitæ. The zygomatic and the body of the maxilla form the inferior boundary which is in the shape of a sharp raised edge, **infraorbital margin,** between the orbital and facial surfaces of these bones. The infraorbital margin is continued medially into the **anterior lacrimal crest,** in front of the fossa of the lacrimal sac, which gives origin to the orbicularis oculi, pars orbitalis. Below the infraorbital margin is to be seen the facial opening of the infraorbital canals, the **infraorbital foramen** for the nerve and artery of the same name.

The orbit communicates with the cranial cavity by the optic foramen and superior orbital fissure; with the nasal fossa, by means of the nasolacrimal canal; with the infratemporal and pterygopalatine fossæ, by the inferior orbital fissure. In addition to these large openings, the orbit has five other foramina—the infraorbital, zygomatico-orbital, and the anterior and posterior ethmoidal canals—opening into it or leading from it. The following points may also be noted:—The suture between the zygomatic process of the frontal bone and the zygomatic; the suture between the frontal bone and the frontal process of the maxilla; and in the lower segment, the zygomaticomaxillary suture.

NASAL SKELETON

The **nasal skeleton** includes the bony and cartilaginous support of the external nose, the nasal fossæ and the paranasal sinuses.

FIG. 124.—SECTION THROUGH THE NASAL FOSSA TO SHOW THE SEPTUM. LEFT HALF, WITH SEPTUM LOOKING TOWARD RIGHT NASAL FOSSA.



Skeleton of the external nose.—The cartilaginous framework is described in the section on the Respiratory System, p. 1225. The bony skeleton forms the bridge of the nose which is composed medially of the **nasal bones** articulating with each other in the **internasal suture,** and laterally of the **frontal processes** of the **maxillæ** articulating with the nasal bones. These elements unite above with the frontal bone in the **nasofrontal** and **frontomaxillary sutures.**

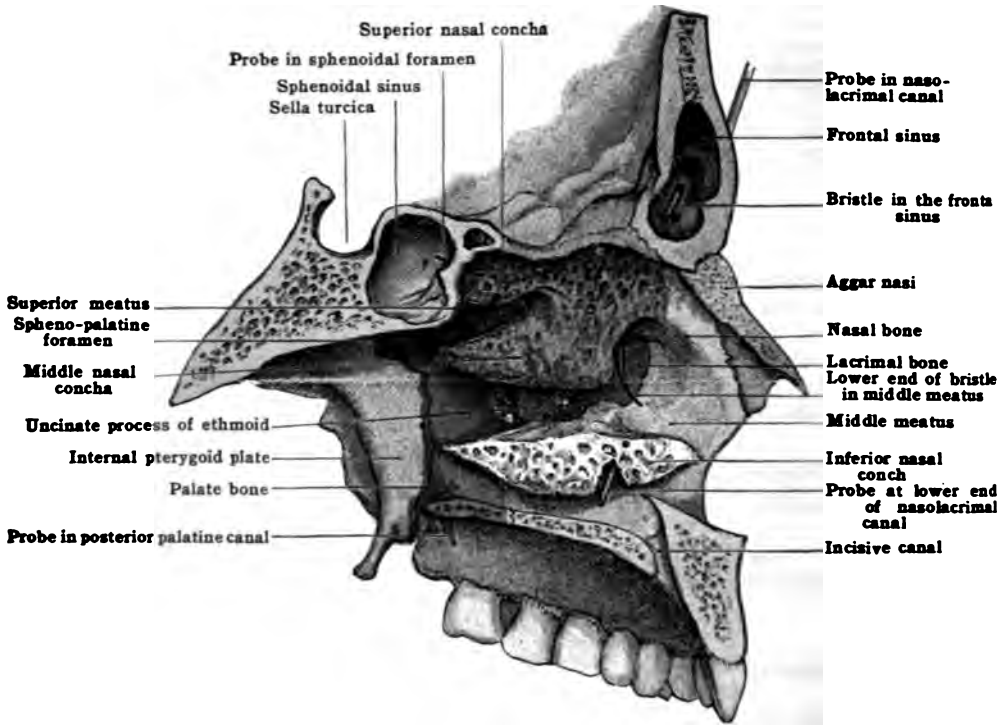
Below the bridge of the nose the cartilaginous portion projects from the margins of the **piriform aperture.** This large opening leads into the bony-walled nasal fossæ, is higher than wide and is bounded by the nasal bones above and the maxillæ laterally and below. In the midline below is the **anterior nasal spine** which supports the extremity of the cartilaginous nasal septum. For muscular attachments in this region, see fig. 121.

The **nasal fossæ** (figs. 124, 125, 975, 1086) are two irregular cavities situated

on each side of a median vertical septum. They open in front by the piriform aperture and communicate behind with the pharynx by the choanæ. They are somewhat oblong in transverse section, and extend vertically from the anterior part of the base of the cranium above to the superior surface of the hard palate below. Their transverse extent is very limited, especially in the upper part. Each fossa presents a roof, floor, medial and lateral walls, and communicates with the paranasal sinuses of the frontal, sphenoid, maxilla, and ethmoid bones.

The **roof** is horizontal in the middle, but sloped downward in front and behind. The anterior slope is formed by the posterior surface of the nasal bone and the nasal process of the frontal; the horizontal portion corresponds to the **cribriform plate of the ethmoid** and the **sphenoidal concha**; the posterior slope is formed by the inferior surface of the body of the sphenoid, the ala of the vomer, and a small portion of the **sphenoidal process of the palate.** The sphenoidal sinus opens at the upper and back part of the roof into the sphenoethmoidal recess, above the superior meatus.

FIG. 125.—SECTION THROUGH THE NASAL FOSSA TO SHOW THE LATERAL WALL WITH THE MEATUSES.



The **floor** is concave from side to side, and in the transverse diameter wider than the roof. It is formed mainly by the palatine process of the maxilla and completed posteriorly by the horizontal part of the palate bone. Near its anterior extremity, close to the septum is the incisive canal.

The **septum** or medial wall is formed by the perpendicular plate of the ethmoid, the vomer, the rostrum of the sphenoid, the crest of the nasal bones, the frontal spine, and the median crest formed by the apposition of the palatine processes of the maxillæ and the horizontal parts of the palate bones. The anterior border has a triangular outline limited above by the perpendicular plate of the ethmoid and below by the vomer, and in the recent state the deficiency is filled up by the septal cartilage of the nose. The posterior border is formed by the pharyngeal edge of the vomer, which separates the two choanæ. The septum, which is usually deflected from the middle line to one side or the other, is occasionally perforated, and in some cases a strip of cartilage, continuous with the triangular cartilage, extends backward between the vomer and perpendicular plate of the ethmoid (*posterior* or *sphenoidal process*).

The **lateral wall** is the most extensive and the most complicated on account of the formation of the meatuses of the nose. It is formed by the frontal process and the medial surface of the maxilla, the lacrimal, the superior and inferior conchæ of the ethmoid, the inferior nasal concha, the vertical part of the palate bone, and the medial surface of the medial pterygoid plate. The three conchæ (frequently four, see p. 1233), which project medially, overhang the three recesses known as the **meatuses** of the nose. The **superior meatus**, the shortest of the three, is situated between the superior and middle nasal conchæ, and into it open the **posterior ethmoidal cells.** The **middle meatus** lies between the middle and inferior **conchæ.** It presents a prominent groove, the **hiatus semilunaris**, bounded by the **ethmoidal bulla above and the uncinate process** of the ethmoid below, and leading into a cleft-like space, **the ethmoidal**

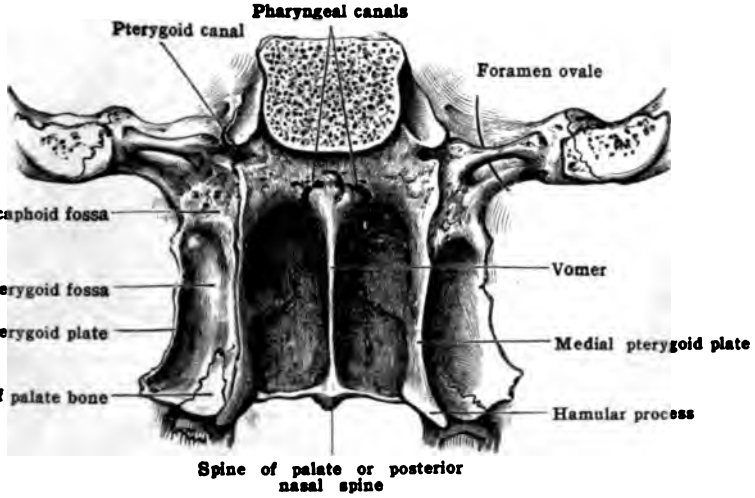
ulum. Into the middle meatus open the **anterior ethmoidal cells** (including the middle · group), the **frontal sinus** and the **maxillary sinus** (frequently by two apertures). (For details concerning the paranasal sinuses, see descriptions under the individual bones; **er Respiratory System,** p. 1233.) Anterior to the middle meatus is a slight elevation, **r nasi,** on the frontal process of the maxilla. The **inferior meatus,** longer than the others, en the inferior nasal concha and the floor of the nasal fossa. Anteriorly and laterally its the lower orifice of the **nasolacrimal canal.**

common meatus of the nose is the narrow space between the conchæ and the nasal the name **nasopharyngeal meatus** is given to the region of the nasal fossa located on e behind the level of the conchæ. The lateral wall is formed by the perpendicular the palate; here the **sphenopalatine foramen,** standing just behind the posterior end iddle conchæ, puts the nasal fossa into communication with the pterygopalatine fossa es passage to the sphenopalatine artery and nasal branches of the sphenopalatine

nasal fossæ open on the face by means of the **apertura piriformis** and into the pharynx **hoanæ.** The paired choanæ (fig. 126) are bounded superiorly by the alæ of the vomer, enoidal processes of the palate, and the inferior surface of the body of the sphenoid; by the medial pterygoid plates; and inferiorly by the posterior edge of the horizontal the palate bones. They are separated from each other by the posterior border of the

nasal fossæ communicate with all the more important fossæ and the air-sinuses of the By means of the foramina in the roof they are in connection with the cranial cavity; niddle meatus each fossa is in communication with the maxillary and frontal sinuses

FIG. 126.—THE CHOANÆ. (Viewed from behind.)



erior ethmoidal cells; the posterior ethmoidal cells open into the superior meatuses and enoidal sinuses into the recesses above; the sphenopalatine foramina connect them with ygopalatine fossæ. The nasolacrimal canals connect with the orbits, and the incisive ith the oral cavity.

SUTURES OF THE ANTERIOR REGION

sutures of the anterior region are numerous and for the most part unimportant:—
transverse suture (fig. 122) extends from one zygomatic process of the frontal to the The upper part of the suture is formed by the frontal bone; below are the zygomatic, d small wings of the sphenoid, lamina papyracea, lacrimal, maxillary, and nasal bones. n of this complex suture, lying between the sphenoidal and frontal bones, appears in rior cranial fossa.

following anthropometric points may also be noticed:—
glabella, a smooth space between the converging superciliary arches.
ophryon, the most anterior point of the metopic suture.
nasion, the middle of the nasofrontal suture.
subnasal point, the middle of the inferior border of the piriform aperture.
alveolar point, the center of the anterior margin of the upper alveolar arch.

THE INTERIOR OF THE CRANIUM

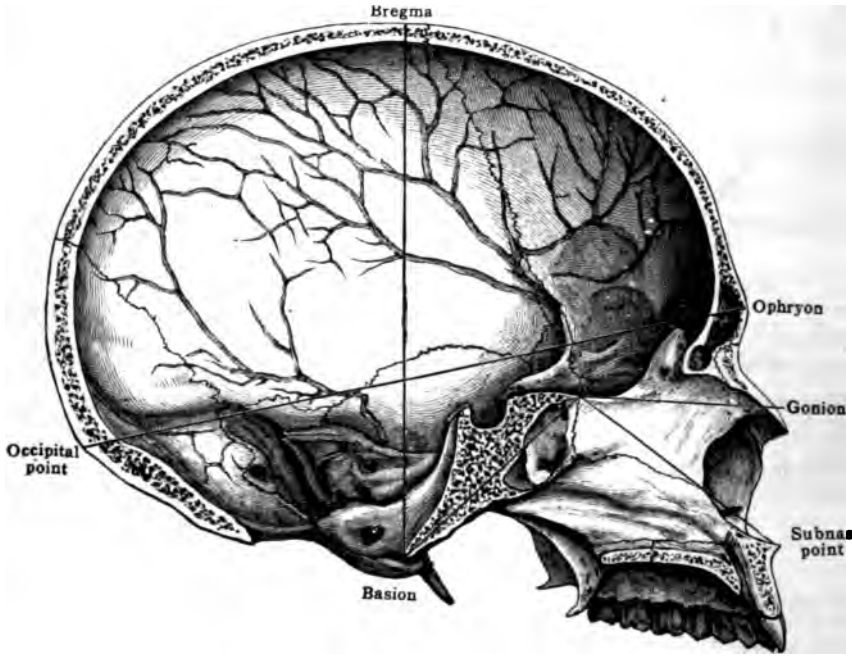
size of the cranial cavity is in relation to that of the contained brain and elopes. The cavity conforms rather closely to the shape of the brain, ger divisions of which all leave their marks upon the base and walls.

Median section (fig. 127).—In this section conditions are presented for an advantageous review of the structure of the cranial wall, and of the size and form of the cranial cavity. The walls of the brain-case are built up mainly from the parietal, frontal and occipital bones; to a lesser extent by the temporals, the sphenoid and ethmoid.

The following anthropometric points and measurements are best understood in the median section. The black line (fig. 127) drawn from the **basion** (anterior margin of the foramen magnum) to the the anterior extremity of the sphenoid represents the **basicranial axis**; whilst the line drawn from this extremity to the **subnasal point** lies in the **basifacial axis.** These two axes form an angle termed the **craniofacial,** which is useful in making comparative measurements of crania. A line prolonged vertically upward from the **basion** will strike the **bregma.** This is the **basibregmatic** axis, and gives the greatest height of the cranial cavity. A line drawn from the **ophryon** to the **occipital point** indicates the greatest length of the cranium.

The structure of the bony capsule in the midplane shows considerable variation. It is thinnest at the cribriform plate of the ethmoid, and thickest through the basilar portion of the occipital and body of the sphenoid. In the cranial walls may be seen the diploë, between the outer and inner tables [laminæ]; also the frontal and sphenoidal air sinuses. For structure of the cranial wall, see also p. 81.

FIG. 127.—THE SKULL IN MEDIAN SECTION.



The inner surface of the cranium presents slight depressions corresponding to the convolutions [gyri] of the cerebrum. A series of branching grooves are occupied by **meningeal vessels;** the largest, for the **middle meningeal vessels,** may be traced to the foramen spinosum in the base. The shallow groove for the **superior sagittal sinus** [sulcus sagittalis] occupies the midline of the roof; and on each side are small pits [foveolæ granulares] for the Pacchionian bodies of the arachnoid. Posteroinferiorly on each side the groove for the **transverse sinus** crosses the occipital, angle of the parietal, and mastoid portion of the temporal bones.

The **floor** [basis cranii interna] of the cranial cavity presents three irregular subdivisions termed the anterior, middle, and posterior fossæ (figs. 128 and 129) in adaption to the contour of the base of the brain.

THE ANTERIOR CRANIAL FOSSA.—The floor of this fossa is on a higher level than the rest of the cranial floor. It is formed by the horizontal plate of the frontal bone, the cribriform plate of the ethmoid, the lesser wings of the sphenoid and the fore part of the body of the sphenoid. It supports the frontal lobes of the cerebrum. The **sutures** traversing the floor of the fossa are the frontoethmoidal, forming three sides of a rectangle, that portion of the transverse facial suture which traverses the roof of the orbit, and the ethmosphenoidal suture, the center of which corresponds to the **gonion.**

In the midline of the floor is the **crista galli,** its alæ articulating with the **frontal and so completing the boundaries of the foramen cecum** (lodging an emissary vein); **beyond, is the**

frontal crest to which as well as to the crista galli the falx cerebri is attached. On either side of the crista galli, the **cribriform plate** presents numerous foramina for filaments of the olfactory nerve. The lateral parts of the floor are constituted by the horizontal parts of the frontal bone, which at the same time form the **roofs of the orbits.** This region is convex here and shows marked grooves and ridges for the cerebral gyri and sulci. In the frontoethmoidal suture are the cerebral openings of the **anterior and posterior ethmoidal canals** transmitting ethmoidal arteries, the anterior carrying besides, the anterior ethmoidal nerve.

The posterior margin of the lesser wing of the sphenoid corresponds to the anterior part of the Sylvian fissure of the cerebrum, separating the frontal lobe occupying the anterior cranial fossa, from the temporal lobe which projects downward and forward into the middle fossa.

The MIDDLE CRANIAL FOSSA, situated on a lower level than the anterior, consists of a central and two lateral portions. In front it is limited by the posterior borders of the lesser wings of the sphenoid and the anterior margin of the optic groove, behind by the dorsum sellæ and the upper margin of the petrous portion of both temporal bones. Laterally it is bounded on each side by the squamous portion of the temporal, great wing of the sphenoid, and the parietal bone, whilst the floor is formed by the body and great wings of the sphenoid and the anterior surface of the petrous portion of the temporals. It contains the following sutures:—sphenoparietal, petrosphenoidal, squamosphenoidal, squamous, and a part of the transverse suture.

In general the form of the lateral portion corresponds to that of the temporal lobe of the brain. A conspicuous groove lodges the middle meningeal vessels in their course from the **foramen spinosum.** The semilunar (Gasserian) ganglion of the trigeminus occupies a slight **depression** on the part of the apex of the petrous bone; its mandibular branch passes to the infratemporal fossa by the **foramen ovale**; its maxillary branch passes into the pterygopalatine fossa via the **foramen rotundum**; its ophthalmic branch goes through the **superior orbital fissure** into the orbit.

Upon the anterior face of the petrous portion is a small opening, **hiatus canalis facialis,** which gives passage to the great superficial petrosal nerve; this runs in a groove to the irregular **lacerated foramen** in the base of the cranium. The internal carotid artery enters the cranial cavity from the **carotid canal** at the apex of the petrous bone, and runs in the **carotid groove** upon the side of the body of the sphenoid, together with the cavernous sinus. Lateral to the carotid aperture is a slender bony process, the **lingula sphenoidalis.** Lateral to the hiatus canalis facialis is the **tegmen tympani,** the thin roof of the middle ear cavity; behind which is the **eminentia arcuata,** made by the superior semicircular canal.

The middle portion of the middle cranial fossa is occupied mainly by the **hypophyseal fossa** (*sella turcica*) lodging the hypophysis or pituitary gland. The fossa is limited in front by a rounded eminence, the **tuberculum sellæ,** and posteriorly by a quadrilateral plate, the **dorsum sellæ.** The **lateral angles** of the dorsum sellæ form the **posterior clinoid processes.** The **anterior clinoid processes** project backward from the lesser wings of the sphenoid. The carotid groove terminates opposite the last-named process. Here the ophthalmic artery is given off which accompanies the optic nerve through the **optic foramen** between the two roots of the lesser wing, into the orbit. A transverse groove [**sulcus chiasmatis**] joins the optic foramina.

The POSTERIOR CRANIAL FOSSA is the deepest and largest of the series. It is bounded in front by the dorsum sellæ of the sphenoid and on each side by the superior border of the petrosal, and the mastoid portion of the temporal bone, the posterior inferior angle of the parietal, and the groove on the occipital bone for the transverse sinus. These bones take part in the formation of its floor, including the petro-occipital, occipitomastoid and parietomastoid sutures.

In the recent state the fossa lodges the cerebellum, pons, and medulla, and is roofed in by the tentorium cerebelli, a tent-like process of the dura mater attached to the superior boundaries of the fossa. It communicates with the general cranial cavity by means of the **foramen ovale of Pacchionius,** a large opening bounded anteriorly by the clivus (basilar groove) and posterolaterally by the free edge of the tentorium; and inferiorly it communicates with the vertebral canal by the **foramen magnum.**

Between the posterior cranial fossa and the middle cranial fossa on each side is the **pyramid,** formed by the petrous portion of the temporal bone and enclosing the inner ear. The features on its anterior surface were mentioned above. On the posterior surface, the most conspicuous mark is the **internal auditory meatus,** which transmits the acoustic, facial and glossopalatine nerves. Posterolateral to this are the *fossa subarcuata* and the *aquaeductus vestibuli* (see fig. 156). The superior margin of the pyramid is grooved for the superior petrosal sinus; the posterior margin for the inferior petrosal sinus.

Through the **foramen magnum** the spinal cord passes into the brain-stem, resting upon the basilar portion of the occipital between two paired eminences, the **jugular tubercles;** higher up this surface is called the **clivus** and continues upon the dorsum sellæ. The cerebellum occupies the greater part of the remaining space of the posterior fossa. A low ridge in the midline of the squama extends from the **internal occipital protuberance** to the foramen magnum and gives attachment to the falx cerebelli. On either side of the foramen magnum is the internal orifice

FIG. 128.—FLOOR OF THE CRANIUM. (Bones colored.)

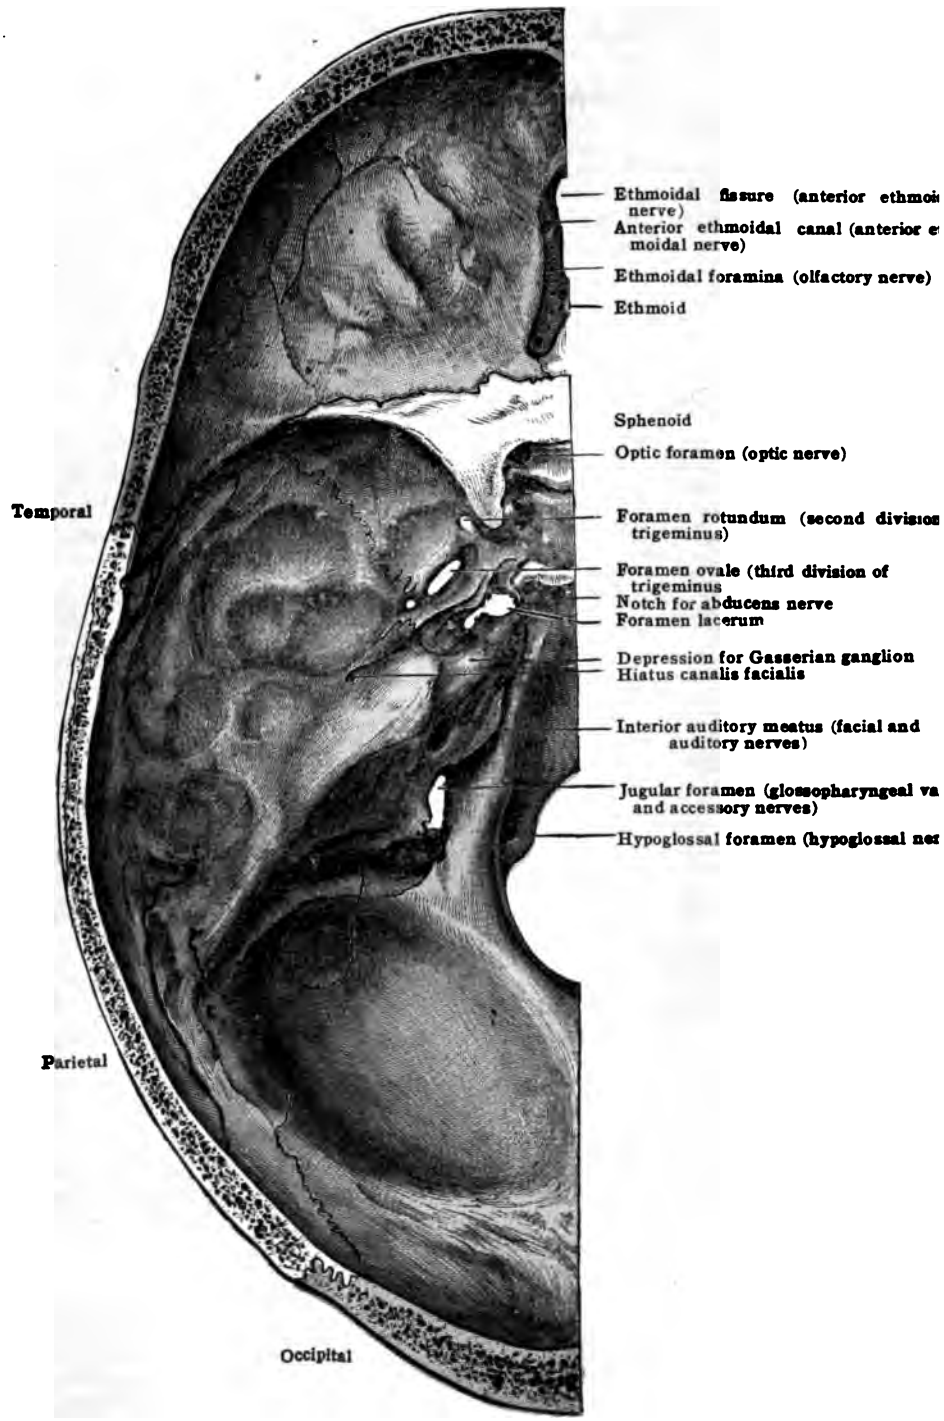


FIG. 129.—FLOOR OF THE CRANIUM.

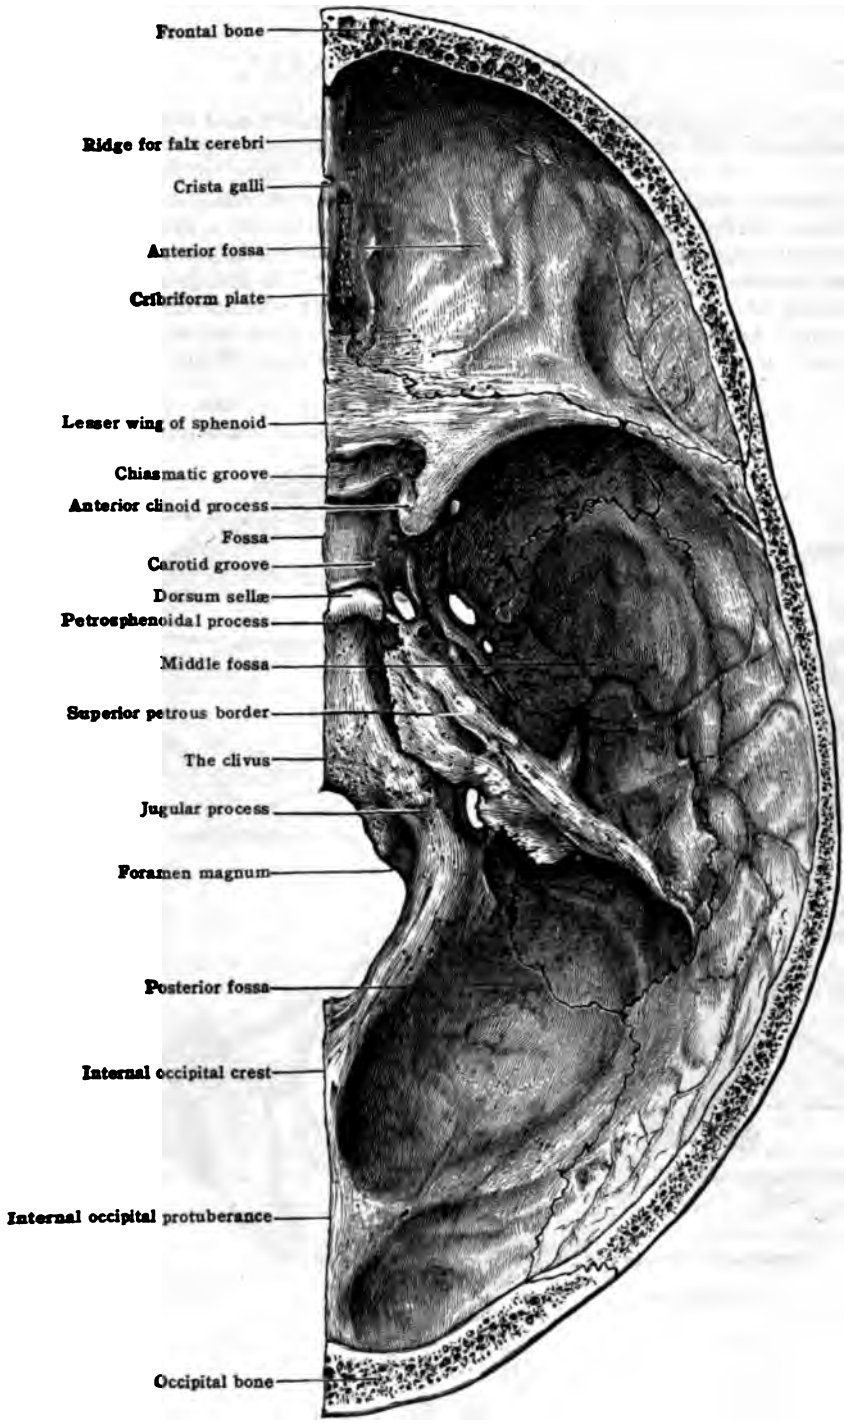
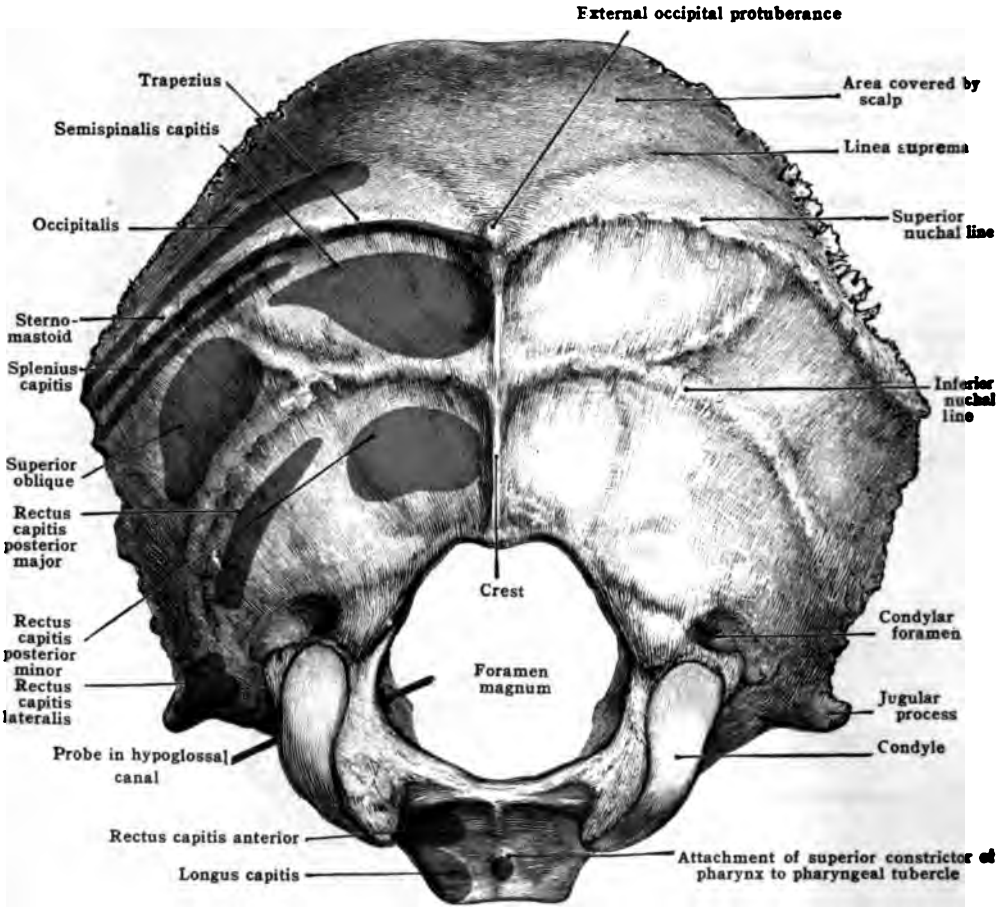


of the **hypoglossal canal,** transmitting the hypoglossal nerve. Still more laterally is the **jugular foramen,** a large opening between the occipital and petrous bones, which transmits the **vagus,** glossopharyngeal and accessory nerves and the transverse sinus. The groove for this sinus is shallow at its beginning (near the internal occipital protuberance) but deeper in its terminal portion [**sulcus sigmoideus**], where it presents a small foramen for the mastoid emissary vein.

BONES OF THE SKULL

The skull or cranium includes the cerebral cranium and the visceral cranium. The bones of the **cerebral cranium** are eight in number—viz., *occipital,* two *parietal, frontal,* two *temporal, sphenoid, ethmoid.* Those of the **visceral cranium** (facial bones), surrounding the mouth and nose, and forming with the cranium the orbital cavity for the reception of the eye, are fourteen in number—viz., two *maxillæ,* two *zygomatic* (*malar*), two *nasal,* two *lacrimal,* two *palate,* two *inferior conchæ* (*turbinates*), the *mandible,* and the *vomer.* A group of movable bones, comprising the *hyoid,* suspended from the basilar surface of the cranium, and three small bones, the *incus, malleus,* and *stapes,* situated in the middle ear or tympanic cavity, are also included in the enumeration of the bones of the skull.

FIG. 130.—THE OCCIPITAL. (External view.)



THE OCCIPITAL

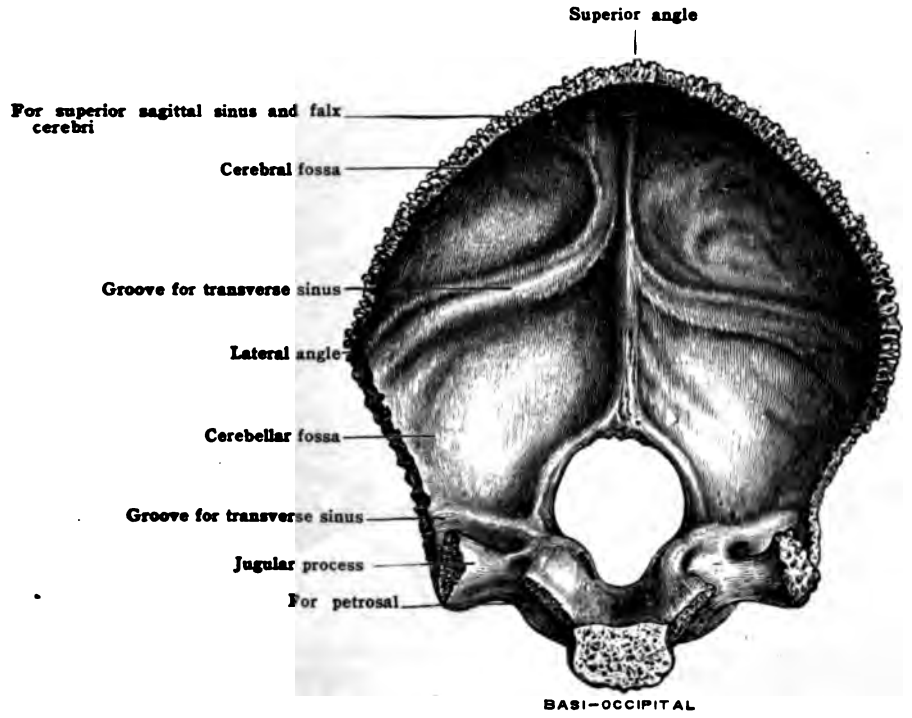
The **occipital bone** [os occipitale] (fig. 130) is situated at the **posterior and inferior** part of the cranium. In general, it is flattened and **trapezoid in shape,** curved upon itself so that one surface is convex and directed **backward** and somewhat downward, while the other is concave and looks in the **opposite** direction. It is pierced in its lower and front part by a large aperture, **the foramen magnum,** by which the vertebral canal communicates with **the cranial** cavity.

The occipital bone is divisible into four parts, **basilar, squamous,** and two **lateral** (or condylar), so arranged around the foramen magnum that the basilar part lies in front, the lateral parts on either side, and the squamous part above and behind.

Speaking generally, this division corresponds to the four separate parts of which the bone consists at the time of birth (fig. 134), known as the **basioccipital, supraoccipital,** and **exoccipital.** In early life these parts fuse together, the lines of junction of the supraoccipital and exoccipitals extending lateralward from the posterior margin of the foramen magnum, and those of the exoccipitals and basioccipital passing through the condyles near their anterior extremities. It must be noted, however, that the upper portion of the squamous part represents an additional bone, the **interparietal.**

The **squamous part** [squama occipitalis] (supraoccipital and interparietal) presents on its convex **posterior surface,** and midway between the superior angle and the posterior margin of the foramen magnum, a prominent tubercle known as the **external occipital protuberance** (or inion), from which a vertical ridge—the **external occipital crest**—runs downward and forward as far as the foramen. The protuberance and crest give attachment to the ligamentum nuchæ.

FIG. 131.—OCCIPITAL BONE, INTERNAL OR CEREBRAL SURFACE.



Arching lateralward on each side from the external occipital protuberance toward the lateral angle of the bone is a semicircular ridge, the **superior nuchal line** [linea nuchæ superior], which divides the surface into two parts—an upper [planum occipitale] and a lower [planum nuchale]. Above this line is a second less distinctly marked ridge—the **highest nuchal line** [linea nuchæ suprema].

It is the most curved of the three lines on this surface and gives attachment to the epicranial aponeurosis and to a few fibers of the *occipitalis* muscle. Between the superior and highest curved lines is a narrow crescentic area in which the bone is smoother and denser than the rest of the surface, whilst the part of the bone above the linea suprema is convex and covered by the scalp.

The lower part of the surface is very uneven and subdivided into an upper and a lower area by the **inferior nuchal line,** which runs laterally from the middle of the crest to the jugular process.

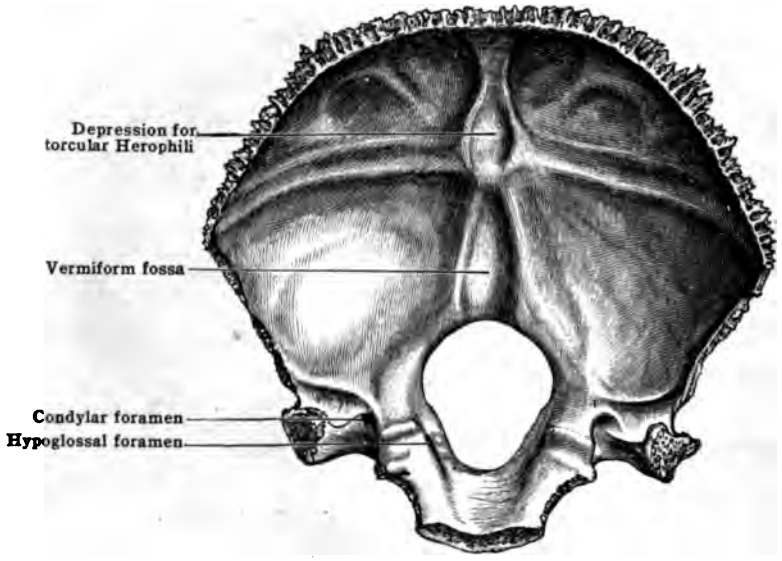
The curved lines and the areas thus mapped out between and below them give attachment to several muscles. To the superior nuchal line are attached, medially the *trapezius,* and laterally the *occipitalis* and *sternocleidomastoid;* the area between the superior and inferior

curved lines receives the *semispinalis capitis* (*complexus*) medially, and *splenius capitis* and *obliquus capitis superior* laterally; the inferior nuchal line and the area below it afford insertion to the *rectus capitis posterior minor* and *major*.

The **internal** or **cerebral surface** is deeply concave and marked by two grooved ridges which cross one another and divide the surface into four fossæ of which the two upper, triangular in form, lodge the occipital lobes of the cerebrum, and the two lower, more quadrilateral in outline, the lobes of the cerebellum. The vertical ridge extends from the superior angle to the foramen magnum and the transverse ridge from one lateral angle to the other. Their intersection forms the **eminentia cruciata,** the midpoint forming the **internal occipital protuberance.** The upper part of the vertical ridge is grooved [sulcus sagittalis] for the superior sagittal (longitudinal) sinus and gives attachment, by its margins, to the falx cerebri; the lower part is sharp and known as the **internal occipital crest,** and affords attachment to the falx cerebelli.

Approaching the foramen magnum the ridge divides, and the two parts become lost upon its margin. The angle of divergence sometimes presents a shallow fossa for the extremity of the vermis of the cerebellum, and is called the **vermiform fossa.** The two parts of the transverse ridge are deeply grooved [sulcus transversus] for the transverse (lateral) sinuses, and the

FIG. 132.—CEREBRAL SURFACE OF THE OCCIPITAL, SHOWING AN OCCASIONAL DISPOSITION OF THE CHANNELS.



margins of the groove give attachment to the tentorium cerebelli. To one side of the internal occipital protuberance is a wide space, where the vertical groove is continued into one of the lateral grooves (more frequently the right), for the confluens sinuum or *torcular Herophili;* it is sometimes exactly in the middle line (fig. 132).

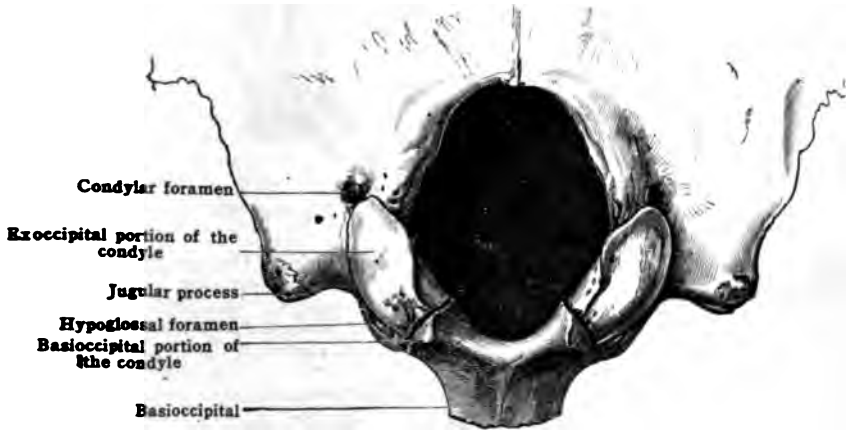
The squamous portion has three angles and four borders. The **superior angle** forming the summit of the bone is received into the space formed by the union of the two parietals. The **lateral angles** are very obtuse and correspond in situation with the lateral ends of the transverse ridges. Above the lateral angle on each side the margin is deeply serrated, forming the **lambdoid** or **superior border** which extends to the superior angle and articulates with the posterior border of the parietal in the lambdoid suture. The **mastoid** or **inferior border** extends from the lateral angle to the jugular process and articulates with the mastoid portion of the temporal.

The **lateral portions** [partes laterales] (exoccipitals) form the lateral boundaries of the foramen magnum and bear the condyles on their inferior surfaces. The **condyles** are two convex oval processes of bone with smooth articular surfaces, covered with cartilage in the recent state, for the superior articular processes of the atlas. They converge in front, and are somewhat everted. Their margins give attachment to the capsular ligaments of the occipitoatlantal joints and on the medial side of each is a prominent tubercle for the alar (lateral odontoid)

ligament. The anterior extremities of the condyles extend beyond the exoccipitals on the basioccipital portion of the bone. The **hypoglossal** (anterior condyloid) **foramen** or **canal** [canalis hypoglossi] perforates the bone at the base of the condyle, and is directed from the interior of the cranium, just above the foramen magnum, forward and laterally; it transmits the hypoglossal nerve and a twig of the ascending pharyngeal artery.

The hypoglossal foramen is sometimes double, being divided by a delicate spicule of bone. Above the canal is a smooth convexity known as the **tuberculum jugulare** sometimes marked by an oblique groove for the ninth, tenth and eleventh cranial nerves. Posterior to each condyle is a pit, the **condylar fossa,** which receives the hinder edge of the superior articular process of the atlas when the head is extended. The floor of the depression is occasionally perforated by the **condylar** (posterior condyloid) **canal** or **foramen** [canalis condyloideus], which transmits a vein from the transverse sinus. Projecting laterally opposite the condyle is a quadrilateral portion of bone known as the **jugular process,** the extremity of which is rough for articulation with the jugular facet on the petrous portion of the temporal bone. Up to twenty-five years the bones are united here by means of cartilage; about this age ossification of the cartilage takes place, and the jugular process thus becomes fused with the petrosal. Its anterior border is deeply notched to form the posterior boundary of the jugular foramen, and the notch is directly continuous with a groove on the upper surface which lodges the termination of the transverse sinus. In or near the groove is seen the inner opening of the condylar foramen. The lower surface of the process gives attachment to the *rectus capitis lateralis* and the oblique occipitoatlantal ligament. Occasionally the mastoid air-cells extend into this process and rarely a process of bone, representing the *paramastoid process* of many mammals, projects downward from its under aspect and may be so long as to join or articulate with the transverse process of the atlas.

FIG. 133.—THE FORAMEN MAGNUM AT THE SIXTH YEAR.



The **basilar portion** (basioccipital) is a quadrilateral plate of bone projecting forward and upward in front of the foramen magnum. Its superior surface presents a deep groove—the **basilar groove** [**clivus**]; it supports the medulla oblongata and gives attachment to the tectorial membrane (occipitoaxial ligament). The lower surface presents in the middle line a small elevation known as the **pharyngeal tubercle** for the attachment of the fibrous raphé of the pharynx.

On each side of the middle line are impressions for the insertions of the *longus capitis* (*rectus capitis anterior major*) and *rectus capitis anterior* (*minor*), the impression for the latter being nearer to the condyle, and near the foramen magnum this surface gives attachment to the anterior occipitoatlantal ligament. Anteriorly the basilar process articulates by synchrondrosis with the body of the sphenoid up to twenty years of age, after which there is complete bony union. Posteriorly it presents a smooth rounded border forming the anterior boundary of the foramen magnum. It gives attachment to the apical odontoid ligament, and above this to the ascending portion of the crucial ligament. In the occipital bone at the sixth year the lateral extremities of this border are enlarged to form the basilar portion of the condyles. The lateral borders are rough below for articulation with the petrous portion of the temporal bones, but above, on either side of the basilar groove, is a half-groove, which, with a similar half-groove on the petrous portion of the temporal bone, lodges the inferior petrosal sinus.

The **foramen magnum** is oval in shape, with its long axis in a sagittal direction. It transmits the medulla oblongata and its membranes, the accessory nerves (spinal portions), the vertebral arteries, the anterior and posterior spinal arteries, and the tectorial membrane (occipitoaxial ligament). It is widest

behind, where it transmits the medulla, and is narrower in front, where it is encroached upon by the condyles.

Occasionally a facet is present on the anterior margin, forming a *third occipital condyle* for articulation with the dens. Between the condyles and behind the margin of the foramen magnum the posterior occipitoatlantal ligament obtains attachment.

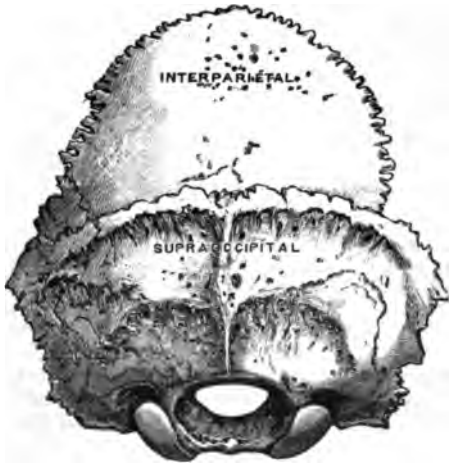
Supraoccipital portion (develops in cartilage)
Exoccipital
FORAMEN MAGNUM
Basioccipital

Blood-supply.—The occipital bone receives its blood-supply from the occipital, posterior auricular, middle meningeal, vertebral and the ascending pharyngeal arteries.

Articulations.—The occipital bone is connected by suture with the two parietals, the two temporals and the sphenoid; the condyles articulate with the atlas, and exceptionally the occipital articulates with the dens of the epistropheus by means of the third occipital condyle.

FIG. 135.—THE OCCIPITAL WITH A SEPARATE INTERPARIETAL.



Ossification.—The occipital bone develops in four pieces. The squamous portion is ossified from four centers, arranged in two pairs, which appear about the eighth week. The upper pair are deposited in membrane, and this part of the squamous portion represents the interparietal bone of many animals. The lower pair, deposited in cartilage, form the true supraoccipital element, and the four parts quickly coalesce near the situation of the future occipital protuberance. For many weeks two deep lateral fissures separate the interparietal and supraoccipital portions, and a membranous space extending from the center of the squamous

portion to the foramen magnum partially separates the lateral portions of the supraoccipital. This space is occupied later by a spicule of bone, and is of interest as being the opening through which the form of hernia of the brain and its meninges, known as occipital meningocele or encephalocele, occurs. The basioccipital and the two exoccipitals are ossified each from a single nucleus which appears in cartilage from the eighth to the tenth week.

At birth the bone consists of four parts united by strips of cartilage, and in the squamous portion fissures running in from the upper and lateral angles are still noticeable (fig. 134). The osseous union of the squamous and exoccipital is completed in the fifth year, and that of the exoccipitals with the basioccipital before the seventh year. Up to the twentieth year the basioccipital is united to the body of the sphenoid by an intervening piece of cartilage, but about that date ossific union begins and is completed in the course of two or three years.

Variations.—A shallow fossa occasionally found on the ventral surface of the basilar portion in front of the pharyngeal tubercle has been interpreted as a vestige of the canal of the notochord. The cerebral fossæ may be of unequal size and dissimilar in form. Various structures comparable to parts of an atlas have been observed about the foramen magnum. The occipital bears many resemblances in its development to an atlas vertebra and some of its varieties become intelligible when seen from this standpoint (Terry, Jour. Morph., 1917, 29: 281). Elevation of the area between the highest two curved lines gives rise to a *torus occipitalis*. Occasionally the interparietal portion remains separate throughout life (fig. 135), forming what has been termed the *inca bone*, or it may be represented by numerous detached ossicles or Wormian bones. In some cases a large Wormian bone, named the preinterparietal, is found, partly replacing the interparietal bone. A preinterparietal bone is found in some mammals, and it has occasionally been observed in the human fetal skull, rarely in the adult.

THE PARIETAL

The two **parietal bones** (figs. 136, 137), interposed between the frontal before and the occipital behind, form a large portion of the roof and sides of the cranium. Each parietal bone [os parietale] is quadrilateral in form, convex externally, concave internally, with two surfaces, four borders, and four angles.

The **parietal surface** is smooth and is crossed, just below the middle, by two curved lines known as the **temporal lines.** The superior line gives attachment to the temporal fascia; the lower, frequently the better marked, limits the origin of the *temporal* muscle; the narrow part of the surface enclosed between them is smoother than the rest. Immediately above the ridges is the most convex part of the bone, termed the **parietal eminence** [tuber parietale], best marked in young bones, and indicating the point where ossification began. Of the two divisions on the parietal surface marked off by the temporal lines, the upper is covered by the scalp, and the lower, somewhat striated, affords origin to the *temporal* muscle. Close to the upper border and near to the occipital angle is a small opening—the **parietal foramen**—which transmits a vein to the superior sagittal (longitudinal) sinus.

The **cerebral surface** is marked with slight depressions corresponding to the cerebral convolutions and by numerous deep, narrow furrows, running upward and backward from the sphenoidal angle and the lower border, for the middle meningeal vessels. A shallow depression running close to the superior border forms, with the one of the opposite side, a channel for the superior sagittal sinus, at the side of which are small irregular pits for the Pacchionian bodies [foveolæ granulares]. The pits are usually present in adult skulls, but are best marked in those of old persons. The margins of the groove for the superior sagittal sinus give attachment to the falx cerebri.

Borders.—The **sagittal** or **superior border,** the longest and thickest, is deeply serrated to articulate with the opposite parietal, with which it forms the **sagittal suture.** The **frontal** or **anterior border** articulates with the frontal to form the **coronal suture.** It is deeply serrated and bevelled, so that it is overlapped by the frontal above, but overlaps the edge of that bone below. The **occipital** or **posterior border** articulates with the occipital to form the **lambdoid suture,** and resembles the superior and anterior in being markedly serrated. The **squamosal** or **inferior border** is divided into three portions:—the anterior, thin and bevelled, is overlapped by the tip of the great wing of the sphenoid; the middle portion, arched and also bevelled, is overlapped by the squamous part of the temporal; and the posterior portion, thick and serrated, articulates with the mastoid portion of the temporal bone.

Angles.—The **frontal** or **anterior superior,** almost a right angle, occupies that part of the bone which at birth is membranous and forms part of the anterior fontanelle. The **sphenoidal** or **anterior inferior** angle is thin and prolonged

downward to articulate with the tip of the great wing of the sphenoid. Its inner surface is marked by a deep groove, sometimes converted into a canal for a short distance for the middle meningeal vessels (chiefly for the sinus). The **occipital** or **posterior superior** angle is obtuse and occupies that part which during fetal life

FIG. 136.—THE LEFT PARIETAL. (Outer surface.)

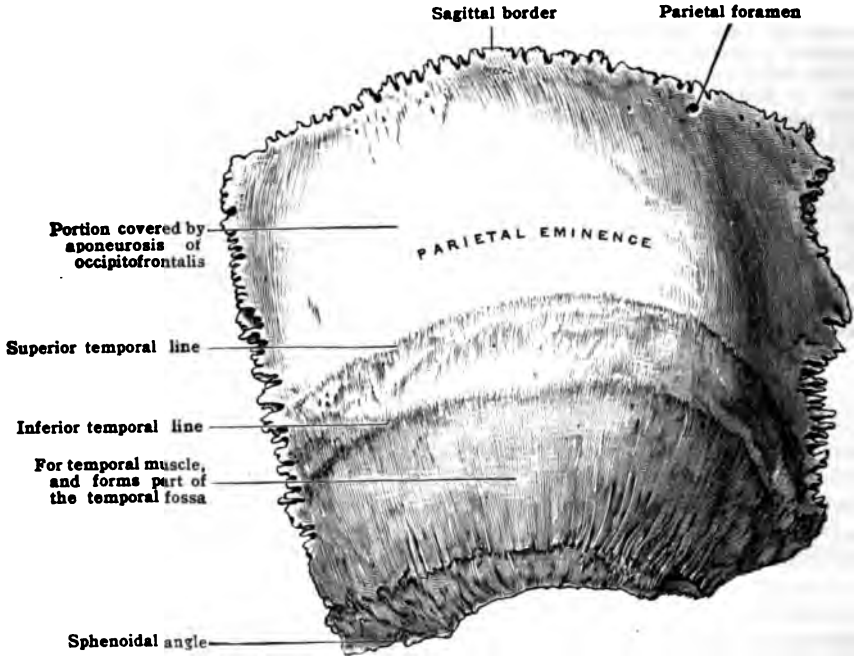


FIG. 137.—THE LEFT PARIETAL. (Inner surface.)

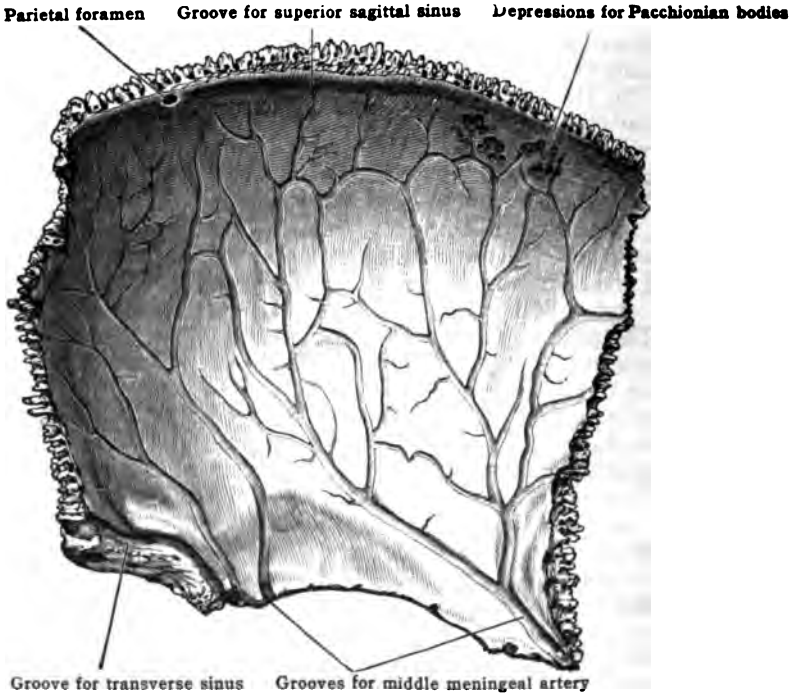


Parietal foramen
Groove for superior sagittal sinus
Depressions for Pacchionian bodies
Groove for transverse sinus
Grooves for middle meningeal artery

enters into the formation of the posterior fontanelle. The **mastoid** or **posterior inferior** angle is thick and articulates with the mastoid portion of the temporal bone. Its inner surface presents a shallow groove which lodges a part of the transverse (lateral) sinus.

Blood-supply.—The parietal bone receives its blood-supply from the middle meningeal, occipital and supraorbital arteries.

Articulations.—The parietal articulates with the occipital, frontal, sphenoid, temporal, its fellow of the opposite side, and the epipteric bone when present. Occasionally the temporal and epipteric bones exclude the parietal from articulation with the great wing of the sphenoid.

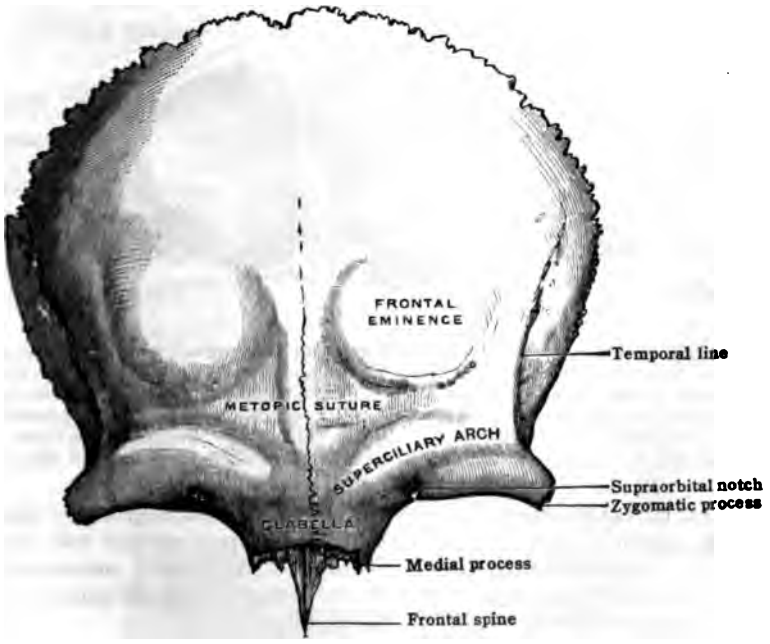
Ossification.—The parietal ossifies from two nuclei, one above the other, which appear in the outer layer of the membranous wall of the skull about the seventh week and fuse to form a single center in the third month. The ossification radiates in such a way as to leave a cleft at the upper part of the bone in front of the occipital angle, the cleft of the two sides forming a lozenge-shaped space across the sagittal suture known as the **sagittal fontanelle.** This is usually closed about the fifth month of intrauterine life, but traces may sometimes be recognized at the time of birth, and the parietal foramina are to be regarded as remains of the cleft. According to Dr. A. W. W. Lea, a well-developed sagittal fontanelle is present in 4.4 per cent. of infants at birth. In such cases it closes within the first two months of life, but at times it may remain open for at least eight months after birth and possibly longer (see p. 29).

Variations.—In addition to those referred to above, the following variations are of interest: conversion of the meningeal sulcus at the anteroinferior angle into a bony-walled canal; the occurrence of an *os bregmaticum;* symmetrical thinning over a large area of both parietals in the aged. Rarely the parietal bone is composed of two pieces, one above the other, and separated by an anteroposterior suture (subsagittal suture), more or less parallel with the sagittal suture. (Cf. Terry, Jour. Anat. & Phys., 1899, 33: 413.) In such cases the two primary centers of ossification fail to fuse.

THE FRONTAL

The **frontal bone** [os frontale] closes the cranium in front and is situated above the skeleton of the face. It consists of two portions—a **frontal** (*vertical*) **portion**

FIG. 138.—THE FRONTAL. (Anterior view.)

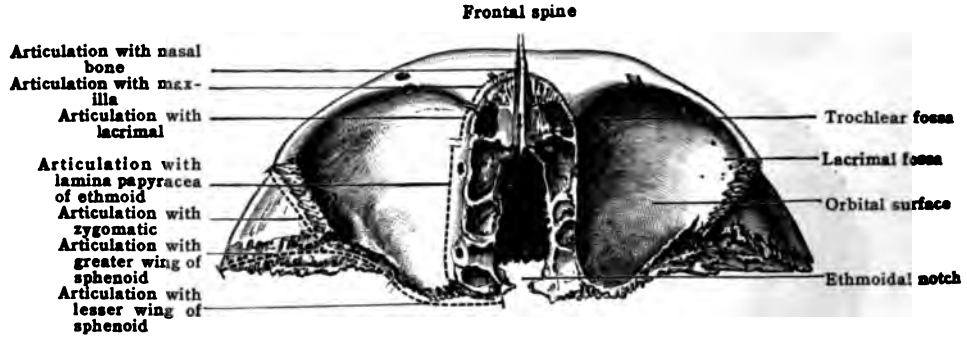


[squama frontalis], forming the convexity of the forehead, and an **orbital** (*horizontal*) **portion,** which enters into formation of the roof of each orbit (figs. 138, 139).

Frontal (*vertical*) **portion.**—The **frontal surface** is smooth and convex, and usually presents in the middle line above the root of the nose some traces of the suture which in young subjects traverses the bone from the upper to the lower part. This suture, known as the **frontal** or **metopic suture,** indicates the line of junction of the two lateral halves of which the bone consists at the time of birth; in the adult the suture is usually obliterated except at its lowest part. On each side is a rounded elevation, the **frontal eminence** [tuber frontale], very prominent in young bones, below which is a shallow groove, the **sulcus transversus,** separating the frontal eminence from the **superciliary arch.** The latter forms an arched projection above the margin of the orbit and corresponds to an air-cavity within

the bone known as the **frontal sinus.** The ridges of the two sides converge toward the median line, but are separated by a smooth surface called the **glabella** (nasal eminence). Below the arch the bone presents a sharp curved margin, the **supraorbital border,** forming the upper boundary of the circumference of the orbit and separating the frontal from the orbital portion of the bone. At the junction of its medial and intermediate third is a notch, sometimes converted into a foramen, and known as the **supraorbital notch** or **foramen;** it transmits the supraorbital nerve, artery, and vein, and presents a small opening for a vein of the diploe. Sometimes, a second less marked notch is present, medial to the supraorbital, and known as the **frontal notch;** it transmits one of the divisions of the supraorbital nerve. The extremities of the supraorbital border are directed downward and form the **medial** and **zygomatic** (**lateral angular**) **processes.** The prominent zygomatic process articulates with the zygomatic bone and receives superiorly two well-marked lines which converge somewhat as they curve downward and forward across the bone. These are the **superior** and **inferior temporal lines,** continuous with the temporal lines on the partietal bone, the upper giving attachment to the temporal fascia and the lower to the temporal muscle. Behind the lines is a slight concavity which forms part of the floor of the temporal fossa (**temporal surface**) and gives origin to the *temporal* muscle. The medial processes articulate with the lacrimals and form the lateral limits of the **nasal notch,** bounded in front by a rough, semilunar surface which articulates with the upper ends of the nasal bones and the frontal (nasal) processes of the maxillæ.

FIG. 139.—THE FRONTAL BONE. (Inferior view.)



In the concavity of the notch lies the **nasal portion** of the frontal, which projects somewhat beneath the nasal bones and the nasal processes of the maxillæ. It is divisible into three parts; —a median **frontal** (nasal) **spine,** which descends in the nasal septum between the crest of the nasal bones in front and the vertical plate of the ethmoid behind, and, on the posterior aspect of the process, two grooved surfaces, one on either side of the median ridge from which the frontal (nasal) spine is continued. Each surface enters into the formation of the roof of the nasal fossa.

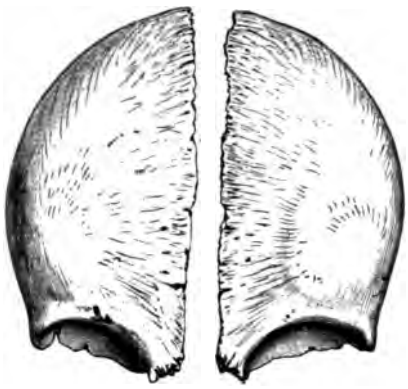
The **cerebral surface** presents in the middle line a vertical groove—the **sagittal sulcus**—which descends from the middle of the upper margin and lodges the superior sagittal (longitudinal) sinus. Below, the groove is succeeded by the **frontal crest,** which terminates near the lower margin at a small notch, converted into a foramen by articulation with the ethmoid.

The foramen is called the **foramen cecum,** and is generally closed below, but sometimes transmits a vein from the nasal fossæ to the superior sagittal (longitudinal) sinus. The frontal crest serves for the attachment of the anterior part of the falx cerebri. On each side of the middle line the bone is deeply concave, presenting depressions for the cerebral convolutions and numerous small furrows which, running medially from the lateral margin, lodge branches of the middle meningeal vessels. At the upper part of the surface, on either side of the frontal sulcus, are some depressions for Pacchionian bodies.

The **horizontal portion** consists of two somewhat triangular plates of bone called the **orbital plates,** which, separated from one another by the **ethmoidal notch** [incisura ethmoidalis], form the greater part of the roof of each orbit. When the bones are articulated, the notch is filled up by the cribriform plate of the ethmoid, and the half-cells on the upper surface of the lateral mass of the ethmoid are completed by the depressions or half-cells which occupy the irregular margins of the notch. Traversing these edges transversely are two grooves which com-

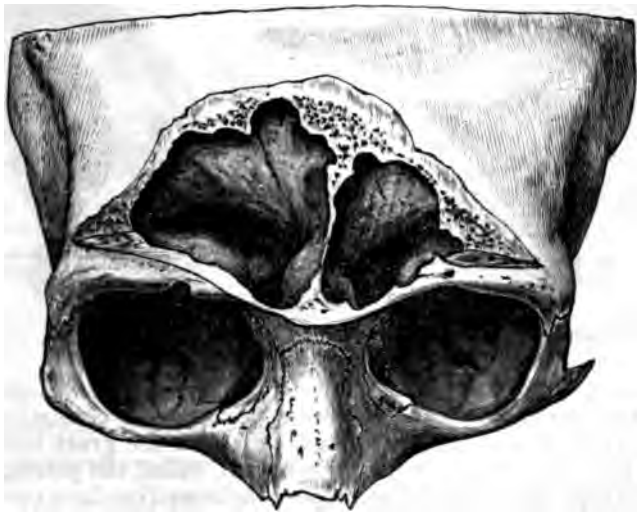
plete, with the ethmoid, the **anterior** and **posterior ethmoidal canals.** The anterior transmits the anterior ethmoidal nerve and vessels; the posterior transmits the posterior ethmoidal nerve and vessels, and both canals open on the medial wall of the orbit. Farther forward, on either side of the nasal spine, are the openings of the **frontal sinuses,** two irregular air-spaces (fig. 141) which extend within the bone for a variable distance and give rise to the superciliary arches. Each is lined by mucous membrane and communicates with the nasal fossa. (Cf. pp. 1235 and 1335.)

FIG. 140.—THE FRONTAL BONE AT BIRTH.



The **inferior surface** of each orbital plate, smooth and concave, presents immediately behind the lateral angular process the **lacrimal fossa,** for the lacrimal gland. Close to the medial angular process is a depression called the **trochlear fossa** [fovea trochlearis], which gives attachment to the cartilaginous pulley for the *superior oblique* muscle. The **superior surface** of each plate is convex and strongly marked by eminences and depressions for the convolutions on the orbital surface of the cerebrum.

FIG. 141.—UNUSUALLY LARGE FRONTAL SINUSES.



Borders.—The articular border of the frontal portion (**parietal margin**) forms a little more than a semicircle. It is thick, strongly serrated, and bevelled so as to overlap the parietal above and to be overlapped by the edge of that bone below. The border is continued inferiorly into a triangular rough surface on either side, which articulates with the great wing of the sphenoid. The posterior border of the orbital portion is thin and articulated with the lesser wing of the sphenoid.

Blood-supply.—The blood-vessels for the supply of the vertical portion are derived from the frontal and supraorbital arteries, which enter on the outer surface, and from the middle and small meningeal, which enter on the cerebral surface. The horizontal portion receives branches from the ethmoidal, and other branches of the ophthalmic, as well as from the meningeal.

Articulations.—The frontal articulates with the parietal, sphenoid, ethmoid, lacrimal, zygomatic (malar), maxilla, and nasal bones. Also, with the epipteric bones when present, and occasionally with the squamous portion of the temporal, and with the sphenoidal concha when it reaches the orbit.

Ossification.—The frontal is ossified from two nuclei deposited in the outer layer of the membranous wall of the cranium, in the situations of the future frontal eminences. These nuclei appear about the eighth week, and ossification spreads quickly through the membrane. At birth the bones are quite distinct, but subsequently they articulate with each other in the median line to form the metopic suture. In the majority of cases the suture is obliterated by osseous union, which commences about the second year, though in a few cases the bones remain distinct throughout life.

After the two halves of the bone have united, osseous material is deposited at the lower end of the metopic suture to form the frontal spine, which is one of the distinguishing features of the human frontal bone. The spine appears about the twelfth year, and soon consolidates with the frontal bone above. Accessory nuclei are sometimes seen between this bone and the lacrimal and may persist as Wormian ossicles.

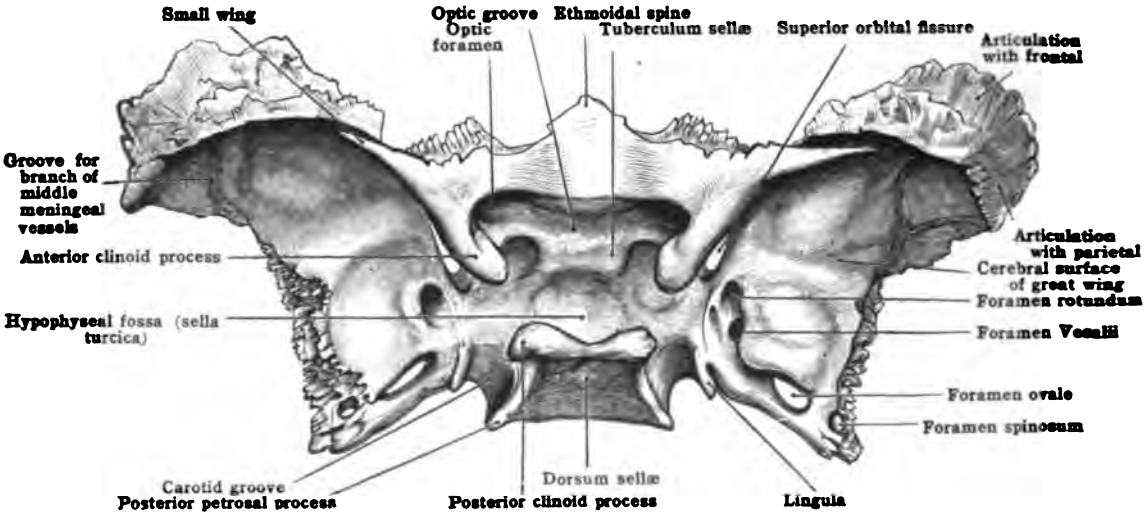
The frontal sinuses appear in the fetus but do not become conspicuous until the seventh year as prolongations upward from the middle nasal meatus (see p. 1238). They increase in size up to old age. As they grow they extend in three directions, viz., upward, laterally, and backward along the orbital roof. A bony septum, usually complete, separates the sinuses of the two sides, and they are larger in the male than in the female. The superciliary arches are not altogether reliable guides as to the size of the sinuses, since examples are seen in which the arches are low and the sinuses large.

Variations.—The frontal sinuses may be extraordinarily large (fig. 141), extending through the orbital plates, into the zygomatic processes and high up into the squama: or they may be quite small or absent entirely. Metopism occurs most frequently in the white races.

THE SPHENOID

The **sphenoid** [os sphenoidale] (figs. 142–145) is situated in the base of the skull and takes part in the formation of the floor of the anterior, middle, and

FIG. 142.—THE SPHENOID, FROM ABOVE.

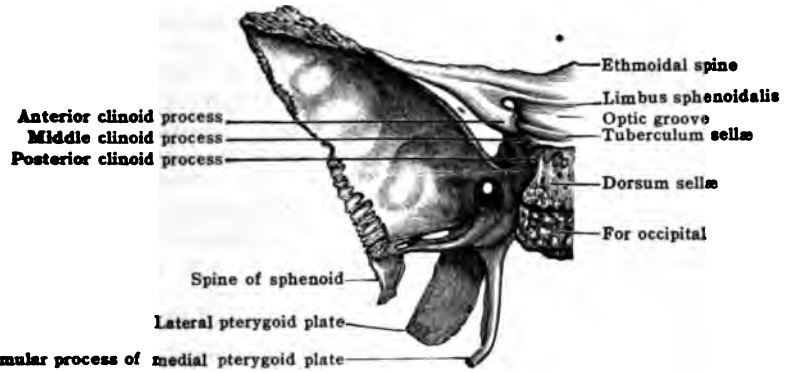


posterior cranial fossæ, of the temporal and nasal fossæ, and of the cavity of the orbit. It is very irregular in shape and is described as consisting of a central part or **body,** two pairs of lateral expansions called the **great** and **small wings,** and a pair of processes which project downward, called the **pterygoid processes.**

The **body,** irregularly cuboidal in shape, is hollowed out into two large cavities known as the **sphenoidal sinuses,** separated by a thin **sphenoidal septum** and opening in front by two large apertures into the nasal fossæ. The **superior surface** presents the following points of interest: In front is seen a prominent spine, the **ethmoidal spine,** which articulates with the hinder edge of the cribriform plate of the ethmoid. The surface behind this is smooth and frequently presents two longitudinal grooves, one on either side of the median line, for the olfactory bulbs; it is limited posteriorly by a ridge, the **limbus sphenoidalis,** which forms the anterior border of the narrow transverse **optic groove** [sulcus chiasmatis], above and behind which lies the optic commissure. The groove terminates on

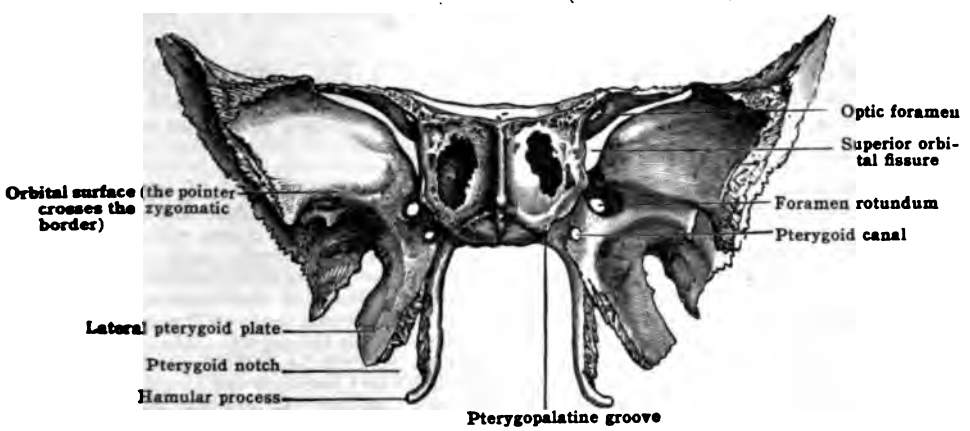
each side in the **optic foramen,** which perforates the root of the small wing and transmits the optic nerve and the ophthalmic artery. Behind the optic groove is the **tuberculum sellæ,** indicating the line of junction of the two parts of which the body is formed (pre- and postsphenoid) and presenting laterally the inconstant **middle clinoid processes;** still further back is a deep depression, the **hypophyseal fossa** [**sella turcica**], which lodges the hypophysis cerebri. The floor of the fossa presents numerous foramina for blood-vessels, and in the fetus the superior orifice of a narrow passage called the **craniopharyngeal canal.** The posterior boundary of the fossa is formed by a quadrilateral plate of bone, the **dorsum**

FIG. 143.—THE LEFT HALF OF THE SPHENOID. (Posterior view.)



sellæ (dorsum ephippii), the posterior surface of which is sloped in continuation with the basilar groove of the occipital bone. The superior angles of the plate are surmounted by the **posterior clinoid processes,** which give attachment to the tentorium cerebelli and the interclinoid ligaments. Below the clinoid process, on each side of the dorsum sellæ (sometimes at the suture between the sphenoid and apex of petrosal), a notch is seen, converted into a foramen by the dura mater, for the passage of the abducens nerve, and at the inferior angle the **posterior petrosal process,** which articulates with the apex of the petrous portion of the temporal bone, forming the medial boundary of the **foramen lacerum.** The dorsum sellæ

FIG. 144.—THE SPHENOID. (Anterior view.)



is slightly concave posteriorly (the clivus) and supports the pons Varoli and the basilar artery.

The inferior surface presents in the middle line a prominent ridge known as the **rostrum,** which is received into a deep depression between the alæ of the vomer. On each side is the **vaginal process** of the medial pterygoid plate, directed horizontally and medially, which, with the alæ of the vomer, covers the greater part of this surface. The remainder is rough and clothed by the mucous membrane of the roof of the pharynx.

The anterior surface is divided into two lateral halves by the **sphenoidal**

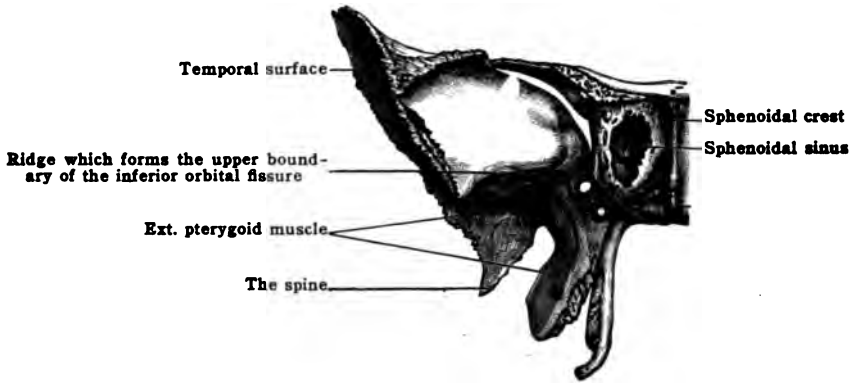
crest, a vertical ridge of bone continuous above with the ethmoidal spine, below with the rostrum, and articulating in front with the perpendicular plate of the ethmoid. The surface on each side presents a rough lateral margin for articulation with the lateral mass of the ethmoid and the orbital process of the palate bone. Elsewhere it is smooth, and enters into the formation of the roof of the nasal fossæ, presenting superiorly the irregular apertures of the sphenoidal sinuses.

The body is not much hollowed until after the sixth year, but from that time the sinuses increase in size as age advances. Except for the apertures just mentioned, they are closed below and in front by the two **sphenoidal conchæ** (turbinate bones) originally distinct, but in the adult usually incorporated with the sphenoid.

The **posterior surface** is united to the basioccipital, up to the twentieth year, by a disk of hyaline cartilage forming a synchondrosis, but afterward this becomes ossified and the two bones then form one piece.

The **lateral surface** of the body gives attachment to the two wings, and its fore part is free where it forms the medial boundary of the superior orbital fissure and the posterior part of the medial wall of the orbit. Above the line of attachment of the great wing is a broad groove which lodges the internal carotid artery and the cavernous sinus, called the **carotid groove.** It is deepest where it curves behind the root of the process, and this part is bounded along its lateral margin by a slender ridge of bone named the **lingula** (fig. 142), which projects backward in the angle between the body and the great wing.

FIG. 145.—RIGHT HALF OF SPHENOID. (Anterior view.)



The **small or orbital wings** [alæ parvæ] are two thin, triangular plates of bone extending nearly horizontally and laterally on a level with the front part of the upper surface of the body. Each arises medially by two processes or roots, the upper thin and flat, the lower thick and rounded.

Near the junction of the lower root with the body is a small tubercle for the attachment of the common tendon of three ocular muscles—viz., the *superior, medial,* and upper head of *lateral rectus*—and between the two roots is the **optic foramen.** The lateral extremity, slender and pointed, approaches the great wing, but, as a rule, does not actually touch it. The superior surface, smooth and slightly concave, forms the posterior part of the anterior fossa of the cranium. The inferior surface constitutes a portion of the roof of each orbit and overhangs the **superior orbital (or sphenoidal) fissure,** the elongated opening between the small and great wings. The anterior border is serrated for articulation with the orbital plate of the frontal, and the posterior border, smooth and rounded, is received into the Sylvian fissure of the cerebrum. Moreover, the posterior border forms the boundary between the anterior and middle cranial fossæ and is prolonged at its medial extremity to form the **anterior clinoid process.** Between the tuberculum sellæ and the anterior clinoid process is a semicircular notch which represents the termination of the carotid groove. It is sometimes converted into a foramen, the **caroticoclinoid foramen,** by a spicule of bone which bridges across from the anterior clinoid to the **middle clinoid process**; the latter is a small tubercle frequently seen on each side, in front of the hypophyseal fossa, and lateral to the tuberculum sellæ; the foramen transmits the internal carotid artery, and the spicule of bone which may complete the foramen is formed by ossification of the caroticoclinoid ligament.

The **great** or **temporal wings** [alæ magnæ], arising from the lateral surface of the body, extend laterally and then upward and forward. The posterior part is placed horizontally and projects backward into the angle between the squamous and petrous portions of the temporal bone. From the under aspect of its pointed

extremity the **spine,** which is grooved medially by the chorda tympani nerve (Lucas), projects downward. The spine serves for the attachment of the sphenomandibular ligament and a few fibers of the *tensor veli palatini*. Each wing presents four surfaces and four borders.

The **cerebral** or **superior surface** is smooth and concave. It enters into the formation of the middle cranial fossa, supports the temporal lobe of the cerebrum, and presents several foramina. At the anterior and medial part is the **foramen rotundum** for the second division of the fifth nerve, and behind and lateral to it, near the posterior margin of the great wing, is the large **foramen ovale,** transmitting the third division of the trigeminal nerve, the small meningeal artery, and an emissary vein from the cavernous sinus.

Behind and lateral to the foramen ovale is the small circular **foramen spinosum,** sometimes incomplete, for the passage of the middle meningeal vessels, and the recurrent branch of the third division of the trigeminal. Between the foramen ovale and the foramen rotundum is the inconstant **foramen Vesalii,** which transmits a small emissary vein from the cavernous sinus; and on the plate of bone, behind and medial to the foramen ovale (sphenopetrosal lamina), a minute canal is occasionally seen—the **canaliculus innominatus**—through which the small superficial petrosal nerve escapes from the skull. When the canaliculus is absent, the nerve passes through the foramen ovale.

The **anterior surface** looks medially and forward and consists of two divisions—a quadrilateral or **orbital** surface, which forms the chief part of the lateral wall of the orbit, and a smaller, inferior or **sphenomaxillary** surface, situated above the pterygoid process and perforated by the foramen rotundum; this inferior part forms the posterior wall of the pterygopalatine fossa.

The lateral or **squamozygomatic surface** is divided by a prominent **infratemporal ridge** into a superior portion, which forms part of the temporal fossa and affords attachment to the *temporal* muscle, and an inferior part, which looks downward into the zygomatic fossa and gives attachment to the *external pterygoid* muscle; the inferior part joins the lateral surface of the lateral pterygoid plate, and presents the inferior orifices of the foramen ovale, foramen spinosum, and foramen of Vesalius.

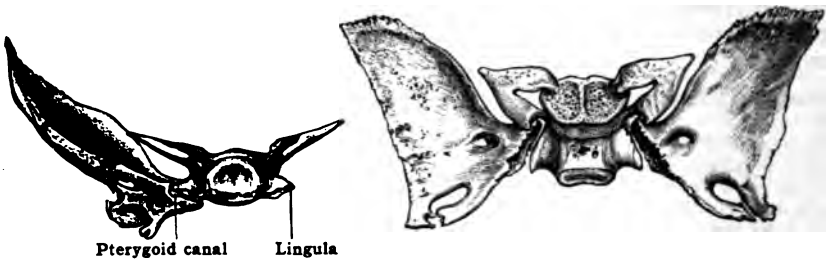
Borders of the great wing.—The **posterior border** extends from the body to the spine. By its lateral third it articulates with the petrous portion of the temporal bone, whilst the medial two-thirds form the anterior boundary of the foramen lacerum. The **squamosal border** is serrated behind and bevelled in front for articulation with the squamous portion of the temporal bone, whilst its upper extremity, or summit, is bevelled on its inner aspect, for the anterior inferior angle of the parietal. Immediately in front of the upper extremity is a rough, triangular, sutural area for the frontal, the sides of which are formed by the upper margins of the superior, anterior, and lateral surfaces respectively. The **zygomatic** or **anterior border** separates the orbital and temporal surfaces and articulates with the zygomatic, and by its lower angle, in many skulls, also with the maxilla. Below the anterior border is a short horizontal ridge, non-articular, which separates the sphenomaxillary and zygomatic surfaces. Above and medially, where the orbital and cerebral surfaces meet, is the sharp **medial border,** which forms the lower boundary of the **superior orbital fissure,** serving for the passage of the third, fourth, three branches of the first division of the trigeminal, and the abducens cranial nerves, the orbital branch of the middle meningeal artery, a recurrent branch from the lacrimal artery, some twigs from the cavernous plexus of the sympathetic, and one or two ophthalmic veins. Near the middle of the border is a small tubercle for the origin of the lower head of the *lateral rectus* muscle.

The **pterygoid processes** project downward from the junction of the body and the great wings. Each consists of two plates, one shorter and broader, the **lateral pterygoid plate** [lamina lateralis], the other longer and narrower, the **medial pterygoid plate** [lamina medialis]. They are united in front, but diverge behind so as to enclose between them the **pterygoid fossa** in which lie the *internal pterygoid* and *tensor veli palatini* muscles. The lateral pterygoid plate is turned a little laterally and by its lateral surface, which looks into the infratemporal fossa, affords origin to the *external pterygoid* muscle, and from its medial surface the *internal pterygoid* takes origin.

In front, the two plates are joined above, but diverge below, leaving a gap—the **pterygoid notch**—occupied, in the articulated skull, by the pyramidal process of the palate. Superiorly, they form a triangular surface which looks into the pterygopalatine fossa and presents the anterior orifice of the pterygoid canal. The anterior border of the medial pterygoid plate articulates with the posterior border of the vertical plate of the palate. The medial pterygoid plate is prolonged below into a slender, hook-like or **hamular process** [hamulus pterygoideus], smooth on the under aspect for the tendon of the *tensor veli palatini*, which plays round it. Superiorly, the medial plate extends medially on the under surface of the body, forming the

vaginal process, which articulates with the ala of the vomer and the sphenoidal process of the palate. The vaginal process presents, on the under surface, a small groove which, with the sphenoidal process of the palate, forms the **pharyngeal canal** for the transmission of branches of the sphenopalatine vessels and ganglion. The medial surface of the medial pterygoid plate forms part of the lateral boundary of the nasal fossa, and the lateral surface, the medial boundary of the pterygoid fossa. The posterior border presents superiorly a well-marked prominence, the **pterygoid tubercle,** above and to the lateral side of which is the posterior orifice of the **pterygoid canal.** The latter pierces the bone in the sagittal direction at the root of the medial

FIG. 146.—THE SPHENOID AT BIRTH.



pterygoid plate and transmits the Vidian vessels and nerve. Some distance below the tubercle is a projection, called the **processus tubarius,** which supports the cartilage of the tuba auditiva (Eustachian tube). From the lower third of the posterior border and from the hamular process, the *superior constrictor* of the pharynx takes origin, and from the depression known as the **scaphoid fossa,** situated in the upper part of the recess between the two pterygoid plates, the *tensor veli palatini* arises.

Blood-supply.—The sphenoid is supplied by branches of the middle and small meningeal arteries, the deep temporal and other branches of the internal maxillary artery—viz., the Vidian and sphenopalatine. The body of the bone also receives twigs from the internal carotid.

FIG. 147.—THE JUGUM SPHENOIDALE.

Articulations.—The sphenoid articulates with all the bones of the cranium—viz., occipital, parietal, frontal, ethmoid, temporal, and sphenoidal conchæ; also with the palate, vomer, zygomatic, epipteric bone when present, and occasionally with the maxilla.

Ossification.—The sphenoid is divided, up to the seventh or eighth month of intrauterine life, into an anterior or **presphenoid** portion, including the part of the body in front of the tuberculum sellæ and the small wings, and a **postsphenoid** portion, the part behind the tuberculum

FIG. 148.—THE INFERIOR SURFACE OF PRESPHENOID AT THE SIXTH YEAR.

sellæ including the hypophyseal fossa and the great wings. The two portions of the body join together before birth, but in many animals the division is persistent throughout life.

The presphenoid portion ossifies in cartilage from four centers, one of which gives rise to each lesser wing (**orbitosphenoid**) and a pair to the body of the presphenoid. In the formation of the postsphenoidal portion both cartilage and membrane bone participate, the pterygoid plates being formed in membrane, while the rest of the portion, together with the hamular process, ossifies from cartilage. (Fawcett.). At about the eighth week a center appears at the base of each greater wing (**alisphenoid**), and at about the same time a pair of centers appear in the body (**basisphenoid**) and later one in each lingula (**sphenotic**). The medial pterygoid

plates are formed from membrane investing the cartilage, in which a center appears for the hamulus. The lateral plate is formed in membrane and a considerable part of the greater wing is also membranous in origin (see epipteric bone).

At birth (fig. 146) the bone consists of three pieces. The median piece includes the basisphenoid and linguläe, conjoined with the presphenoid, carrying the orbitosphenoids. The two lateral pieces are the alisphenoids, carrying the medial pterygoid plates. The dorsum sellæ is cartilaginous. A canal, known as the **craniopharyngeal canal**, extends into the body from the sella turcica and sometimes reaches its under surface. It contains a process of dura mater, and represents the remains of the canal in the base of the cranium, through which the hypophyseal stalk extended upward to the hypophysis.

The great wings are joined to the linguläe by cartilage, but in the course of the first year bony union takes place. About the same time the orbitosphenoids meet and fuse in the midline to form the **jugum sphenoidale** (fig. 147), which thus excludes the anterior part of the presphenoid from the cranial cavity. For some years the body of the presphenoid is broad and rounded inferiorly (fig. 148). The posterior clinoid processes chondrify separately, a fact which throws some light on the occasional absence of these processes.

THE SPHENOIDAL CONCHÆ

The **sphenoidal conchæ (or turbinate bones;** bones of Bertin) (figs. 149, 150) may be obtained as distinct ossicles about the fifth year, and resemble in shape two hollow cones flattened in three planes. At this date each is wedged in between the under surface of the presphenoid and the orbital and sphenoidal processes of the palate bone, with the apex of the cone directed backward as far as the vaginal process of the medial pterygoid plate. Of its three surfaces, the lateral is in relation with the pterygopalatine fossa, and occasionally extends upward between the sphenoid and the lamina papyracea of the ethmoid, to appear on the medial wall of the orbit (fig. 168). The inferior surface forms the upper boundary of the sphenopalatine foramen and enters into formation of the posterior part of the roof of the nasal fossa. The superior surface lies flattened against the under surface of the presphenoid, while the base of the cone is in contact with the lateral mass of the ethmoid.

FIG. 149.—THE SPHENOIDAL CONCHA AT THE SIXTH YEAR.

FIG. 150.—THE SPHENOIDAL CONCHÆ FROM AN OLD SKULL.

The deposits of earthy matter from which the sphenoidal conchæ are formed appear at the fifth month. At birth each forms a small triangular lamina in the perichondrium of the ethmovomerine plate near its junction with the presphenoid, and partially encloses a small recess from the mucous membrane of the nose, which becomes the sphenoidal sinus. By the third year the bone has surrounded the sinus, forming an osseous capsule, conical in shape, the circular orifice which represents the base becoming the sphenoidal foramen. As the cavity enlarges the medial wall is absorbed, and the medial wall of the sinus is then formed by the presphenoid. The bones are subsequently ankylosed in many skulls with the ethmoid, whence they are often regarded as parts of that bone. More frequently they fuse with the presphenoid, and less frequently with the palate bones. After the twelfth year they can rarely be separated from the skull without damage. In many disarticulated skulls they are so broken up that a portion is found on the sphenoid, fragments on the palate bones, and the remainder attached to the ethmoid. Sometimes, even in old skulls, they are represented by a very thin triangular plate on each side of the rostrum of the sphenoid (fig. 150).

Variations.—The variability of the middle clinoid process has been mentioned. The superior part of the dorsum sellæ may consist of a separate bar of bone, or may be connected with the apex of the petrous bone. Foramina brought about by bridges of bone between the posterior margin of the greater wing and the spine (pterygospinous, transmitting the nerve of the internal pterygoid) and between the process and the great wing (crotaphitico-buccinatorius, for the lesser division of the mandibular nerve) are rarely observed. Persistence of the craniopharyngeal canal is sometimes seen.

THE EPIPTERIC AND WORMIAN BONES

The **epipterics** are scale-like bones which occupy anterolateral fontanelles. Each epipteric bone is wedged between the squamozygomatic portion of the temporal, frontal, great wing of sphenoid, and the parietal, and is present in most skulls between the second and fifteenth year. After that date it may persist as a separate ossicle, or unite with the sphenoid, the frontal, or the squamozygomatic. The epipteric bone is preformed in membrane, and appears as a series of bony granules in the course of the first year.

The **Wormian or sutural bones** (ossa suturarum) are small, irregularly shaped ossicles, often found in the sutures of the cranium, especially those in relation with the parietal bones. They sometimes occur in great numbers; as many as a hundred have been counted in one skull. They are rarely present in the sutures of the face.

THE TEMPORAL BONE

The **temporal bone** [os temporale], situated at the side and the base of the cranium, contains the organ of hearing and articulates with the lower jaw. It is

FIG. 151.—THE TEMPORAL BONE AT BIRTH. (Constituent parts.)

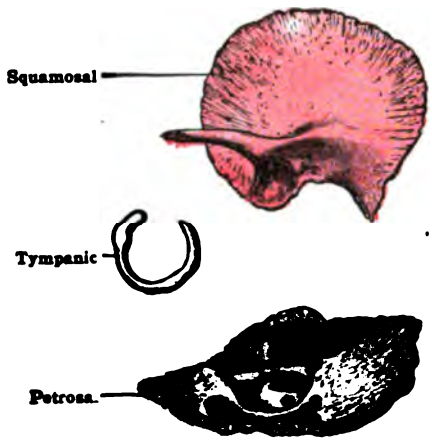


FIG. 152.—TEMPORAL BONE AT BIRTH. (Inner view.)

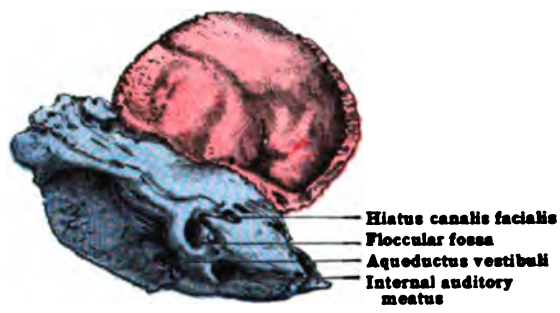
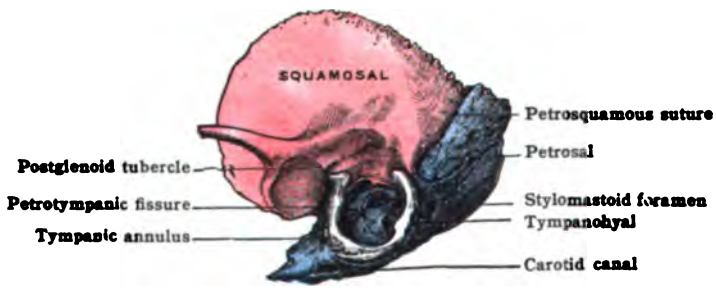


usually divided into three parts—viz., the **squamous portion,** forming the anterior and superior part of the bone, thin and expanded and prolonged externally into the zygomatic process; the **mastoid portion,** the thick conical posterior part, behind the external aperture of the ear; and a pyramidal projection named the **petrous portion,** situated in a plane below and to the medial side of the two parts already mentioned, and forming part of the base of the skull.

When it is considered in reference to its mode of development, the temporal bone is found to be built up of three parts (figs. 151–153), which, however, do not altogether correspond to the arbitrary divisions of the adult bone. The three parts are named **squamosal, petrosal,** and **tympanic,** and a knowledge of their arrangement in the early stages of growth greatly facilitates the study of the fully formed bone.

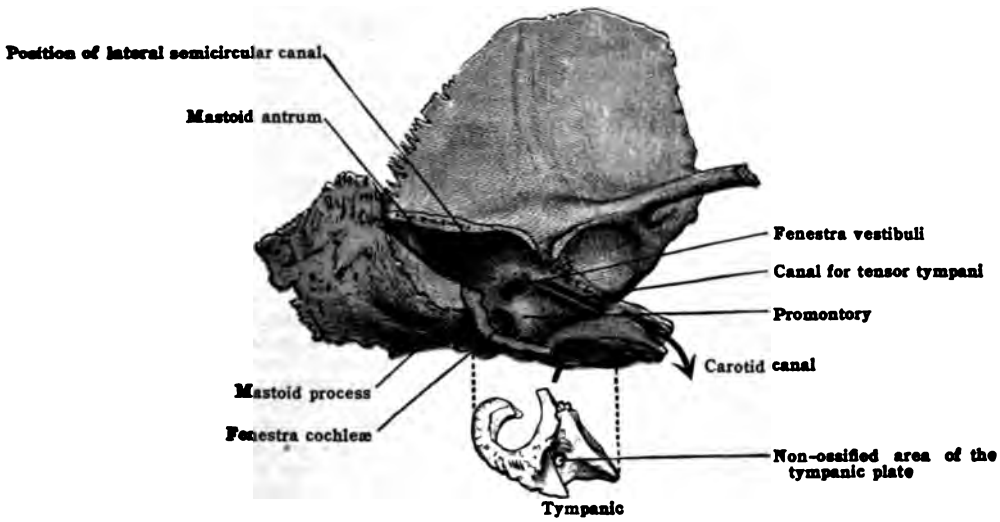
FIG. 153.—THE TEMPORAL BONE AT BIRTH. (Outer view,)



The more important division of the temporal bone is the **petrous portion.** It is pyramidal in shape, and contains the essential part of the organ of hearing, around which it is developed as a cartilaginous capsule. This is known as the **periotic capsule** or **petrosal** element, and its **base** abuts on the outer aspect of the cranium, where it forms a large part of the so-called mastoid portion of the temporal bone. Besides containing the internal ear, it bears on its cranial side a foramen (internal auditory meatus) for the facial and auditory nerves, and on its outer side two openings—the fenestra vestibuli and fenestra cochleæ (fig. 154). The **squamosal** is a superadded element and is formed as a membrane bone in the lateral wall of the cranium. It is especially developed in man in consequence of

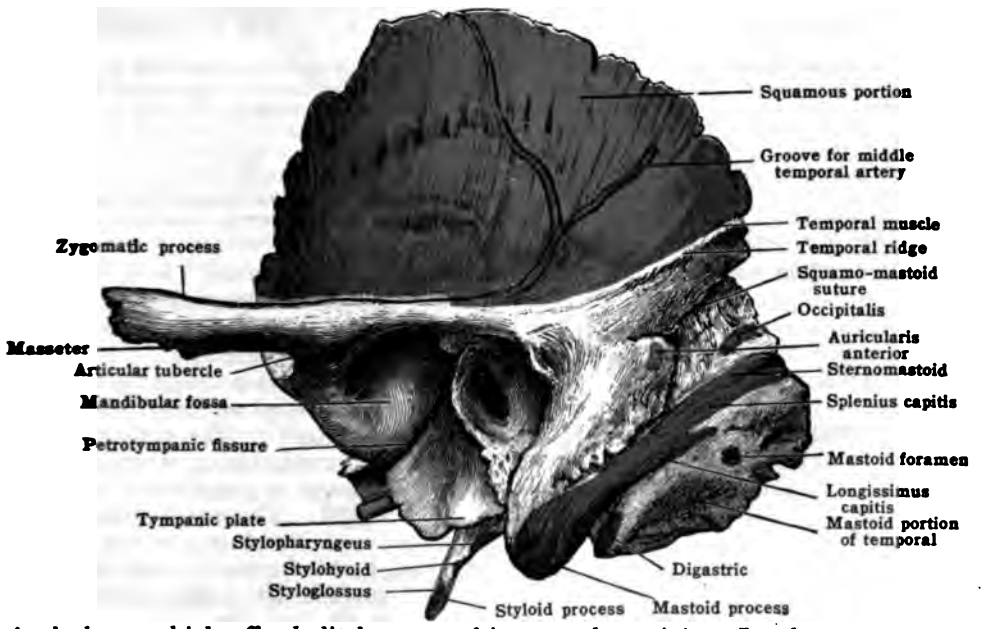
the large size of the brain, and forms the squamous division of the adult bone, and by a triangular shaped process which is prolonged behind the aperture of the ear it also contributes to the formation of the mastoid portion. It is obvious, therefore, that the mastoid is not an independent element, but belongs in part to the petrous,

FIG. 154.—RIGHT TEMPORAL BONE AT ABOUT SIX YEARS.
The tympanic plate has been separated and drawn below. A portion of the postauditory process of the squamosal has been removed to show the mastoid antrum.



and in part to the squamous. The **tympanic** portion, also superadded, is a ring of bone developed in connection with the external auditory meatus, and eventually forms a plate constituting part of the bony wall of this passage. These three parts are easily separable at birth, but eventually become firmly united to form a

FIG. 155.—THE LEFT TEMPORAL BONE. (Outer view.)



single bone which affords little trace of its complex origin. Lastly a process of bone, developed in the second visceral arch, coalesces with the under surface of the temporal bone and forms the **styloid process.**

The **squamous portion** [squama temporalis] is flat, scale-like, thin, and translucent. It is attached almost at right angles to the petrous portion, forms part

of the side wall of the skull and is limited above by an uneven border which describes about two-thirds of a circle. The *outer surface* is smooth, slightly convex near the middle, and forms part of the temporal fossa. Above the external auditory meatus it presents a nearly vertical groove for the middle temporal artery. Connected with its lower part is a narrow projecting bar of bone known as the **zygomatic process.** At its base the process is broad, directed laterally, and flattened from above downward. It soon, however, becomes twisted on itself and runs forward, almost parallel with the squamous portion. This part is much narrower and compressed laterally so as to present medial and lateral surfaces with upper and lower margins. The lateral surface is subcutaneous; the medial looks toward the temporal fossa and gives origin to the *masseter* muscle. The lower border is concave and rough for fibers of the same muscle, whilst the upper border, thin and prolonged further forward than the lower, receives the temporal fascia. The extremity of the process is serrated for articulation with the zygomatic bone. At its base the zygomatic process presents three roots—anterior, middle, and posterior.

The *anterior root* continuous with the lower border, is short, broad, convex, and directed medially to terminate in the **articular tubercle,** which is covered with cartilage in the recent state, for articulation with the condyle of the lower jaw. The *middle root,* sometimes very prominent, forms the **postglenoid process.** It separates the articular portion of the mandibular fossa from the external auditory meatus and is situated immediately in front of the **petrotympanic (Glaserian)** fissure. The *posterior root,* prolonged from the upper border, is strongly marked and extends backward as a ridge above the external auditory meatus. It is called the **temporal ridge** (supramastoid crest), and marks the arbitrary line of division between the squamous and mastoid portions of the adult bone. It forms part of the posterior boundary of the temporal fossa, from which, as well as from the ridge, fibers of the *temporal* muscle arise. Where the anterior root joins the zygomatic process is a slight tubercle—the **preglenoid tubercle**—for the attachment of the temporomandibular ligament, and between the anterior and middle roots is a deep oval depression, forming the part of the mandibular fossa for the condyle of the lower jaw. The **mandibular fossa** is a considerable hollow, bounded in front by the articular tubercle and behind by the tympanic plate which separates it from the external auditory meatus. It is divided into two parts by a narrow slit—the **petrotympanic (Glaserian) fissure.** The anterior part [facies articularis], which belongs to the squamous portion, is articular, and, like the articular tubercle, is coated with cartilage. The posterior part, formed by the tympanic plate, is non-articular and lodges a lobe of the parotid gland. Immediately in front of the articular tubercle is a small triangular surface which enters into the formation of the roof of the zygomatic fossa.

The inner or *cerebral surface* of the squamous portion is marked by furrows for the convolutions of the brain and grooves for the middle meningeal vessels.

At the upper part of the surface the inner table is deficient and the outer table is prolonged some distance upward, forming a thin scale, with the bevelled surface looking inward to overlap the corresponding edge of the parietal. Anteriorly the border is thicker, serrated, and slightly bevelled on the outer side for articulation with the posterior border of the great wing of the sphenoid. Posteriorly it joins the rough serrated margin of the mastoid portion to form the parietal notch. The line separating the squamous from the petrous portion is indicated at the lower part of the inner surface by a narrow cleft, the internal **petrosquamous suture,** the appearance of which varies in different bones according to the degree of persistence of the original line of division.

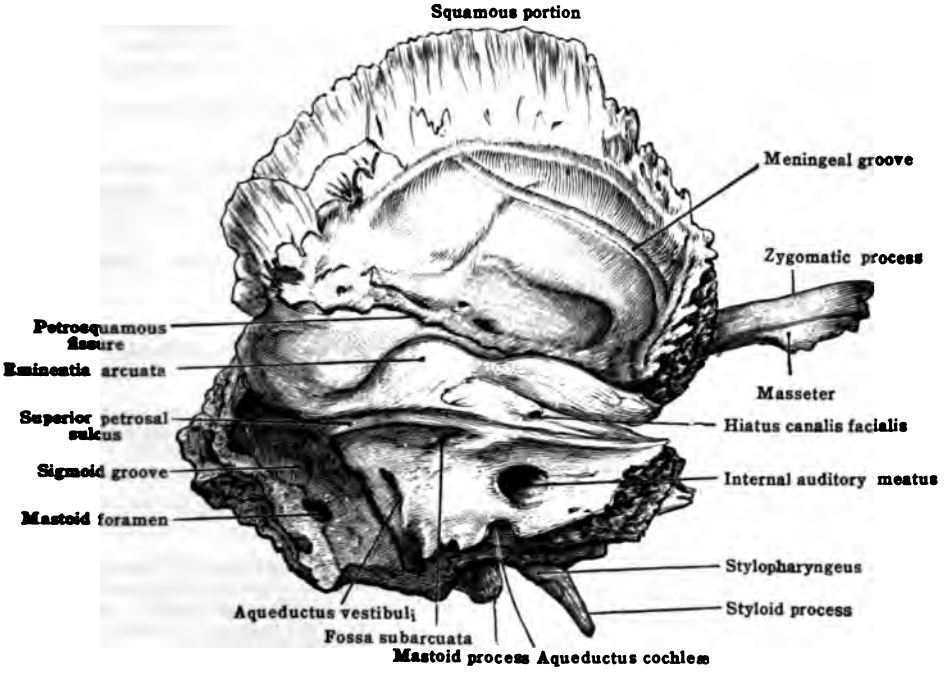
The **mastoid portion** [pars mastoidea] is rough and convex. It is bounded above by the temporal ridge and the parietomastoid suture; in front, by the external auditory meatus and the **tympanomastoid** fissure; and behind, by the suture between the mastoid and occipital. As already pointed out, it is formed by the squamous portion in front and by the base of the petrosal behind, the line of junction of the two component parts being indicated on the outer surface by the **external petrosquamous suture** (squamomastoid). The appearance of the suture varies, being in some bones scarcely distinguishable, in others, a series of irregular depressions, whilst occasionally it is present as a well-marked fissure (fig. 155) directed obliquely downward and forward. The mastoid portion is prolonged downward behind the external acoustic meatus into a nipple-shaped projection, the **mastoid process,** the tip of which points forward as well as downward. The process is marked, on its medial surface, by a deep groove, the **mastoid notch** (diagastric fossa), for the origin of the *digastric* muscle, and again medially by the **occipital groove** for the occipital artery.

The *outer surface* is perforated by numerous foramina, one, of large size, being usually situated near the posterior border and called the **mastoid foramen.** It transmits a vein to the transverse (lateral) sinus and the mastoid branch of the occipital artery. The **mastoid portion**

gives attachment externally to the *auricularis posterior* (*retrahens aurem*) and *occipitalis*, and, along with the mastoid process, to the *sternomastoid*, *splenius capitis*, and *longissimus capitis* (*trachelomastoid*). Projecting from the posterosuperior margin of the external auditory meatus there is frequently a small tubercle—the **suprameatal spine**—behind which the surface is depressed to form the **mastoid (suprameatal) fossa.**

The *inner surface* of the mastoid portion presents a deep curved **sigmoid groove,** in which is lodged a part of the transverse sinus; the mastoid foramen is seen opening into the groove. The interior of the mastoid portion, in the adult, is usually occupied by cavities, of which some are lined by mucous membrane and known as the **mastoid air-cells** (fig. 160). These open into a small chamber—the **mastoid antrum**—which communicates with the upper part of the tympanic cavity. The mastoid cells are arranged in three groups: (1) anterosuperior, (2) middle, and (3) apical. The apical cells, situated at the apex of the mastoid process, are small and usually contain marrow.

FIG. 156.—THE LEFT TEMPORAL BONE. (Seen from the inner side and above.)



Borders.—The superior border is broad and rough for articulation with the hinder part of the inferior border of the parietal bone. The posterior border, very uneven and serrated, articulates with the inferior border of the occipital bone, extending from the lateral angle to the jugular process.

The **petrous portion** [pars petrosa; pyramis] is a pyramid of very dense bone presenting a base, an apex, three (or four) surfaces, and three (or four) borders or angles. Two sides of the pyramid look into the cranial cavity, the posterior into the posterior cranial fossa, and the anterior into the middle cranial fossa. The inferior surface appears on the under surface of the cranium. The medial and posterior walls of the tympanic cavity in the temporal bone are sometimes described as a fourth side of the pyramid. The base forms a part of the lateral surface of the cranium; the apex is placed medially.

The **posterior surface** of the pyramid is triangular in form, bounded above by the superior angle and below by the posterior angle. Near the middle is an obliquely directed foramen [porus acusticus internus] leading into a short canal—the **internal auditory meatus**—at the bottom of which is a plate of bone, pierced by numerous foramina, and known as the **lamina cribrosa.** The canal transmits the facial, auditory and glossopalatine (pars intermedia) nerves, and the internal auditory artery. The bottom of the internal auditory meatus can be most advantageously studied in a temporal bone of the newborn, when the canal is shallow and the openings relatively wide.

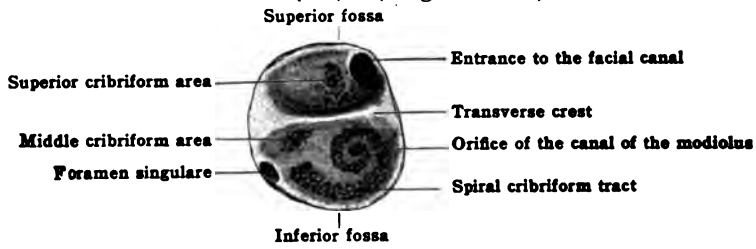
The fundus of the meatus (fig. 157) is divided by a transverse ridge of bone, the *transverse crest*, into a superior and inferior fossa. Of these, the superior is the smaller, and presents anteriorly the beginning of the **facial canal** (aqueduct of Fallopius), which transmits the facial nerve. The rest of the surface above the crest is dotted with small foramina (the superior vestibular area) which transmit nerve-twigs to the recessus ellipticus (fovea hemielliptica) and the ampullæ of the superior and lateral semicircular canals (vestibular division of the auditory nerve). Below the crest there are two depressions and an opening. Of these, an anterior curled tract (the spiral cribriform tract) with a central foramen (foramen centrale **cochleare**) marks the base of the cochlea; the central foramen indicates the orifice of the canal of the modiolus, and the smaller foramina transmit the cochlear twigs of the auditory nerve. The posterior opening (foramen singulare) is for the nerve to the ampulla of the posterior semicircular canal. The middle depression (inferior vestibular area) is dotted with minute foramina for the nerve-twigs to the saccule, which is lodged in the recessus sphæricus (fovea hemisphærica). The inferior fossa is subdivided by a low vertical crest. The fossa in front of the crest is the *fossula cochlearis*, and the recess behind it is the *fossula vestibularis*.

Behind and lateral to the meatus is a narrow fissure, the **aqueductus vestibuli**, covered by a scale of bone. In the fissure lies the ductus endolymphaticus, a small arteriole and venule, and a process of connective tissue which unites the dura mater to the sheath of the internal ear. Occasionally a bristle can be passed through it into the vestibule. Near the upper margin, and opposite a point about midway between the meatus and the aqueduct of the vestibule, is an irregular opening, the **fossa subarcuata**, the remains of the **floccular fossa**, a conspicuous depression in the fetal bone. In the adult the depression usually lodges a process of dura mater and transmits a small vein, though in some bones it is almost obliterated.

The **anterior surface** of the pyramid, sloping downward and forward, forms the back part of the floor of the middle fossa of the cranium.

Upon the anterior surface of the pyramid will be found the following points of interest, proceeding from the apex toward the base of the pyramid:—(1) a shallow **trigeminal impression** for the semilunar (Gasserian) ganglion of the trigeminal nerve; (2) two small grooves

FIG. 157.—THE FORAMINA IN THE FUNDUS OF THE LEFT INTERNAL AUDITORY MEATUS OF A CHILD AT BIRTH (×4). (Diagrammatic.)



running backward and laterally toward two small foramina overhung by a thin osseous lip, the larger and medial of which, known as the **hiatus canalis facialis**, transmits the great superficial petrosal nerve and the petrosal branch of the middle meningeal artery, whilst the smaller and lateral foramen is for the small superficial petrosal nerve; (3) behind and lateral to these is an eminence—the **eminentia arcuata**—best seen in young bones, corresponding to the superior semicircular canal in the interior; (4) still more laterally is a thin transulcent plate of bone, roofing in the tympanic cavity, and named the **tegmen tympani**.

The **inferior** or **basilar surface** of the pyramid is very irregular and presents numerous important structures, including the carotid canal, jugular fossa, stylomastoid process and foramen (fig. 158).

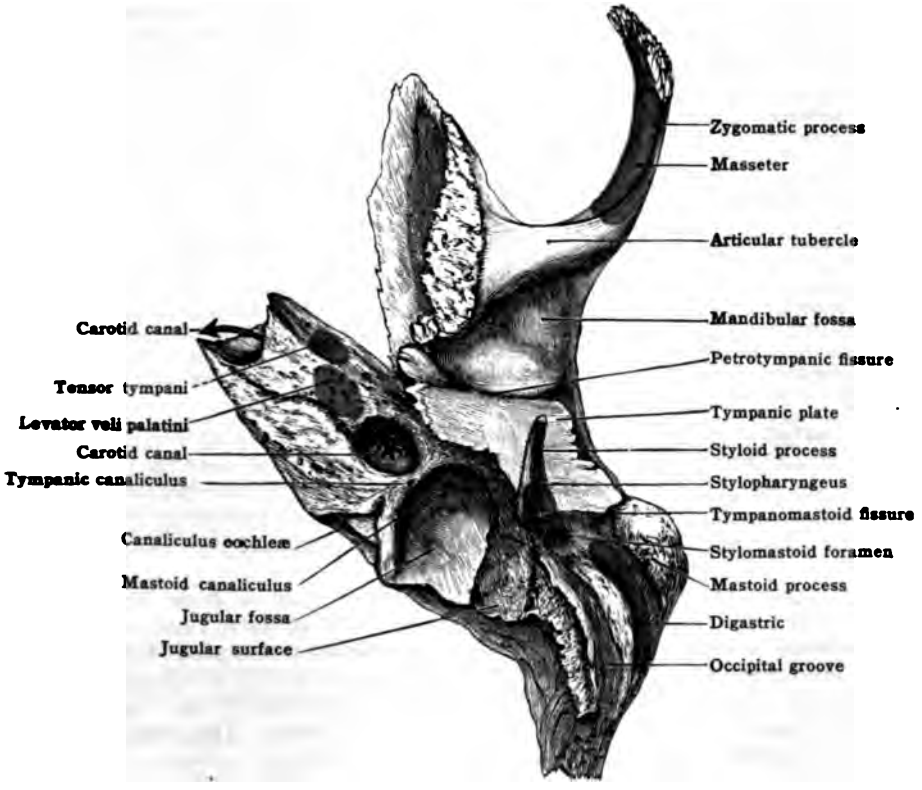
At the apex the basilar surface is rough, quadrilateral, and gives attachment to the *tensor tympani*, *levator veli palatini*, and the pharyngeal aponeurosis. Behind this is seen the large circular orifice of the **carotid canal** for the transmission of the carotid artery and a plexus of sympathetic nerves. On the same level, near the posterior border, is a small three-sided depression, the **canaliculus cochleæ**, which transmits a small vein from the cochlea to the internal jugular. Behind these two openings is the large elliptical **jugular fossa** which forms the anterior and lateral part of the bony wall of the jugular foramen, in which is contained a dilation on the commencement of the internal jugular vein; on the lateral wall of the jugular fossa is a minute foramen, the **mastoid canaliculus**, for the entrance of the auricular branch of the vagus (Arnold's nerve) into the interior of the bone. Between the inferior aperture of the carotid canal and the jugular fossa is the sharp **carotid ridge**, on which is a small depression, the **fossula petrosa**, and at the bottom of this a minute opening, the **tympanic canaliculus**, for Jacobson's nerve (tympanic branch of the glossopharyngeal) and the small tympanic branch from the ascending pharyngeal artery.

Behind the jugular fossa is the rough **jugular surface** for articulation with the **jugular process** of the occipital bone, on the lateral side of which is the prominent cylindrical spur known as the **styloid process** with the **stylomastoid** foramen at its base. This foramen, which is the external orifice of the facial canal, transmits the facial nerve, the stylomastoid artery and sometimes the auricular branch of the vagus. Running backward from the foramen are the **mastoid** and **occipital grooves** already described.

The **tympanic surface** of the pyramid, forming the medial and posterior **walls** [paries labyrinthica] of the tympanic cavity, is shown by removing the tympanic plate (fig. 154).

The tympanic surface presents near the base an excavation, known as the tympanic or mastoid antrum, covered by the triangular part of the squamous below and behind the temporal line. **The opening of the antrum into the tympanic cavity is situated immediately above the fenestra vestibuli,** an oval-shaped opening which receives the base of the stapes; below the **fenestra vestibuli is a convex projection or promontory,** marked by grooves for the tympanic **plexus of nerves and containing the commencement of the first turn of the cochlea. In the lower and posterior part of the promontory is the fenestra cochleæ,** closed in the recent state **by the secondary membrane** of the tympanum. Running downward and forward from the **front of the fenestra vestibuli is a thin curved plate of bone [septum canalis musculotubarii], separating two grooves converted into canals by the overlying tympanic plate. The lower is the groove for the Eustachian tube** [semicanalis tubæ auditivæ], the communicating passage **between the tympanum and the pharynx; the upper is the semicanalis m. tensoris tympani, and the lateral apertures of both canals are visible in the retiring angle, between thep etrous and squamous portions of the bone.**

FIG. 158.—THE LEFT TEMPORAL BONE. (Inferior view.)



The **apex** of the pyramid is truncated and presents the medial opening of the carotid canal. The latter commences on the inferior surface, and, after ascending for a short distance, turns forward and medially, tunnelling the bone as far as the apex, and finally opens into the upper part of the **foramen lacerum** formed between the temporal and sphenoid bones.

One or two minute openings in the wall of the carotid canal, known as the caroticotympanic canaliculi, transmit communicating twigs between the carotid and tympanic plexuses. The upper part of the apex is joined by cartilage to the posterior petrosal process of the sphenoid.

The **base** is the part of the pyramid which appears laterally at the side of the cranium and takes part in the formation of the mastoid portion. It is described above with that division of the bone.

Angles.—The superior angle (border) of the pyramid is the longest and separates the posterior from the anterior surface. It is grooved for the superior petrosal sinus, gives attachment to the tentorium cerebelli, and presents near the apex a semilunar notch upon which the trigeminal nerve lies. Near its medial end there is often a small projection for the attachment

of the petrosphenoidal ligament, which arches over the inferior petrosal sinus and the abducens nerve. The **posterior angle** separates the posterior from the inferior surface, and when articulated with the occipital, forms the groove for the inferior petrosal sinus, and completes the **jugular foramen** formed by the temporal in front and on the lateral side, and by the occipital behind and on the medial side. The **jugular foramen** is divisible into three compartments: an anterior for the inferior petrosal sinus, a middle for the glossopharyngeal, vagus and accessory nerves, and a posterior for the internal jugular vein and some meningeal branches from the occipital and ascending pharyngeal arteries. The **anterior angle** is the shortest and consists of two parts, one joined to the squamous in the petrosquamous suture and a small free part internally which articulates with the sphenoid. A fourth or inferior border may be distinguished which runs along the line of junction with the tympanic plate and is continued on to the rough area below the apex.

The **tympanic portion** [pars tympanica] is quadrilateral in form, hollowed out above and behind, and nearly flat, or somewhat concave, in front and below. It forms the whole of the anterior and inferior walls, and part of the posterior wall, of the external auditory meatus, and is separated behind from the mastoid process by the **tympanomastoid** (auricular) fissure through which the auricular branch of the vagus in some cases leaves the bone.

In front it is separated by the **petrotympanic** fissure from the squamous portion. Through the petrotympanic fissure the tympanic branch of the internal maxillary artery passes. The processus gracilis of the malleus is lodged within it, and a narrow subdivision at its inner end, known as the **canal of Huguier**, transmits the chorda tympani nerve. The tympanic part presents for examination two surfaces and four borders.

The **anteroinferior surface**, directed downward and forward, lodges part of the parotid gland. Near the middle it is usually very thin, and sometimes presents a small foramen (the foramen of Huschke), which represents a non-ossified portion of the plate. The **posterosuperior surface** looks into the external auditory meatus and tympanic cavity, and at its medial end is a narrow groove, the **sulcus tympanicus**, deficient above, which receives the membrana tympani.

The **lateral border** is rough and everted, forming the **external auditory process** for the attachment of the cartilage of the pinna; the **superior border** enters into the formation of the petrotympanic fissure; the **inferior border** is uneven and prolonged into the **vaginal process** [vagina processus styloidei] which surrounds the lateral aspect of the base of the styloid process and gives attachment to the front part of the fascial sheath of the carotid vessels; the **medial border**, short and irregular, lies immediately below and to the lateral side of the opening of the Eustachian tube, and becomes continuous with the rough quadrilateral area on the inferior aspect of the apex.

The **external auditory meatus** is formed partly by the tympanic and partly by the squamous portion. It is an elliptical bony tube leading into the tympanum, the extrance of which is bounded throughout the greater part of its circumference by the external auditory process of the tympanic plate. Above, the entrance is limited by the temporal ridge or posterior root of the zygomatic process.

The **styloid process** is a slender, cylindrical spur of bone fused with the inferior aspect of the temporal immediately in front of the stylomastoid foramen. It consists of two parts, **basal** (tympanohyal), which in the adult lies under cover of the tympanic plate, and a **projecting** portion (stylohyal), which varies in length from five to fifty millimeters. When short, it is hidden by the vaginal process, but, on the other hand, it may reach to the hyoid bone. The projecting portion gives attachment to three muscles and two ligaments.

The *stylopharyngeus* arises near the base from the medial and slightly from the posterior aspect; the *stylohyoid* from the posterior and lateral aspect near the middle; and the *styloglossus* from the front near the tip. The tip is continuous with the stylohyoid ligament, which runs down to the lesser cornu of the hyoid bone. A band of fibrous tissue—the **stylomandibular** ligament—passes from the process below the origin of the styloglossus to the **angle of the lower jaw.**

Blood-supply.—The arteries supplying the temporal bone are derived from various sources. The chief are:

Stylomastoid from posterior auricular: it enters the stylomastoid foramen.

Anterior tympanic from internal maxillary: it passes through the petrotympanic fissure.

Superficial petrosal from middle meningeal: transmitted by the hiatus canalis facialis.

Caroticotympanic from internal carotid whilst in the carotid canal.

Internal auditory from the basilar: it enters the internal auditory meatus, and is distributed to the cochlea and vestibule.

Other less important twigs are furnished by the middle meningeal, the meningeal branches of the occipital, and by the ascending pharyngeal artery. The squamous portion is supplied, on its internal surface, by the middle meningeal, and externally by the branches of the deep temporal from the internal maxillary.

Articulations.—The temporal bone articulates with the occipital, parietal, sphenoid, zygomatic, and, by a movable joint, with the mandible. Occasionally the squamous portion pre-

ents a process which articulates with the frontal. A frontosquamosal suture is common in ne skulls of the lower races of men, and is normal in the skulls of the chimpanzee, gorilla, and ibbon.

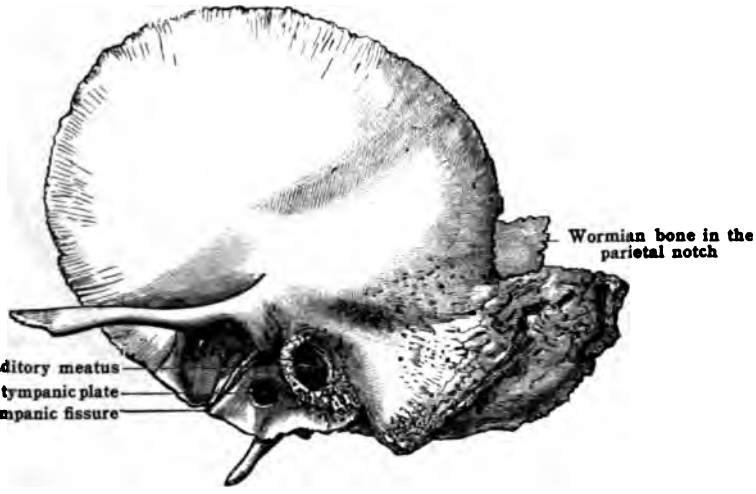
Ossification.—Of the three parts which constitute the temporal bone at birth, the squaosal and tympanic develop in membrane and the petrosal in cartilage. The squamosal is ormed from one center, which appears as early as the eighth week, and ossification extends nto the zygomatic process, which grows concurrently with the squamosal. At first the tymanic border is nearly straight, but soon assumes its characteristic horsesboe shape. At birth he postglenoid tubercle is conspicuous, and at the hinder end of the squamosal there is a procss which comes into relation with the mastoid antrum. The center for the tympanic elenent appears about the twelfth week. At birth it forms an incomplete ring, open above, and ightly ankylosed to the lower border of the squamosal. The anterior extremity terminates n a small irregular process, and the medial aspect presents, in the lower half of its circumfernce, a groove for the reception of the tympanic membrane.

Up to the middle of the fifth month the periotic capsule is cartilaginous; it then ossifies rapidly that by the end of the sixth month its chief portion is converted into porous bone. he ossific material is deposited in four centers, or groups of centers, named according to eir relation to the ear-capsule in its embryonic position.

The nuclei are deposited in the following order:

1. The opisthotic appears at the end of the fifth month. The osseous material is seen first n the promontory, and it quickly surrounds the fenestra cochleæ from above downward, and rms the floor of the vestibule, the lower part of the fenestra vestibuli, and the internal audiry meatus; it also invests the cochlea. Subsequently a plate of bone arises from it to surund the internal carotid artery and form the floor of the tympanum.

FIG. 159.—TEMPORAL BONE AT THE SIXTH YEAR.



Wormian bone in the parietal notch
External auditory meatus
Non-ossified area of the tympanic plate
Petrotympanic fissure

2. The pro-otic nucleus is deposited behind the internal auditory meatus near the medial mb of the superior semicircular canal. It covers in a part of the cochlea, the vestibule, and he internal auditory meatus, completes the fenestra vestibuli, and invests the superior semiircular canal.

3. The pterotic nucleus ossifies the tegmen tympani and covers in the lateral semicircular anal; the ossific matter is first deposited over the lateral limb of this canal.

4. The epiotic, often double, is the last to appear, and is first seen at the most posterior art of the posterior semicircular canal.

At birth (figs. 151–153) the bone is of loose and open texture, thus offering a striking conrast to the dense and ivory-like petrosal of the adult. It also differs from the adult bone in everal other particulars. The floccular fossa is widely open and conspicuous. Voltolini has ointed out that a small canal leads from the floor of the floccular fossa and opens posteriorly n the mastoid surface of the bone; it may open in the mastoid antrum. The hiatus canalis acialis is unclosed and the tympanum is filled with gelatinous connective tissue. The mastoid rocess is not developed, and the jugular fossa is a shallow depression.

After birth the parts grow rapidly. The tympanum becomes permeated with air, the varius elements fuse, and the tympanic annulus grows rapidly and forms the tympanic plate. Development of the tympanic plate takes place by an outgrowth of bone from the lateral spect of the tympanic annulus. This outgrowth preceeds most rapidly from the tubercles or pines at its upper extremities, and in consequence of the slow growth of the lower segment a eep notch is formed; gradually the tubercles coalesce, lateral to the notch, so as to enclose a oramen which persists until puberty, and sometimes even in the adult. In most skulls a cleft tympanomastoid fissure) remains between the tympanic element and the mastoid process. he anterior portion of the tympanic plate forms with the inferior border of the squamosal a left known as the petrotympanic fissure, which is subsequently encroached upon by the growth f the petrosal. As the tympanic plate increases in size it joins the lateral wall of the carotid anal and presents a prominent lower edge, known as the vaginal process (sheath of the styloid).

The **mastoid process** becomes distinct about the first year, coincident with the obliteration of the petrosquamous suture, and increases in thickness by deposit from the periosteum. According to most writers, the process becomes pneumatic about the time of puberty, but it has been shown by Young and Milligan that the mastoid air-cells develop at a much earlier period than is usually supposed. Air-cells were present, as small pit-like diverticula from the mastoid antrum, in a nine months' fetus and in an infant one year old. In old skulls the air-cells may extend into the jugular process of the occipital bone.

At birth the mastoid antrum is relatively large and bounded laterally by a thin plate of bone belonging to the squamosal (postauditory process). As the mastoid increases in thickness the antrum comes to lie at a greater depth from the surface and becomes relatively smaller.

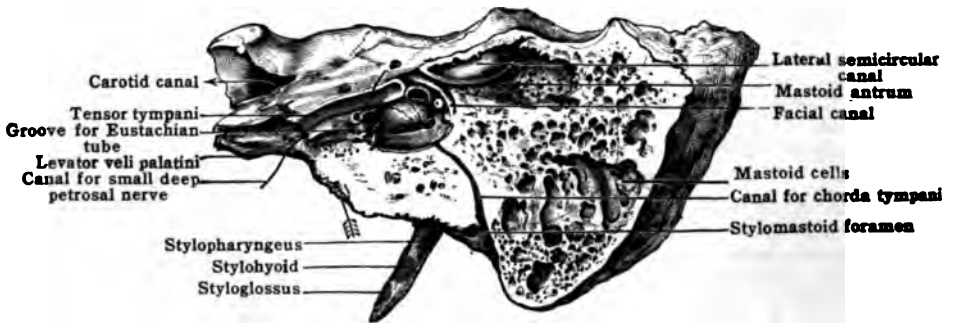
The styloid process is ossified in cartilage from two centers, one of which appears at the base in the tympanohyal before birth. This soon joins with the temporal bone, and in the second year a center appears for the stylohyal, which, however, remains very small until puberty. In the adult it usually becomes firmly united with the tympanohyal, but it may remain permanently separate.

Variations.—A bar of bone in the dura over the trigeminal nerve has been interpreted as a vestige of the primitive cranial wall as presented in the reptilia. The petrosquamous suture may persist. In the heritable defect, known as *cleidocranial dysostosis*, the temporal squama is rudimentary and the zygomatic arch is incomplete. The mastoid cells vary greatly in extent, and may even invade the squamous part.

THE TYMPANUM

The **tympanum** (middle ear) includes a cavity [cavum tympani] of irregular form in the temporal bone, situated over the jugular fossa, between the petrous portion medially and the tympanic and squamous portions laterally. When fully developed, it is completely surrounded by bone except where it communicates

FIG. 160.—THE MEDIAL WALL OF THE TYMPANUM.



with the external auditory meatus, and presents six walls—lateral, medial, posterior, anterior, superior (roof), and inferior (floor). The lateral and medial walls are flat, but the remainder are curved, so that they run into adjoining surfaces, without their limits being sharply indicated.

The **roof** or **tegmen tympani** [paries tegmentalis] is a translucent plate of bone, forming part of the superior surface of the petrous portion and separating the tympanum from the middle fossa of the skull. The **floor** [paries jugularis] is the plate of bone which forms the roof of the jugular fossa. The **medial wall** [paries labyrinthica] (figs. 160, 1075) is formed by the tympanic surface of the petrous portion. In the angle between it and the roof is a horizontal ridge which extends backward as far as the posterior wall and then turns downward in the angle between the medial and posterior walls. This is the **facial (Fallopian) canal, and is** occupied by the facial nerve. The other features of this surface—viz., the **fenestra vestibuli,** the **fenestra cochleæ,** and the **promontory**—have been previously described with the tympanic surface of the petrous portion of the temporal bone. The **posterior wall** [paries mastoidea] of the tympanum is also formed by the anterior surface of the petrous portion. At the superior and lateral angle of this wall an opening leads into the **mastoid antrum.** Immediately below this opening there is a small hollow cone, the **pyramidal eminence,** the cavity of which is continuous with the descending limb of the facial canal. The cavity is occupied by the *stapedius* and the tendon of the muscle emerges at the apex. One or more bony spicules often connect the apex of the pyramid with the promontory.

The roof and floor converge toward the **anterior extremity** (wall) of the tympanum, which is, in consequence, very low; it is occupied by two semicanals, the lower for the Eustachian tube, the upper for the *tensor tympani* muscle. These channels are sometimes described together as the **canalis musculotubarius.** In carefully prepared bones the upper semicanal is a small horizontal hollow cone (anterior pyramid), 12 mm. in length; the apex is just in front of the fenestra vestibuli, and is perforated to permit the passage of the tendon of the muscle. As a rule, the thin walls of the canal are damaged, and represented merely by a thin ridge of bone. The posterior portion of this ridge projects into the tympanum, and is known as the **processus**

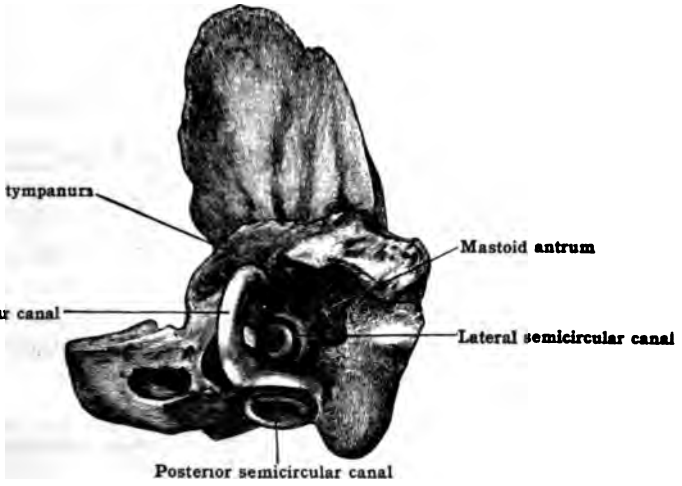
cochleariformis. The thin septum between the semicanal for the tensor tympani and the tube is pierced by a minute opening which transmits the small deep petrosal nerve.

The lateral wall [paries membranacea] is occupied mainly by the external auditory meatus. This opening is closed in the recent state by the tympanic membrane. The rim of bone to which the membrane is attached is incomplete above, and the defect is known as the **tympanic notch (notch of Rivinus).** Anterior to this notch, in the angle between the squamous portion and the tympanic plate, is the **petrotympanic (Glaserian) fissure,** and the small passage which transmits the chorda tympani nerve, known as the **canal of Huguier.**

Up to this point the description of the middle ear conforms to that in general usage. But **Young** and **Milligan** have laid stress on the fact that the middle ear is really a cleft, named by them the '*middle-ear cleft*,' which intervenes between the periotic capsule, on the one hand, and the squamozygomatic and tympanic elements of the temporal bone on the other. This cleft, as development proceeds, gives rise to three cavities:—(1) the mastoid antrum; (2) tympanum; and (3) the Eustachian tube. They point out that 'the cleft is primarily continuous, and however much it may be altered in shape and modified in parts to form these three cavities, that continuity is never lost.' It will be clear that the mastoid antrum, according to this view, is not an outgrowth from the tympanum, but is simply the lateral end of the middle-ear cleft.

The tympanic cavity may be divided into three parts. The part below the level of the superior margin of the external auditory meatus is the **tympanum proper;** the portion above this level is the **epitympanic recess** or **attic;** it receives the head of the malleus, the body of the incus, and leads posteriorly into the

FIG. 161.—TEMPORAL BONE AT BIRTH DISSECTED FROM ABOVE AND BEHIND TO SHOW THE SEMICIRCULAR CANALS AND THE MASTOID ANTRUM. (Enlarged ½.)



recess known as the **mastoid antrum.** The third part is the downward extension known as the **hypotympanic recess.** (For additional details and figures of the tympanic cavity, see p. 1121.)

The tympanic or mastoid antrum.—The air-cells which in the adult are found in the interior of the mastoid portion of the temporal bone open into a small cavity termed the **mastoid antrum (figs. 160, 161, 1075).** This is an air-chamber, communicating with the attic of the tympanum, and separated from the middle cranial fossa by the posterior portion of the tegmen tympani. The floor is formed by the mastoid portion of the petrosal, and the lateral wall by the squamosal, below the temporal ridge. In children the outer wall is exceedingly thin, but in the adult it is of considerable thickness. The **lateral semicircular canal** projects into the antrum on its medial wall, and is very conspicuous in the fetus. Immediately below and in front of the canal is the facial nerve, contained in the facial canal.

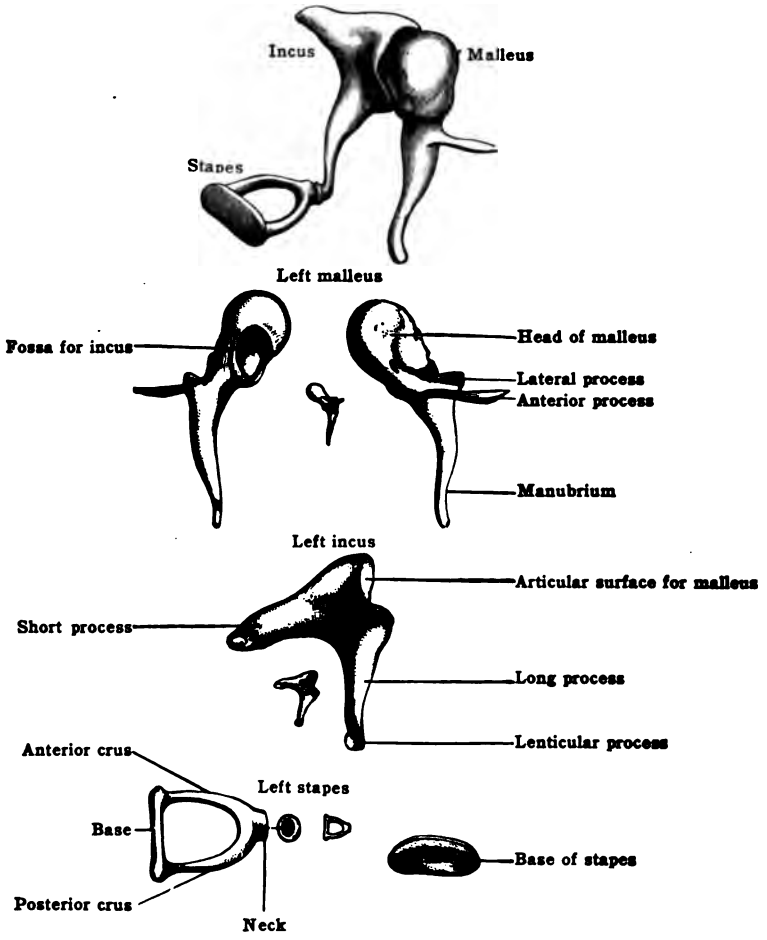
The mastoid antrum has somewhat the form of the bulb of a retort (Thane and Godlee) compressed laterally, and opening by its narrowed neck into the attic or epitympanic recess. Its dimensions vary at different periods of life. It is well developed at birth, attains its maximum size about the third year, and diminishes somewhat up to adult life. In the adult the plate of bone which forms the lateral wall of the antrum is 12 to 18 mm. (½ to ¾ in.) in thickness, whereas at birth it is about 1.8 mm. or less. The deposition of bone laterally occurs, therefore, at average rate of nearly 1 mm. a year in thickness. In the adult the antrum is about 12 mm. from front to back, 9 mm. from above downward, and 4.5 mm. from side to side. A canal occasionally leads from the mastoid antrum through the petrous bone to open in the recess which indicates the position of the floccular fossa; it is termed the petromastoid canal. (Gruber.)

The facial (Fallopian) canal.—This canal begins at the anterior angle of the superior fossa of the internal auditory meatus, and passes forward and laterally above the vestibular portion

of the internal ear for a distance of 1.5–2.0 mm. At the lateral end of this portion of its course it becomes dilated to accommodate the geniculate ganglion, and then turns abruptly backward and runs in a horizontal ridge on the medial wall of the tympanum, lying in the angle between it and the tegmen tympani, immediately above the fenestra vestibuli, and extending as far backward as the entrance to the mastoid antrum. Here it comes into contact with the inferior aspect of the projection formed by the lateral semicircular canal, and then turns vertically downward, running in the angle between the medial and posterior walls of the tympanum to terminate at the stylomastoid foramen.

The canal is traversed by the facial nerve. Numerous openings exist in the walls of this passage. At its abrupt bend, or **genu**, the greater and smaller superficial petrosal nerves escape from, and a branch from the middle meningeal artery enters, the canal, and in the vertical part of its course the cavity of the pyramid opens into it. There is also a small orifice by which the auricular branch of the vagus joins the facial, and near its termination the **iter chordæ posterius** for the chorda tympani nerve leads from it into the tympanum.

FIG. 162.—THE BONES OF THE MIDDLE EAR. (Modified from Henle.)



The small bones of the tympanum.—These bones [ossicula auditus], the malleus, incus and stapes, are contained in the upper part of the tympanic cavity. Together they form a jointed column of bone connecting the membrana tympani with the fenestra vestibuli (fig. 162).

The malleus.—This is the most external of the auditory ossicles, and lies in relation with the tympanic membrane. Its upper portion, or **head**, is lodged in the epitympanic recess. It is of rounded shape, and presents posteriorly an elliptical depression for articulation with the incus. Below the head is a constricted portion or **neck**, from which three processes diverge. The largest is the **handle** or **manubrium**, which is slightly twisted and flattened. It forms an obtuse angle with the head of the bone, and lies between the membrana tympani and the mucous membrane covering its inner surface. The *tensor tympani* tendon is inserted into the manubrium near its junction with the neck on the medial side.

The **anterior process** (processus gracilis or Folii) is a long, slender, delicate spiculum of bone [illegible]rely seen of full length except in the fetus), projecting nearly at right angles to the anterior of the neck, and extending obliquely downward. It lies in the petrotympanic fissure,

and in the adult usually becomes converted into connective tissue, except a small basal stump. The **lateral process** is a conical projection from the lateral aspect of the base of the manubrium. Its apex is connected to the upper part of the tympanic membrane, and its base receives the lateral ligament of the malleus. The malleus also gives attachment to a superior and an anterior ligament, the latter of which was formerly described as the *laxator tympani* muscle.

The incus.—This bone is situated between the malleus externally and the stapes internally. It presents for examination a body and two processes. The **body** is deeply excavated anteriorly for the reception of the head of the malleus. The **short process** projects backward, and is connected by means of ligamentous fibers to the posterior wall of the tympanum, near the entrance to the mastoid antrum. The **long process** is slender, and directed downward and inward, and lies parallel with the manubrium of the malleus. On the medial aspect of the distal extremity of this process is the **lenticular process** (orbicular tubercle), separate in early life, but subsequently joined to the process by a narrow neck. Its free surface articulates with the head of the stapes.

The **stapes** is the innermost ossicle. It has a **head** directed horizontally outward, capped at its outer extremity by a disk resembling the head of the radius. The cup-shaped depression receives the lenticular process of the incus. The **base** occupies the fenestra vestibuli, and like this opening, the inferior border is straight, and the superior curved. The base is connected with the head by means of two **crura**, and a narrow piece of bone called the neck. Of the two crura, the anterior is the shorter and straighter. The crura with the base form a stirrup-shaped arch, of which the inner margin presents a groove for the reception of the membrane stretched across the hollow of the stapes. In the early embryo this hollow is traversed by the stapedial artery. The **neck** is very short, and receives on its posterior border the tendon of the *stapedius*.

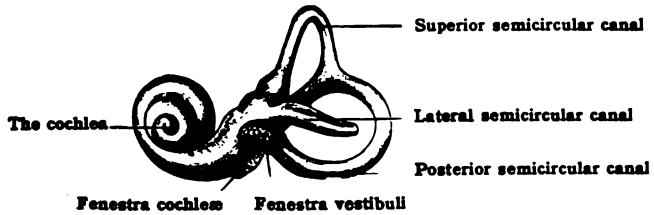
Development.—For the early development of the auditory tube and tympanic cavity from the first branchial pouch, see p. 17. The auditory ossicles are formed from the upper extremities of the axial skeletons of the first and second branchial arches, the malleus and incus belonging to the first arch and the stapes to the second (Reichert). The ossicles consequently lie originally in the walls of the cavity, but they are surrounded by a loose spongy tissue, which, on the entrance of air into the cavity, becomes compressed, allowing the cavity to enfold the ossicles. These therefore are enclosed within an epithelium which is continuous with that lining the tympanic cavity.

The mastoid cells are outgrowths of the cavity into the adjacent bone, and are therefore lined with an epithelium continuous with that of the cavity.

THE OSSEOUS LABYRINTH

The **osseous labyrinth** [labyrinthus osseus] (figs. 163, 865–867) is a complex cavity hollowed out of the petrous portion of the temporal bone and containing

FIG. 163.—THE LEFT OSSEOUS LABYRINTH. (After Henle. From a cast.)



the membranous labyrinth, the essential part of the organ of hearing. The osseous labyrinth is incompletely divided into three parts, named the vestibule, the semicircular canals, and the cochlea.

The vestibule.—This is an oval chamber situated between the base of the internal auditory meatus and the medial wall of the tympanum, with which it communicates by way of the fenestra vestibuli. Anteriorly, the vestibule leads into the cochlea, and posteriorly it receives the extremities of the semicircular canals. It measures about 3 mm. transversely, and is somewhat longer anteroposteriorly.

Its medial wall presents at the anterior part a circular depression, the **spherical recess** (fovea hemispherica), which is perforated for the passage of nerve-twigs. This recess is separated by a vertical ridge (the **crista vestibuli**) from the vestibular orifice of the **aqueductus vestibuli**, which passes obliquely backward to open on the posterior surface of the petrosal. The roof contains an oval depression—the **elliptical recess** (fovea hemielliptica).

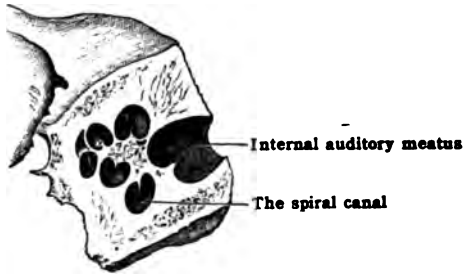
The **semicircular canals** are three in number. Arranged in different planes, each forms about two-thirds of a circle. One extremity of each canal is dilated to form an **ampulla**.

The **superior canal** lies transversely to the long axis of the petrosal, and is nearly vertical; its highest limb makes a projection on the superior surface of the bone. The ampulla is at the lateral end; the medial end opens into the vestibule conjointly with the superior limb of the posterior canal. The **posterior canal** is nearly vertical and lies in a plane nearly parallel to the posterior surface of the petrosal. It is the longest of the three; its upper extremity joins the medial limb of the superior canal, and opens in common with it into the vestibule. The lower is the ampullated end. The **lateral canal** is placed horizontally and arches laterally; its lateral limb forms a prominence in the mastoid antrum. This canal is the shortest; its ampulla is at the lateral end near the fenestra vestibuli.

The cochlea.—This is a cone-shaped cavity lying with its base upon the internal auditory meatus, and the apex directed forward and laterally. It measures about five mm. in length, and the diameter of its base is about the same. The center of this cavity is occupied by a column of bone—the **modiolus**—around which a canal is wound in a spiral manner, making about two and a half turns. This is the **spiral canal** of the cochlea; its first turn is the largest and forms a bulging, the **promontory**, on the medial wall of the tympanum. Projecting into the canal throughout its entire length there is a horizontal, shelf-like lamella, the **lamina spiralis**, which terminates at the apex of the cochlea in a hook-like process, the **hamulus**. The free edge of the lamina spiralis gives attachment to the membranous cochlea, a canal having in section the form of a triangle whose base is attached to the lateral wall of the spiral canal. By this the spiral canal is divided into a portion above the lamina spiralis, termed the **scala vestibuli**, which communicates at its lower end with the osseous vestibule, and a portion below, termed the **scala tympani**, which abuts at its lower end upon the fenestra cochleæ. The two scalæ communicate at the apex of the cochlea by the **helicotrema**. Near the commencement of the scala tympani, and close to the fenestra rotunda, is the cochlear orifice of the **canaliculus cochleæ** (ductus perilymphaticus). In the adult this opens below, near the middle of the posterior border of the petrous bone, and transmits a small vein from the cochlea to the jugular fossa.

Measurements of the principal parts connected with the auditory organs:—
Internal auditory meatus: Length of anterior wall, 13–14 mm.; of posterior wall, 6.7 mm.
External auditory meatus: 14–16 mm. (Gruber.)
Tympanum: Length, 13 mm.; height in center of cavity, 15 mm.; width opposite the membrana tympani, 2 mm.; width opposite the tubal orifice, 3–4 mm. (Von Tröltsch.)
The capsule of the osseous labyrinth is in length 22 mm. (Schwalbe.)
The superior semicircular canal measures along its convexity 20 mm.
The posterior semicircular canal measures along its convexity 22 mm.
The lateral semicircular canal measures along its convexity 15 mm.
The canal is in diameter 1.5 mm. (Huschke.) The ampulla of the canal, 2.5 mm.

FIG. 164.—THE COCHLEA IN SAGITTAL SECTION. (After Henle.)



Development.—For the origin of the otocyst from the surface ectoderm, see p. 38. The mesodermal tissue which surrounds the otocyst becomes later the petrous portion of the temporal bone, the perilymph and the internal periosteal layer; the osseous labyrinth is therefore merely the portions of the petrous which enclose the cavity occupied by the membranous internal ear.

THE ETHMOID

The **ethmoid** [os ethmoidale] is a bone of delicate texture, situated at the anterior part of the base of the cranium (figs. 165–167). Projecting downward from between the orbital plates of the frontal, it enters into the formation of the orbital and nasal fossæ. It is cubical in form, and its extreme lightness and delicacy are due to an arrangement of very thin plates of bone surrounding irregular spaces known as air-cells. The ethmoid consists of four parts: the horizontal or cribriform plate, the ethmoidal labyrinth on each side, and a perpendicular plate.

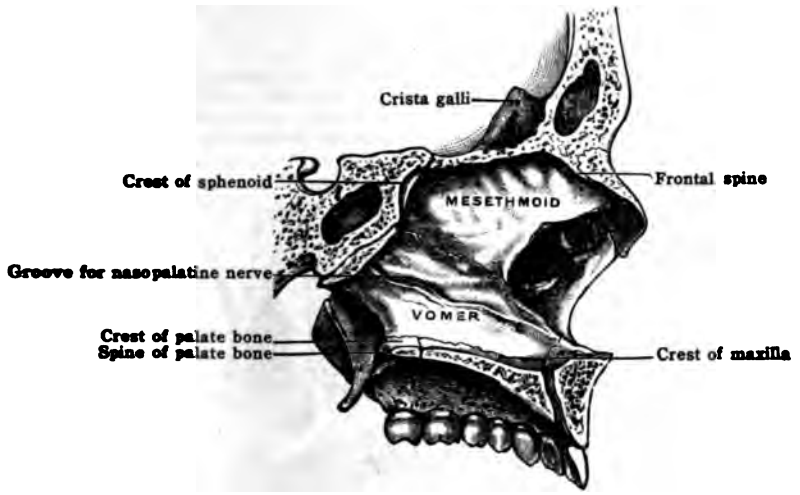
The **cribriform plate** [lamina cribrosa] forms part of the anterior cranial fossa, and is received into the ethmoidal notch of the frontal bone. It presents on its upper surface, in the median line, the intracranial portion of the perpendicular plate, known as the **crista galli**, a thick, vertical, triangular process with the highest point in front, and a sloping border behind which gives attachment to the falx cerebri. The anterior border is short and in its lower part broadens out to form two **alar processes** which articulate with the frontal bone and complete the **foramen cecum**. The crista galli is continuous behind with a median ridge, and on each side of the midline is a groove which lodges the olfactory bulb.

The cribriform plate is pierced, on each side, by numerous foramina, arranged in two or three rows, which transmit the filaments of the olfactory nerves ascending to the bulb. Those in the middle of the groove are few and are simple perforations, through which pass the nerves from the roof of the nose; the medial and lateral series are more numerous and constitute the

upper ends of small canals, which subdivide as they course downward to the upper parts of the septum and the lateral wall of the nasal fossa. At the front part of the cribriform plate is a narrow longitudinal slit, on each side of the crista galli, which transmits the anterior ethmoidal (nasal) branch of the ophthalmic division of the trigeminal nerve. The posterior border articulates with the ethmoidal spine of the sphenoid.

The **perpendicular plate** [lamina perpendicularis] (mesethmoid) is directly continuous with the crista galli on the under aspect of the cribiform plate, so

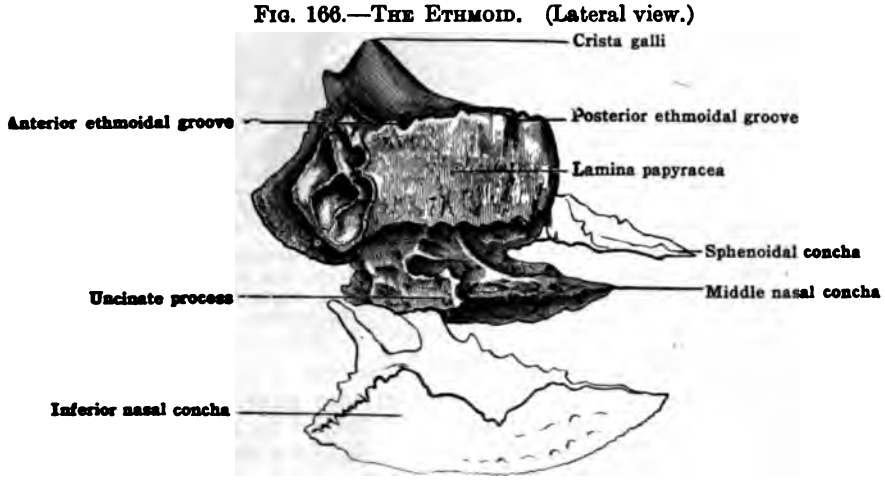
FIG. 165.—SECTION THROUGH THE NASAL FOSSA TO SHOW THE MESETHMOID. (LAMINA PERPENDICULARIS).



that the two plates cross each other at right angles. The larger part of the perpendicular plate is below the point of intersection and forms the upper third of the septum of the nose. It is quadrangular in form with unequal sides.

The **anterior border** articulates with the spine of the frontal and the crest of the nasal bones. The **inferior border** articulates in front with the septal cartilage of the nose and behind with the anterior margin of the vomer. The **posterior border** is very thin and articulates with the

FIG. 166.—THE ETHMOID. (Lateral view.)



crest of the sphenoid. This plate, which is generally deflected a little to one side, presents above a number of grooves and minute canals which lead from the inner set of foramina in the cribriform plate and transmit the olfactory nerves from the septum.

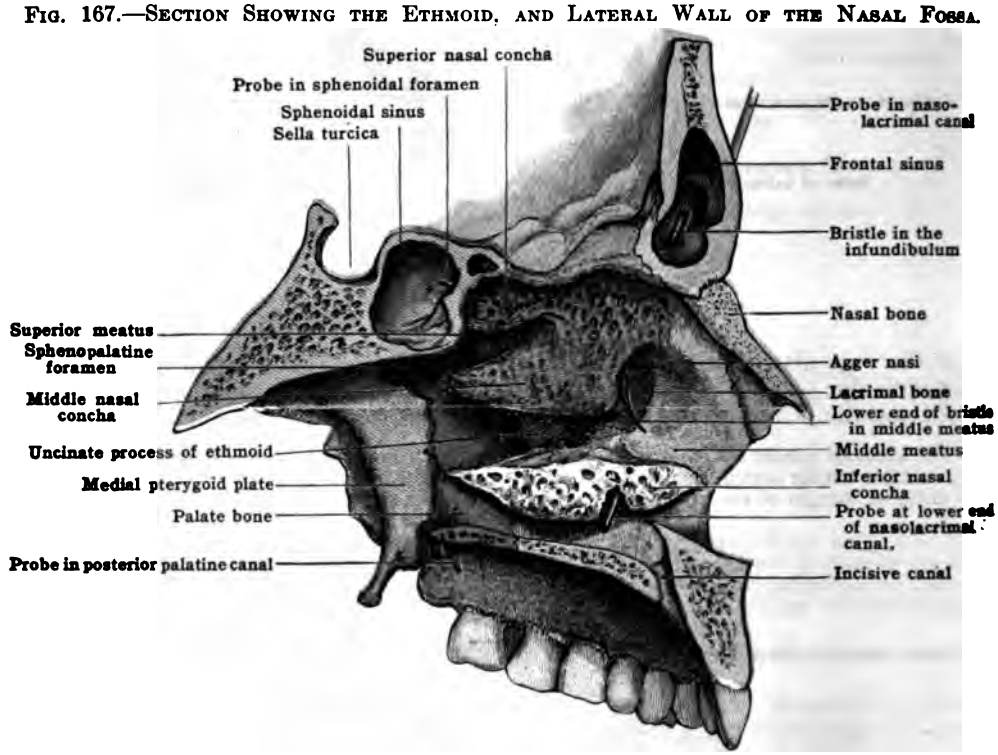
The **ethmoidal labyrinth** (lateral mass) is oblong in shape and suspended from the under aspect of the lateral part of the cribriform plate. It includes two scroll-like pieces of bone, the **superior** and **middle nasal conchæ** (turbinate bones), and encloses numerous irregularly shaped air-spaces, known as the **ethmoidal cells.** These are arranged in two main sets—anterior and posterior ethmoidal cells

—and, in the recent state, are lined with prolongations of the nasal mucous membrane. Laterally the labyrinth presents a thin, smooth, quadrilateral plate of bone—the **lamina papyracea** (os planum)—which closes in the ethmoidal cells and forms a large part of the medial wall of the orbit (figs. 123, 975).

By its anterior border the lamina articulates with the lacrimal, and by its posterior border with the sphenoid; the inferior border articulates with the medial margin of the orbital plate of the maxilla and the orbital process of the palate bone, whilst the superior border articulates with the horizontal plate of the frontal. Two notches in the superior border lead into grooves running horizontally across the lateral mass to the cribriform plate, which complete, with the frontal bone, the **ethmoidal canals**. The anterior canal transmits the anterior ethmoidal vessels and nerve; the posterior transmits the posterior ethmoidal vessels and nerve.

At the lower part of the lateral surface is a deep groove, which belongs to the middle meatus of the nose, and is bounded below by the thick curved margin of the inferior nasal concha. Anteriorly the middle meatus forms the **infundibulum**, a sinuous passage often communicating with the frontal sinus through the anterior part of the labyrinth. The anterior ethmoidal cells in part open into the lower portion of the infundibulum, and in this way communicate with the nose; some (the middle ethmoidal cells) open directly into the meatus. In front of

FIG. 167.—SECTION SHOWING THE ETHMOID, AND LATERAL WALL OF THE NASAL FOSSA.



the lamina papyracea are seen a few broken cells, which extend under, and are completed by, the lacrimal bone and the frontal process of the maxilla; from this part of the labyrinth an irregular lamina, known as the **uncinate process**, projects downward and backward. The uncinate process articulates with the ethmoidal process of the inferior nasal concha and forms a small part of the medial wall of the maxillary sinus.

Medially the labyrinth takes part in the formation of the **lateral wall** of the nasal fossa, and presents the **superior** and **middle nasal conchæ** (turbinate processes), continuous anteriorly, but separated behind by a space directed forward from the posterior margin (fig. 167). This channel is the **superior meatus** of the nose and communicates with the posterior ethmoidal cells.

The conchæ are covered in the recent state with mucous membrane and present numerous foramina for blood-vessels and, above, grooves for twigs of the olfactory nerves. Each concha has an attached upper border and a free, slightly convoluted, lower border, and in the case of the middle concha, the lower margin has already been noticed on the outer aspect, where it overhangs the middle meatus of the nose. The posterior extremity of the labyrinth articulates with the anterior surface of the body of the sphenoid and is commonly united with the sphenoidal concha.

A rounded prominence on the lateral wall of the middle meatus, inclosing an air cell, is known as the **bulla ethmoidalis**. Anteroinferior to the bulla is a large semilunar depression [hiatus semilunaris] which communicates with the infundibulum.

Many of the ethmoidal cells are imperfect and are completed by adjacent bones. Those along the superior edge of the lateral mass are the frontoethmoidal; those at the anterior border, usually two in number, are known as lacrimoethmoidal. Those along the lower edge of the lamina papyracea are the maxilloethmoidal; and posteriorly, are the sphenoethmoidal, completed by the sphenoidal concha, and a palatoethmoidal cell. The anterior extremity presents one or two incomplete cells closed by the nasal process of the maxilla. For further details concerning the ethmoidal cells, see p. 1236.

Blood-supply.—The ethmoid receives its blood-supply from the anterior and posterior ethmoidal arteries and from the sphenopalatine branch of the internal maxillary.

Articulations.—With the frontal, sphenoid, two palate bones, two nasals, vomer, two inferior nasal conchæ, two sphenoidal conchæ, two maxillæ, and two lacrimal bones. The posterior surface of each labyrinth is in relation with the sphenoid on each side of the crest and rostrum, and helps to close in the sphenoidal sinus.

Ossification.—The ethmoid has three centers of ossification. Of these, a nucleus appears in the fourth month of intrauterine life in each labyrinth, first in the lamina papyracea and afterward extending into the middle concha. At birth each lateral portion is represented by two scroll-like bones, very delicate and covered with irregular depressions, which give it a worm-eaten appearance. Six months after birth a nucleus appears in the ethmovomerine cartilage for the vertical plate which gradually extends into the crista galli, and the cribriform plate is formed by ossification extending laterally from this center, and medially from the labyrinth. The three parts coalesce to form one piece in the fifth or sixth year.

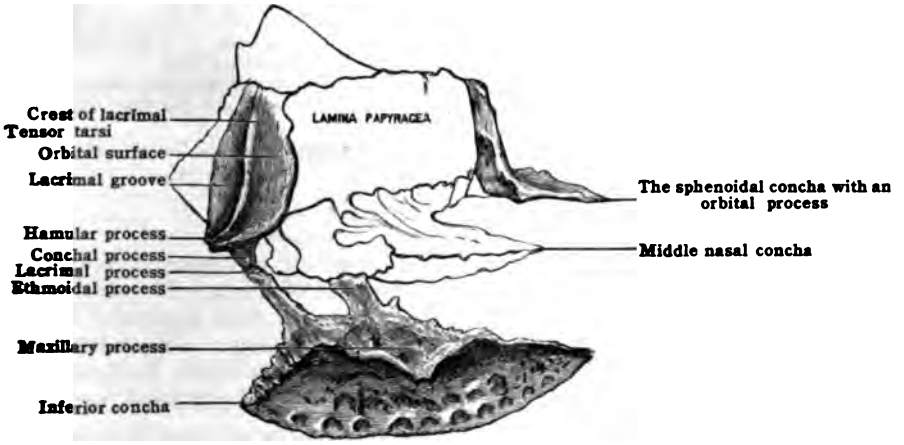
The ethmoidal cells arise before birth and become more prominent about the third year gradually invading the labyrinths. In many places there is so much absorption of bone that the cells perforate the ethmoid. Along the lower border, near its articulation with the maxilla the absorption leads to the partial detachment of a narrow strip known as the uncinate process. Sometimes a second but smaller hook-like process is formed, above and anterior to this, so fragile that it is difficult to preserve it in disarticulated bones. The relations of the uncinate process are best studied by removing the lateral wall of the maxillary sinus.

Variations.—Secondary foramina of the lamina papyracea are not infrequent in the aged. Reduction of this plate is met with where either the maxilla or the frontal or both send processes to participate in forming the medial wall of the orbit. Increase in the number of conchæ is common.

THE INFERIOR NASAL CONCHA

The **inferior nasal concha** (inferior turbinate) (fig. 168) is a slender, scroll-like lamina, attached by its upper margin to the lateral wall of the nasal fossa, and hanging into the cavity in such a way as to separate the middle from the inferior

FIG. 168.—THE INFERIOR CONCHA, ADULT SPHENOIDAL TURBINATE, AND LACRIMAL BONES.



meatus of the nose. It may be regarded as a dismemberment of the ethmoidal labyrinth, with which it is closely related. It presents two surfaces, two borders, and two extremities.

The lateral surface is concave, looks toward the lateral wall of the nasal fossa, and is overhung by the maxillary process. The medial surface is convex, pitted with depressions, and grooved for vessels, which, for the most part, run longitudinally. The superior or attached border articulates in front with the conchal crest of the maxilla, then ascends to form the lacrimal process, which articulates with the lacrimal bone and forms part of the wall of the lacrimal canal. Behind this, it is turned downward to form the maxillary process, already mentioned, which overhangs the orifice of the maxillary sinus and serves to fix the bone firmly to the lateral wall of the nasal fossa. The projection behind the maxillary process is the ethmoidal process, joined in the articulated skull with the uncinate process of the ethmoid across the opening of the maxillary sinus. Posteriorly the upper border articulates with the conchal

crest of the palate. The **inferior border** is free, rounded, and somewhat thickened. The **anterior extremity** is blunt and flattened, and broader than the **posterior extremity,** which is elongated, narrow, and pointed.

Articulations.—With the maxilla, lacrimal, palate, and ethmoid.

Ossification.—The inferior nasal concha is ossified in cartilage from a single nucleus which appears in the fifth month of intrauterine life. At birth it is a relatively large bone and fills up the lower part of the nasal fossa.

Variation.—A more or less prominent line, running the length of the medial surface, may be elevated to form a ridge or give rise to an additional scroll. It is probable that this is a persistence of the maxilloturbinal of the chondrocranium, from the base of which the inferior concha is derived.

THE LACRIMAL

The **lacrimal bone** [os lacrimale] (figs. 123, 168) is extremely thin and delicate quadrilateral in shape, and situated at the anterior part of the medial wall of the orbit. It is the smallest of the facial bones.

The **orbital surface** is divided by a vertical ridge, the **posterior lacrimal crest,** into two unequal portions. The anterior, smaller portion is deeply grooved to form the **lacrimal groove,** which lodges the lacrimal sac and forms the commencement of the canal for the nasolacrimal duct. The portion behind the ridge is smooth, and forms part of the medial wall of the orbit. The ridge gives origin to the *orbicularis oculi* (*pars lacrimalis*) muscle and ends below in a hook-like process, the **lacrimal hamulus,** which curves forward to articulate with the lacrimal tubercle of the maxilla and completes the superior orifice of the nasolacrimal canal. The **medial surface** is in relation with the two anterior cells of the ethmoid (lacrimoethmoidal), forms part of the infundibulum, and inferiorly looks into the middle meatus of the nose.

The **superior border** is short, and articulates with the medial angular process of the frontal. The **inferior border** posterior to the crest joins the medial edge of the orbital plate of the maxilla. The narrow piece, anterior to the ridge, is prolonged downward as the **descending process** to join the lacrimal process of the inferior nasal concha. The **anterior border articulates** with the posterior border of the frontal process of the maxilla and the **posterior border** with the lamina papyracea of the ethmoid.

The vessels of the lacrimal bone are derived from the infraorbital, dorsal nasal branch of the ophthalmic, and anterior ethmoidal arteries.

Articulations.—The lacrimal articulates with the ethmoid, maxilla, frontal, and inferior nasal concha.

Ossification.—This bone arises in the membrane overlying the cartilage of the frontonasal plate, and in its mode of ossification is very variable. As a rule, it is formed from a single nucleus which appears in the third or fourth month of intrauterine life.

Variations.—Division into two or more parts; fusion with neighboring bones; absence and extensive development of the hamulus to project out of the orbit are the chief variations of the lacrimal.

The hamular process is regarded as representing the remains of the facial part of the lacrimal seen in lower animals.

THE VOMER

The **vomer** (figs. 165, 169) (ploughshare bone) is an unpaired flat bone, which lies in the median plane and forms the lower part of the nasal septum. It is thin and irregularly quadrilateral in form, and is usually bent somewhat to one side, though the deflection rarely involves the posterior margin. Each **lateral surface** is covered in the recent state by the nasal mucous membrane, and is traversed by a narrow but well-marked groove, which lodges the nasopalatine nerve.

The **superior border,** by far the thickest part of the bone, is expanded laterally into two **alæ.** The groove between them receives the rostrum of the sphenoid, and the margin of each ala comes into contact with the sphenoidal process of the palate and the vaginal process of the medial pterygoid plate. The **inferior border** is uneven and lies in the groove formed by the crests of the maxillary and palate bones of the two sides. The **anterior border slopes downward** and forward and is grooved below for the septal cartilage of the nose; above it is united with the perpendicular plate of the ethmoid. The **posterior border,** smooth, rounded, and covered by mucus membrane, separates the choanæ (posterior nares). The anterior and inferior borders meet at the anterior extremity of the bone which forms a short vertical ridge behind the incisor crest of the maxillæ. From near the anterior extremity, a small projection passes downward between the incisive foramina.

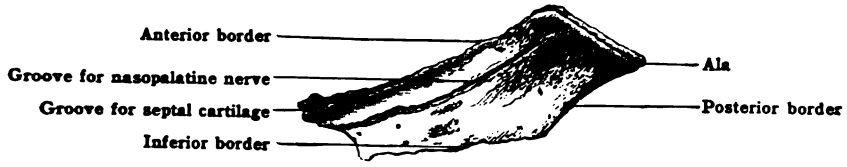
Blood-supply.—The arterial supply of the vomer is derived from the anterior and posterior ethmoidal and the sphenopalatine arteries. Branches are also derived from the posterior palatine through the foramen incisivum.

Ossification.—The vomer is ossified from two centers which appear about the eighth week in the membrane investing the ethmovomerine cartilage. The two lamellæ unite below during

the third month and form a shallow bony trough in which the cartilage lies. In the process of growth the lamellæ extend upward and gradully fuse to form a rectangular plate of bone, the cartilage enclosed between them undergoing absorption at the same time. The alæ on the superior margin and the groove in front are evidence of the original bilaminar condition. However, a bilateral origin of the vomer is not the general rule among mammals. (Terry, Anat. Rec., 1909, 3 : 525.)

Variation.—The inferior margin of the vomer has been observed in the intermaxillary suture participating with the palatal processes in the formation of the hard palate.

FIG. 169.—THE VOMER. (Side view.)



THE NASAL BONES

The **nasal** (figs. 170, 171) are two small oblong bones situated at the upper part of the face and forming the bridge of the nose. Each bone is thicker and narrower above, thinner and broader below, and presents two surfaces and four borders.

The **facial surface** is concave from above downward, convex from side to side, and near the center is perforated by a small foramen, which transmits a small tributary to the anterior facial vein. The posterior or **nasal surface,** covered in the recent state by mucous membrane, is concave laterally, and traversed by a longitudinal groove [sulcus ethmoidalis] for the anterior ethmoidal branch of the ophthalmic division of the trigeminal nerve.

FIG. 170.—THE LEFT NASAL BONE, FACIAL SURFACE.

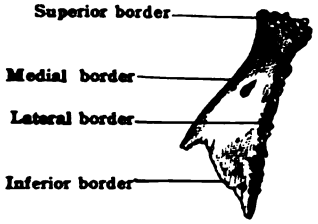


FIG. 171.—THE LEFT NASAL BONE, NASAL SURFACE.

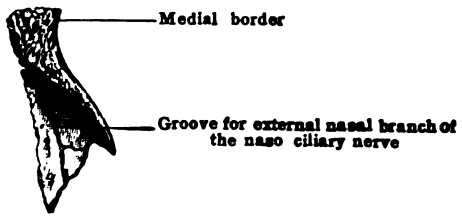


The short **superior border** is thick and serrated for articulation with the medial part of the nasal notch of the frontal. The **inferior border** is thin, and serves for the attachment of the lateral nasal cartilage. It is notched for the external nasal branch of the anterior ethmoidal nerve. The nasal bones of the two sides are united by their **medial borders,** forming the internasal suture. The contiguous borders are prolonged backward to form a crest which rests on the frontal spine and the anterior border of the perpendicular plate of the ethmoid. The **lateral border** articulates with the frontal process of the maxilla.

Blood-supply.—Arteries are supplied to this bone by the nasal branch of the ophthalmic the frontal, the angular, and the anterior ethmoidal arteries.

Articulations.—With the frontal, maxilla, ethmoid, and its fellow of the opposite side.

Ossification.—Each nasal bone is developed from a single center which appears about the eighth week in the membrane overlying the frontonasal cartilage. The cartilage, which is continuous with the ethmoid cartilage above and the lateral cartilage of the nose below, subsequently undergoes absorption. At birth the nasal bones are nearly as wide as they are long, whereas in the adult the length is three times greater than the width.

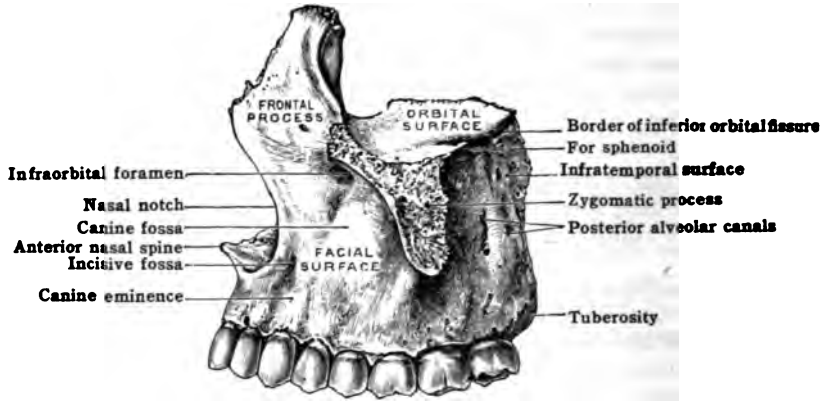
Variations.—Reduction of the nasal bones with concavity of the lateral margins and accompanied by expansion of the frontal process of the maxilla is not uncommon. Rarely the nasal bones are absent.

THE MAXILLA

The **maxilla** or upper jaw-bone (figs. 172–174) is one of the largest and most important of the bones of the face. It supports the maxillary teeth and takes part in the formation of the orbit, the hard palate, and the nasal fossa. It is divisible into a **body** and four processes, of which two—the **frontal** and **zygomatic** —belong to the upper part, and the **palatine** and **alveolar** to the lower part of the bone.

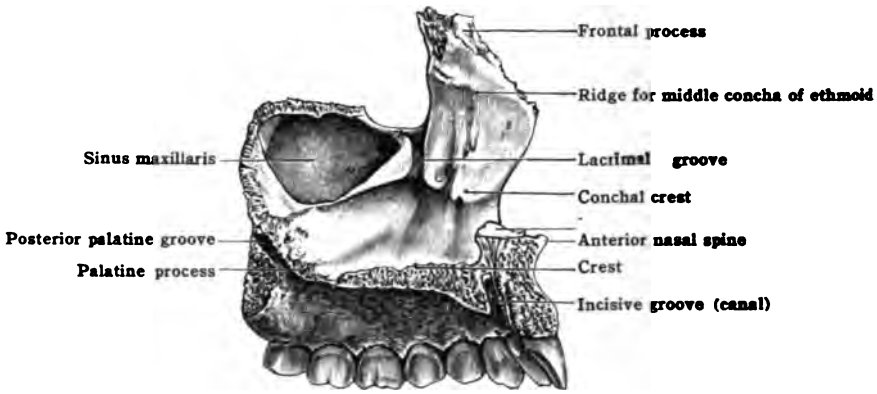
The **body** is somewhat pyramidal in shape and hollowed by a large cavity known as the **sinus maxillaris** (antrum of Highmore), lined by mucous membrane in the recent state, and opening at the base of the pyramid into the **nasal cavity**, the zygomatic process forming the apex. The **anterior** (or facial) **surface** looks forward and outward and is marked at its lower part by a series of eminences which indicate the positions of the roots of the teeth. The eminence produced by the fang of the canine tooth is very prominent and separates two fossæ. That on the medial side is the **incisive fossa**, and gives origin to the *alar* and *transverse portions* of the *nasalis*, and just above the socket of the lateral incisor tooth, to a

FIG. 172.—THE LEFT MAXILLA. (Lateral view.)



slip of the *orbicularis oris;* on the lateral side is the **canine fossa**, from which the *caninus* (*levator anguli oris*) arises. Above the canine fossa, and close to the margin of the orbit, is the **infraorbital foramen**, through which the terminal branches of the infraorbital nerve and vessels emerge, and from the ridge immediately above the foramen the *quadratus labii superioris* takes origin. The medial margin of the anterior surface is deeply concave, forming the **nasal notch**, the lateral boundary of the **piriform aperture** (fig. 122), and is prolonged below into the **anterior nasal spine**.

FIG. 173.—THE LEFT MAXILLA. (Medial view.)

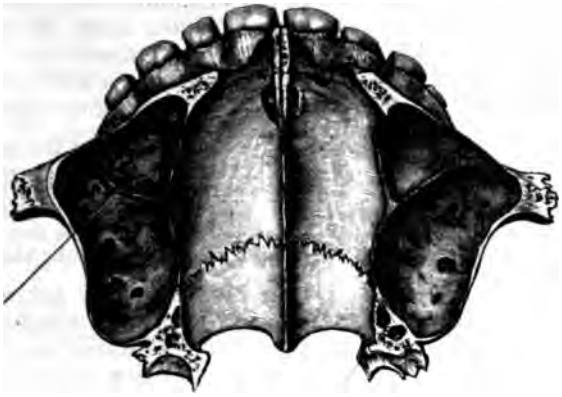


A ridge of bone extending upward from the socket of the **first molar tooth** separates the anterior from the **infratemporal** (zygomatic) **surface**. This latter surface is convex and presents near the middle the orifices of the **posterior alveolar canals**, transmitting the posterior alveolar vessels and nerves. The posterior inferior angle, known as the **tuberosity** [tuber maxillare], is rough and is most prominent after eruption of the wisdom tooth. It gives origin to a few fibers of the *internal pterygoid* muscle and articulates with the tuberosity of the palate.

The **orbital surface** [planum orbitale] is smooth, irregularly **triangular**, and forms the greater part of the floor of the orbit.

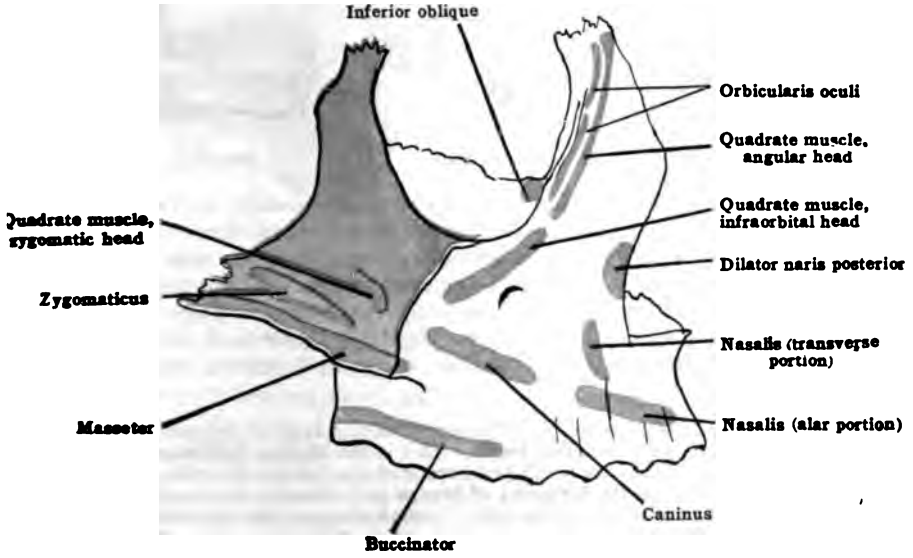
Anteriorly, it is rounded and reaches the orbital circumference for a short distance at the ot of the nasal process; laterally is the rough surface for the zygomatic bone. The posterior order, smooth and rounded, forms the inferior boundary of the inferior orbital fissure. The edial border is nearly straight and presents, behind the frontal process, a smooth rounded ngle forming part of the circumference of the orbital orifice of the nasolacrimal canal, and a otch which receives the lacrimal bone. The rest of the medial border is rough for articulation ith the lamina papyracea of the ethmoid and orbital process of the palate bone.

FIG. 174.—SECTION OF MAXILLÆ TO SHOW THE FLOOR OF THE MAXILLARY ANTRUM. (Reduced ¼.)



The orbital surface is traversed by the **infraorbital groove**, which, commencing at the posterior border, deepens as it passes forward and finally becomes closed in to form the **infraorbital canal**. It transmits the second division of the trigeminal nerve and the infraorbital vessels and terminates on the anterior surface immediately below the margin of the orbit. From the infraorbital, other canals—the **anterior** and **middle alveolar**—run downward in the wall of the

FIG. 175.—MAXILLA AND ZYGOMATIC BONE, TO SHOW MUSCULAR ATTACHMENTS. (Poirier.



antrum and transmit the anterior and middle alveolar vessels and nerves. Lateral to the commencement of the lacrimal canal is a shallow depression for the origin of the *inferior oblique* muscle of the eye.

The **nasal surface** takes part in the formation of the lateral wall of the nasal ossa. It presents a large irregular aperture which leads into the antrum and, immediately in front of this, the **lacrimal groove**, directed downward, backward, and laterally into the inferior meatus of the nose. The groove is converted into a canal by the lacrimal and inferior nasal concha and transmits the nasolacrimal duct.

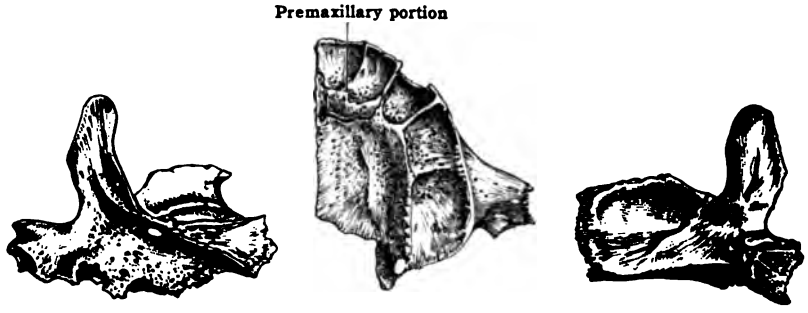
In front of the groove is a smooth surface crossed obliquely by a ridge, the **conchal crest**, for articulation with the inferior nasal concha. The surface below the crest is smooth, concave, and belongs to the inferior meatus; the surface above the crest extends on to the lower part of the frontal process and forms the wall of the atrium of the middle meatus. Behind the opening of the antrum the surface is rough for articulation with the vertical plate of the palate bone and crossing it obliquely is a smooth groove converted by the palate into the **pterygopalatine canal** for the passage of the (descending) palatine nerves and the descending palatine artery.

The **frontal process,** somewhat triangular in shape, rises vertically from the **angle** of the maxilla. Its lateral surface is continuous with the anterior surface of the body, and gives attachment to the *orbicularis oculi,* the medial palpebral ligament and the *quadratus labii superioris* (*caput angulare*). The medial surface forms part of the lateral boundary of the nasal fossa and is crossed obliquely by a low ridge, known as the **agger nasi,** limiting the atrium of the middle meatus.

The hinder part of this surface rests on the anterior extremity of the labyrinth of the ethmoid and completes the maxilloethmoidal cells. The superior border articulates with the frontal; the anterior border articulates with the nasal bone; the posterior border is thick and vertically grooved, in continuation with the lacrimal groove, and lodges the lacrimal sac. The medial margin of the groove articulates with the lacrimal bone, and the junction of its lateral margin with the orbital surface is indicated by the **lacrimal tubercle.**

The **zygomatic process,** rough and triangular, forms the summit of the prominent ridge of bone separating the anterior and infratemporal surfaces. It articulates above with the zygomatic, and from its inferior angle a few fibers of the *masseter* take origin. The anterior and posterior surfaces are continuous with the anterior and infratemporal surfaces of the body.

FIG. 176.—THE MAXILLA AT BIRTH.



The **palatine process** projects horizontally from the medial surface and with the corresponding process of the opposite side, forms about three-fourths of the hard palate. The superior surface is smooth, concave from side to side, and constitutes the larger part of the floor of the nasal fossa. The inferior surface is vaulted, rough, and perforated with foramina for nutrient vessels. Near its lateral margin is a longitudinal groove for the transmission of the vessels and nerves which issue at the posterior palatine canal and course along the lower aspect of the palate.

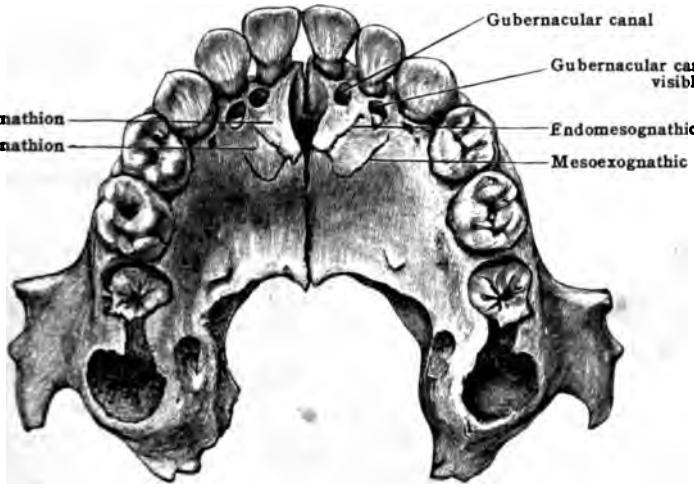
When the bones of the two sides are placed in apposition, a large orifice may be seen in the middle line immediately behind the incisor teeth. This is the **incisive foramen,** at the bottom of which are four foramina. Two are small and arranged one behind the other exactly in the **mesopalatine suture.** These are the **foramina of Scarpa** and transmit the nasopalatine nerves, the left passing through the anterior and the right through the posterior aperture. The lateral and larger orifices are the **foramina of Stenson,** representing the lower apertures of the incisive canals by which the nose communicates with the mouth; they transmit some terminal branches of the descending palatine artery to the nasal fossæ, and may contain recesses or remnants of the nasal mucous membrane.

Running laterally from the incisive foramen to the space between the second incisor and canine tooth, an indistinct suture may sometimes be seen, indicating the line of junction of the maxillary and premaxillary portions of the bone. The **premaxilla** or **incisive bone** is the part which bears the incisor teeth and in some animals exists throughout life as an independent element. The posterior border of the palate process is rough and serrated for articulation with the horizontal plate of the palate bone which completes the hard palate. The **medial border** joins with its fellow to form the **nasal crest** upon which the vomer is received. The more elevated anterior portion of this border is known as the **incisor crest,** and is continued forward into the **anterior nasal spine.** The septal cartilage of the nose rests on its summit and the an-

tremity of the vomer lies immediately behind it. At the side of the incisor crest is upper aperture of a canal leading from the nose to the mouth, which in its course d becomes a groove by a deficiency of its medial wall. Thus when the two bones are ıd the incisive canal is formed, communicating above with the nasal fossa on either side.

alveolar process is crescentic in shape, spongy in texture, and presents [alveoli dentales] in which the upper teeth are lodged. When complete e eight sockets (alveoli), with wide mouths, gradually narrowing as they o the substance of the bone, and forming exact impressions of the cor- ing fangs of the teeth. The pit for the canine tooth is the deepest; r the molars are the widest and subdivided. Along the lateral aspect of olar process the *buccinator* arises as far forward as the first molar tooth. **maxillary sinus** or antrum of Highmore (figs. 128, 174), the air-chamber ng the body of the bone, is somewhat pyramidal in shape, the **base** being ıted by the nasal or medial surface, and the **apex** corresponding to the tic process. In addition it has four walls: the superior is formed by the plate, and the inferior by the alveolar ridge. The anterior wall corre- to the anterior surface of the maxilla, and the posterior is formed by the ıporal surface. The medial boundary or base presents a very irregular ıt its posterior part; this is partially filled in by the vertical plate of the

.—MAXILLÆ AT THE END OF THE FIRST DENTITION IN BOTH OF WHICH THE SUTURES VEEN MAXILLA AND PREMAXILLA, AND BETWEEN THE TWO PARTS OF THE PREMAXILLA, SEEN.



one, the uncinate process of the ethmoid, the maxillary process of the nasal concha, and a small portion of the lacrimal bone. Even when these re in their relative positions, the orifice is very irregular in shape, and the mucous membrane to form the definite rounded aperture (or aper- or they are often multiple) known as the **opening of the sinus** through he cavity communicates with the middle meatus of the nose.

cavity of the sinus varies considerably in size and shape. In the young, it is small walls are thick: as life advances it enlarges at the expense of its walls, and in old age often extremely thin, so that occasionally the cavity extends even into the substance gomatic bone. The floor of the sinus is usually very uneven, due to prominences cor- ng to the roots of the molar teeth. In most cases the bone separating the teeth from is very thin, and occasionally the roots project into it. The teeth which come into lationship with the sinus are the first and second molars, but the sockets of any of the lged in the maxilla may, under diseased conditions, communicate with it. As a rule, y of the sinus is single, but occasionally specimens are seen in which it is divided by ta into chambers, and it is not uncommon to find recesses separated by bony processes. of the sinus presents near its anterior aspect what appears to be a thick rib of bone; llow and corresponds to the infraorbital canal. For further details, see p. 1235.

-supply.—The maxilla is a very vascular bone and its arteries are numerous and large. derived from the infraorbital, alveolar, descending palatine, sphenopalatine, eth- rontal, nasal, and external maxillary vessels.

lations.—With the frontal, nasal, lacrimal, ethmoid, palate, vomer, zygomatic, in- al concha and its fellow of the opposite side. Occasionally it articulates with the great l the pterygoid process, of the sphenoid.

Ossification.—The maxilla is developed from several centers which are deposited in membrane during the second month of intrauterine life. Several pieces are formed which speedily fuse, so that at birth, with the exception of the incisor fissure separating the maxilla from the premaxilla, there is no trace of the composite character of the bone. The centers of ossification comprise—(1) the **malar,** which gives rise to the portion of bone outside the infraorbital canal; (2) the **maxillary,** from which the greater part of the body and the frontal process are developed; (3) the **palatine,** forming the hinder three-fourths of the palatal process and adjoining part of the nasal wall; (4) the **premaxillary,** giving rise to the independent premaxillary bone (os incisivum), which lodges the incisor teeth and completes the anterior fourth of the hard palate. In the early stages of growth the premaxilla may consist of two pieces arising from two centers of ossification which Albrecht has named as follows:—the *endognathion,* or medial division for the central incisor, and the *mesognathion,* or lateral division for the lateral incisor; the rest of the maxilla is named the *exognathion;* (5) the **prepalatine,** corresponding to the infravomerine center of Rambaud and Renault, forms a portion of bone interposed between the premaxillary in front and the palatine process behind. It gives rise to a part of the nasal surface and completes the medial wall of the incisive canal.

At birth the maxillary sinus is narrow from side to side and does not extend laterally to any appreciable extent between the orbit and the alveoli of the teeth. During the early years of life it gradually enlarges, but does not attain its full growth until after the period of the second dentition. For further description of the maxillary sinus, see p. 1235.

Variations.—The walls of the infraorbital canal may be incomplete toward the maxillary sinus, putting the nerve into direct contact with the lining mucosa. The infraorbital foramen may be double. Cleft palate is apparently due to non-union of the embryonic palatine shelves (p. 38). The cleft which occurs to one side of the midline, falls through the incisive bone and germ of the lateral incisor tooth and not as a rule in the plane of the suture between the incisive and maxillary bones.

THE PALATE

The **palate bone** [os palatinum] (figs. 178, 179) forms the posterior part of the hard palate, the medial wall of the nasal fossa between the maxilla and the

FIG. 178.—LEFT PALATE BONE. (Medial view.)

Ethmoidal crest
Middle meatus
Conchal crest
Inferior meatus

medial pterygoid plate, and, by its orbital process, the hinder part of the floor of the orbit. It is somewhat L-shaped and presents for examination a **horizontal** part and a **perpendicular** part; at their point of junction is the **pyramidal process,** and surmounting the top of the vertical plate are the **orbital** and **sphenoidal** processes, separated by the **sphenopalatine notch.**

The **horizontal** part resembles the palatine process of the maxilla, but is much shorter. The **superior surface** is smooth, concave from side to side, and forms the back part of the floor of the nasal fossa; the **inferior surface** completes the hard palate behind and presents near its posterior border a **transverse ridge** which gives attachment to the *tensor veli palatini* muscle.

The anterior border is rough for articulation with the palatine process of the maxilla; the posterior is free, curved, and sharp, giving attachment to the soft palate. Medially it is thick and broad for articulation with its fellow of the opposite side, forming a continuation of the crest of the palatal processes of the maxillæ and supporting the vomer. The posterior extremity of the crest is the **posterior nasal spine,** from which the *azygos uvulæ* arises. Laterally, at its junction with the perpendicular part, it is grooved by the pterygopalatine canal.

The **perpendicular** part is longer and thinner than the horizontal plate. The **lateral surface** is in relation with the maxilla and is divided into two parts by a vertical groove which forms with the maxilla the **pterygopalatine canal** for the transmission of the anterior palatine nerve and the descending palatine

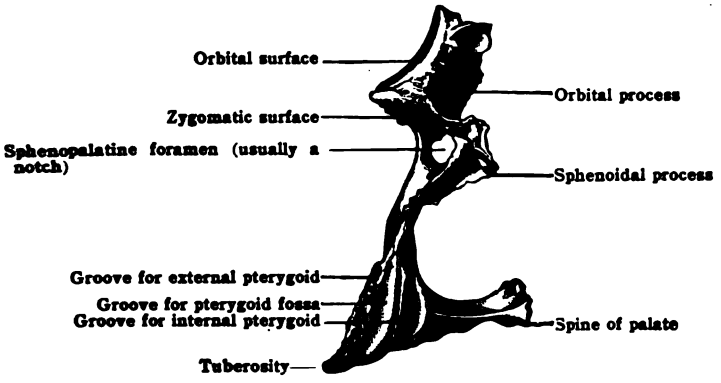
artery. The part of the surface in front of the groove articulates with the nasal surface of the maxilla and overlaps the orifice of the antrum by the **maxillary process,** a variable projection on the anterior border. Behind the groove the surface is rough for articulation with the maxilla below and the medial pterygoid plate above.

The medial or nasal surface presents two nearly horizontal ridges separating three shallow depressions. Of the depressions, the lower forms part of the inferior meatus of the nose, and the limiting ridge or **conchal** (inferior turbinate) **crest** articulates with the inferior nasal concha. Above this is the depression forming part of the middle meatus, and the ridge or **ethmoidal** (superior turbinate) **crest,** constituting its upper boundary, articulates with the middle nasal concha.

The upper groove is narrower and deeper than the other two and forms a large part of the superior meatus of the nose. The anterior border of the vertical plate is thin and bears the **maxillary process,** a tongue-like piece of bone, which extends over the opening of the maxillary sinus from behind. This border is continuous above with the orbital process. The posterior border is rough and articulates with the anterior border of the medial pterygoid plate. It is continuous superiorly with the sphenoidal process.

The pyramidal process or **tuberosity** fits into the notch between the lower extremities of the pterygoid plates and presents posteriorly three grooves. The middle, smooth and concave, completes the pterygoid fossa, and gives origin to a few fibers of the *internal pterygoid;* the medial and lateral grooves are rough for articulation with the anterior border of the corresponding pterygoid plate. Inferiorly, close to its junction with the horizontal plate, are the openings of the **greater palatine** and **smaller palatine canals,** of which the latter are less constant; they

FIG. 179.—PALATE BONE. (Posterior view.)



transmit the palatine nerves. Medially the pyramidal process gives origin to a few fibers of the *superior constrictor* of the pharynx, and laterally a small part appears in the infratemporal fossa between the tuberosity of the maxilla and the pterygoid process of the sphenoid.

The sphenoidal process, the smaller of the two processes surmounting the vertical part, curves upward and medially and presents three surfaces and two borders. **The superior surface** is in contact with the body of the sphenoid, and the top of the medial pterygoid plate, where it completes the **pharyngeal canal.** The **medial** or **inferior surface** forms part of the lateral wall and roof of the nasal fossa, and at its medial end touches the ala of the vomer. The **lateral surface** looks forward and laterally into the pterygopalatine (sphenomaxillary) fossa. Of the two borders, the posterior is thin and articulates with the medial pterygoid plate; the anterior border forms the posterior boundary of the **sphenopalatine** foramen.

The orbital process is somewhat pyramidal in shape, and presents for examination five surfaces, three of which—the posterior, anterior, and medial—are articular and the rest non-articular. **The posterior or sphenoidal surface** is small and joins the anterior surface of the body of the sphenoid; **the medial or ethmoidal** articulates with the labyrinth of the ethmoid; and **the anterior or maxillary,** which is continuous with the lateral surface of the perpendicular part, is joined with the maxilla. Of the two non-articular surfaces, the **superior or orbital,** directed upward and laterally, is slightly concave, and forms the posterior angle of the floor of the orbit; **the lateral or zygomatic,** smooth and directed laterally looks into the pterygopalatine (sphenomaxillary) and infratemporal fossæ, and forms the anterior boundary of the sphenopalatine foramen. The process is usually hollow and the cavity completes one of the posterior ethmoidal cells or communicates with the sphenoidal sinus.

Between the orbital and sphenoidal processes is the **sphenopalatine notch,** converted by the body of the sphenoid, into a complete foramen. It leads from the pterygopalatine fossa into the back part of the nasal cavity close to its roof, and transmits the medial branches from the sphenopalatine ganglion and the sphenopalatine vessels.

Blood-supply.—The palate bone receives branches from the descending palatine and the sphenopalatine arteries.

Articulations.—With the sphenoid, maxilla, vomer, inferior nasal concha, ethmoid, and its fellow of the opposite side.

Ossification.—The palate is ossified in membrane from a single center which appears about the eighth week at the angle between the horizontal and perpendicular parts. At birth the two parts are nearly equal in length, but as the nasal fossæ increase in vertical depth, the perpendicular part is lengthened until it becomes about twice as long as the horizontal part.

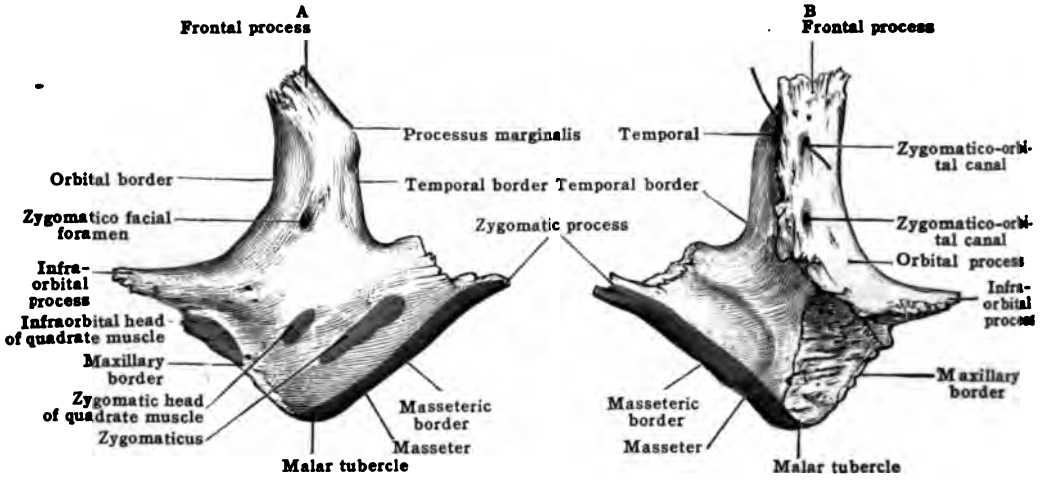
Variations.—Conversion of the sphenopalatine notch into a foramen (fig. 179) is rather frequent. Variation in the size of the orbital process is often observed; by enlargement it may reach the frontal bone in the medial wall of the orbit. The air-cell of this process may communicate with one of the posterior ethmoidal cells. The horizontal plate may be invaded by the maxillary antrum.

THE ZYGOMATIC

The **zygomatic** [os zygomaticum] or **malar bone** (fig. 180) forms the prominence of the cheek and joins the zygomatic process of the temporal with the maxilla. It is quadrangular in form with the angles directed vertically and horizontally. The **malar** (or external) **surface** is convex and presents one or two small orifices for the transmission of the zygomaticofacial nerves and vessels. It is largely covered by the *orbicularis oculi* and near the middle is slightly elevated to form the **malar tuberosity,** which gives origin to the ***zygomaticus*** and zygomatic head of the *quadratus labii superioris* muscle.

The **temporal** (or internal) **surface** is concave and looks into the temporal and infratemporal fossæ; it is excluded from the orbit by a prominent curved plate

FIG. 180.—THE LEFT ZYGOMATIC BONE.
A, the malar surface. B, the temporal and orbital surfaces.



of bone, the **orbital process,** which forms the anterior boundary of the temporal fossa. The upper part gives origin to a few fibers of the *temporal* muscle, while at the lower part is a large rough area for articulation with the zygomatic process of the maxilla.

The **orbital process** is placed at right angles to the remaining part of the bone and forms the anterior portion of the lateral wall of the orbit. On the **orbital surface** of the process are seen the foramina of two **zygomatico-orbital canals,** which transmit the zygomaticofacial and zygomaticotemporal branches of the zygomatic branch of the fifth, together with two small arteries from the lacrimal. In some cases, however, the canal is single at its commencement on the orbital plate and bifurcates as it traverses the bone. The rough free edge of the process articulates above with the zygomatic border of the great wing of the sphenoid, and below with the maxilla. When the orbital process is large, it excludes the great wing of the sphenoid from articulation with the maxilla, and the border then presents near the middle a short, non-serrated portion which closes the anterior extremity of the inferior orbital (sphenomaxillary) fissure.

All the four angles of the zygomatic bone have distinguishing features. **The superior,** forming the **frontosphenoidal process,** is the most prominent, and is serrate for articulation with the zygomatic process of the frontal; the anterior or **infraorbital process,** sharp and pointed, articulates with the maxilla and occasionally forms the superior boundary of the infra-

orbital foramen; the posterior or **temporal process** is blunt and serrated mainly on its medial aspect for articulation with the zygomatic process of the temporal; the inferior angle, blunt and rounded, is known as the **malar tubercle.**

Of the four borders, the **orbital** is the longest and extends from the frontosphenoidal to the **infraorbital process.** It is thick, rounded, and forms more than one-third of the circumference of the orbit; the **temporal border,** extending from the frontosphenoidal to the temporal process, is sinuously curved and gives attachment to the temporal fascia. Near the frontal angle is usually seen a slight elevation, the **processus marginalis,** to which a strong slip of the fascia is attached; the **masseteric** border, thick and rough, completes the lower edge of the zygomatic arch and gives origin to the anterior fibers of the *masseter;* the **maxillary** border, rough and concave, is connected by suture with the maxilla, and near the margin of the orbit gives origin to the infraorbital head of the *quadratus labii superioris.*

Blood-supply.—The arteries of the zygomatic are derived from the infraorbital, lacrimal, transverse facial, and deep temporal arteries.

Articulations.—With the maxilla, frontal, temporal, and sphenoid.

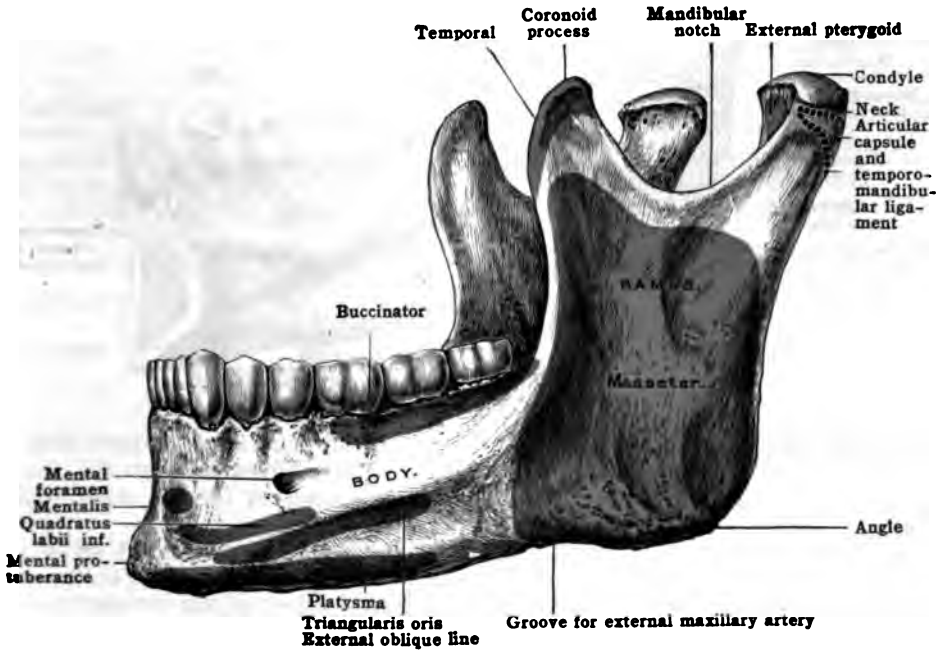
Ossification.—The zygomatic is ossified in membrane from three centers which appear in the eighth week of intrauterine life. The three pieces, which have received the names of *premalar, postmalar,* and *hypomalar,* unite about the fifth month.

Variations.—The canals and foramina, which transmit branches of the zygomatic ramus of the maxillary nerve, are subject to frequent variation in number and position. Occasionally the primary nuclei fail to coalesce, and the bone is then represented in the adult by two or three portions separated by sutures. The bipartite zygomatic has been observed in skulls obtained from at least a dozen different races of mankind, but because of its greater frequency in the crania of the Japanese (seven per cent.), the name of *os Japonicum* has been given to it.

THE MANDIBLE

The **mandible** [mandibula] or lower jaw-bone (figs. 181, 182) is the largest and strongest bone of the face. It supports the lower teeth, and by means of a pair of condyles, moves on the skull at the mandibular fossæ of the temporal

FIG. 181.—THE MANDIBLE. (Lateral view.)



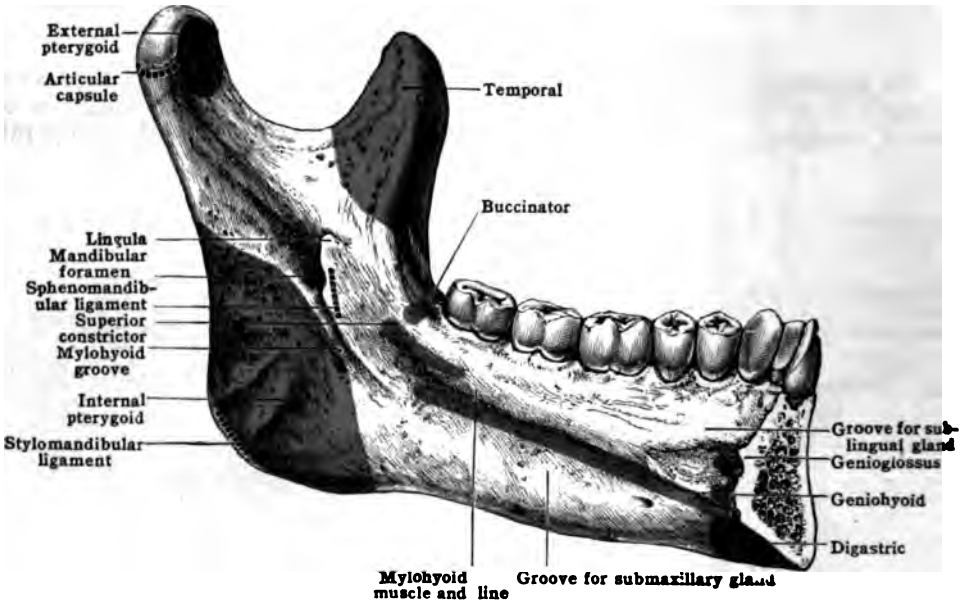
bones. It consists of a horizontal portion—the **body**—strongly curved, so as to somewhat resemble in shape a horseshoe, from the ends of which two branches or **rami** ascend almost at right angles.

The **body** is marked in the middle line in front by a faint groove which indicates the **symphysis** or place of union of the two originally separate halves of the bone. This ends below in the elevation of the chin known as the **mental protuberance,** the lowest part of which is slightly depressed in the center and raised on each side to form the **mental tubercle.** Each half of the mandible presents two surfaces and two borders. On the **lateral surface,** at the side of the symphysis, and below the incisor teeth, is a shallow depression, the **incisor**

fossa, from which the *mentalis* and *the incisivus labii inferioris* muscle arise; and more laterally, opposite the second bicuspid tooth, and midway between the upper and lower margins, is the **mental foramen,** which transmits the mental nerve and vessels. Below the foramen is the **oblique line,** extending backward and upward from the mental tubercle to the anterior border of the ramus; it divides the body into an upper or **alveolar** part and a lower or **basilar** part and affords origin to the *quadratus labii inferioris* and the *triangularis* muscles.

The **medial surface** presents at the back of the symphysis four small projections, forming the **mental spine** (genial tubercles). These are usually arranged in two pairs, one above the other; the upper comprising, a pair of prominent spines, gives origin to the *genioglossi,* and the lower, represented in some bones by a median ridge or only a slight roughness, gives origin to the *geniohyoid* muscles. At the side of the symphysis near the inferior margin is an oval depression, the **digastric fossa,** for the attachment of the anterior belly of the *digastric* muscle. Commencing below the mental spine, and extending upward and backward to the ramus, is the **mylohyoid line,** which becomes more prominent as it approaches the alveolar border; it gives attachment along its whole length to the *mylohyoid* muscle, at its posterior fifth to the *superior constrictor* of the pharynx,

FIG. 182.—THE MANDIBLE. (Medial view.)



and at the posterior extremity to the pterygomandibular raphe. Above this line at the side of the symphysis is a smooth depression [fovea sublingualis] for the sublingual gland, and below it, farther back, is another for the submaxillary gland.

The **alveolar part** or superior border is hollowed out into **eight sockets** or alveoli. These are conical in shape and form an exact counterpart of the roots of the teeth which they contain. From the lateral aspect of the alveolar process, as far forward as the first molar tooth, the *buccinator* muscle takes origin.

The **base** or inferior border is thick and rounded. In the anterior part of its extent it gives attachment to the *platysma,* and near its junction with the ramus is a groove for the external maxillary artery which here turns upward into the face.

The **ramus** is thinner than the body and quadrilateral in shape. The lateral surface is flat, gives insertion to the *masseter,* and at the lower part is marked by several oblique ridges for the attachment of tendinous bundles in the substance of the muscle. The medial surface presents near the middle the **mandibular** (inferior dental) **foramen,** leading into the **mandibular** (inferior dental) **canal.**

The canal traverses the bone and terminates at the mental foramen on the lateral surface of the body. From the canal, which in its posterior two-thirds is nearer to the medial, and in its anterior third nearer to the lateral, surface of the mandible, a series of small channels pass

upward to the sockets of the posterior teeth and transmit branches of the inferior alveolar (dental) vessels and nerve; in front of the mental foramen a continuation of the canal extends forward and conveys the vessels and nerves to the canine and incisor teeth. The mandibular foramen is bounded medially by a sharp margin forming the **lingula** (mandibular spine), which gives attachment to the sphenomandibular ligament. The posterior margin of the lingula is notched. This notch forms the commencement of a groove, the **mylohyoid groove** [sulcus mylohyoideus], which runs obliquely downward and forward and lodges the mylohyoid nerve and artery, and, in the embryo, Meckel's cartilage. Behind the spine is a rough area for the insertion of the *internal pterygoid* muscle.

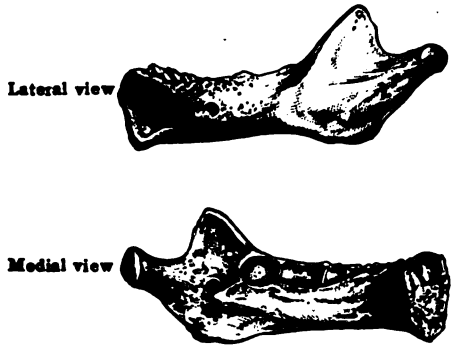
The posterior border of the ramus is thick and rounded, and in meeting the inferior border of the ramus forms the **angle** of the jaw, which is rough, obtuse, usually everted, and about 122° in the adult; the angle gives attachment to the

FIG. 183.—MANDIBLE SHOWING RELATIONS OF MECKEL'S CARTILAGE IN HUMAN FETUS OF 8 CM. CROWN-RUMP LENGTH. (After Kollmann.)

stylomandibular ligament. The inferior border is thick, rounded, and continuous with the base. The anterior border is continuous with the oblique line whilst the upper border presents two processes separated by a deep concavity, the **mandibular** (sigmoid) **notch.** Of the processes, the anterior is the **coronoid;** the posterior, the **condylar.**

The **condylar process** consists of the **condyle** [capitulum mandibulæ] and the narrowed portion by which it is supported, the **neck. The condyle** is oval in shape, with its long axis transverse to the upper border of the ramus, but oblique with regard to the median axis of the skull, so that the lateral extremity, which presents the **condylar tubercle** for the temporomandibular ligament of the

FIG. 184.—THE MANDIBLE AT BIRTH.



mandibular articulation, is a little more forward than the medial extremity. The convex surface of the condyle is covered with cartilage in the recent state, and rests in the mandibular fossa; the **neck** is flattened from before backward, and presents, in front, a depression [fovea pterygoidea] for the insertion of the *external pterygoid* muscle.

The **coronoid process,** flattened and triangular, is continued upward from the anterior part of the ramus. The lateral surface is smooth and gives insertion to the *temporal* and *masseter* muscles; the medial surface is marked by a ridge which descends from the tip and becomes continuous with the posterior part of the mylohyoid line. On the medial surface, as well as on the tip of the coronoid process, the *temporal* muscle is inserted. The **mandibular notch,** the deep semi-

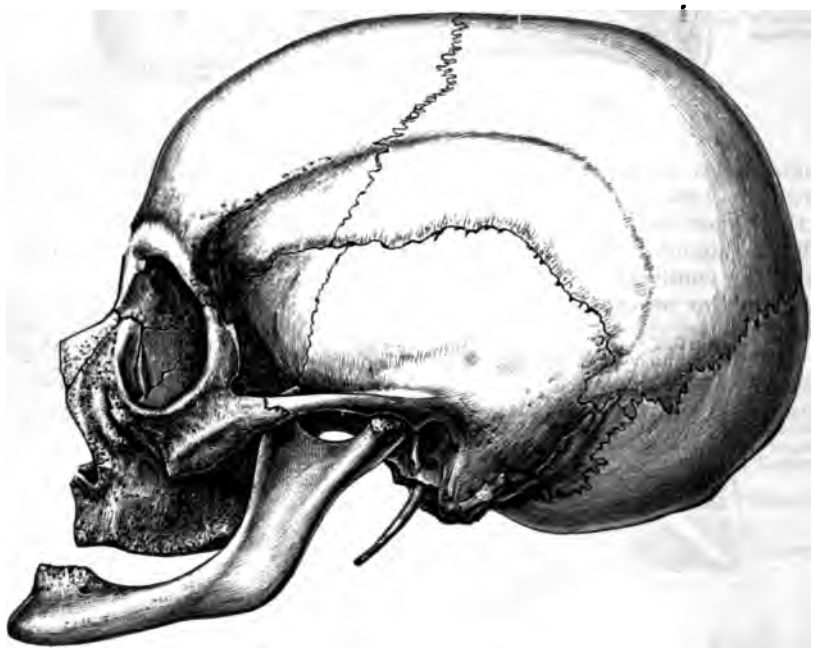
lunar excavation separating the coronoid from the condylar process, is crossed by the masseteric nerve and vessels.

Blood-supply.—Compared with other bones, the superficial parts of the mandible are not so freely supplied with blood. The chief artery is the inferior alveolar which runs in the mandibular canal, and hence, as the bone is exposed to injury and sometimes actually laid bare in its alveolar portion, it often necroses, especially if the artery is involved at the same time.

Ossification.—The mandible is mainly formed by ossification in the fibrous tissue investing the cartilage of the first branchial arch or Meckel's cartilage, although a small portion of the cartilage itself is directly converted into bone.

It is now generally admitted that the lower jaw is developed in membrane as a single skeletal element. The center of ossification appears in the sixth week of intrauterine life in the outer aspect of Meckel's cartilage and gives rise to the bony plate comparable to the *dentale* in lower animals. This plate extends forward right up to the midline in front, and from it a shelf grows upward for the support of the tooth-germs. Meckel's cartilage lies below and medial to the dentary plate, and the inferior alveolar nerve passes forward between the two structures. Meckel's cartilage itself takes some small part in the formation of the lower jaw. Ossification from the primary nucleus invades the cartilage at a point opposite the interval between the first and second tooth-germs, and the resulting bone contributes to the formation of the alveolar margin opposite these two teeth. Behind this point the cartilage atrophies except in so far as it helps to form the sphenomandibular ligament and the malleus and incus. Behind the symphysis the anterior extremity of the cartilage does not enter into the formation of the jaw, but it usually persists throughout fetal life as one or two small, rounded, cartilaginous masses. Occasionally they become ossified and give rise to accessory ossicles in this situation. The lamella of bone situated on the medial side of Meckel's cartilage, corresponding to the distinct splenial element in some animals, arises in man as an extension from the dentary element.

FIG. 185.—THE SKULL OF A WOMAN EIGHTY-THREE YEARS OLD, TO SHOW THE CHANGES IN THE MANDIBLE AND MAXILLA.



In connection with the condylar and coronoid processes, cartilaginous masses are developed. These do not, however, indicate separate elements, but are adaptations to the growth of the lower jaw. They are ossified by an extension from the surrounding membrane bone.

The process of ossification of the lower jaw commences as early as the thirty-ninth day (Mall), and proceeds rapidly, so that by the fourth month the various parts are formed.

Age-changes.—At birth the mandible is represented by two nearly horizontal troughs of bone, lodging unerupted teeth, and joined at the symphysis by fibrous tissue. The body is mainly alveolar, the basal part being but little developed; the condyle and the upper edge of the symphysis are nearly on a level; the mental foramen is nearer the lower than the upper margin, and the angle is about 175°. The inferior alveolar nerve lies in a shallow groove between the splenial and dentary plates.

During the first year osseous union of the two halves takes place from below upward, but is not complete until the second year. After the first dentition, the ramus forms with the body of the mandible an angle of about 140°, and the mental foramen is situated midway between the upper an lower borders of the bone opposite the second milk-molar. In the adult, the angle formed by the ramus and body is nearer to a right angle, and the mental foramen is opposite the second bicuspid, so that its relative position remains unaltered after the first dentition.

In old age, after the fall of the teeth, the alveolar margin is absorbed, the angle formed by the ramus and body is again increased, and the mental foramen approaches the alveolar margin. In a young and vigorous adult the mandible is, with the exception of the petrous portion of the temporal, the densest bone in the skeleton; in old age it becomes exceedingly porous, and often so soft that it may easily be broken.

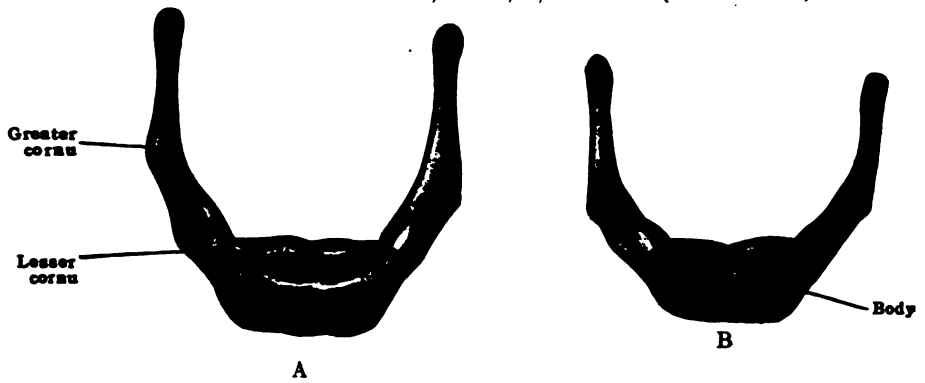
Variations.—Besides the extensive changes in weight and form to which the mandible is normally subjected in the life cycle many sorts of variation may occur. The chin may be protruding or receding. There may be but one eminence instead of a pair of mental tubercles. A median foramen is rarely present at the symphysis, comparable with an arterial canal normally present in certain apes. The coronoid and condylar processes vary considerably in form and size. They are rarely united with the rest of the ramus by sutures. A process of the inferior margin near the angle is often observed and has been compared with a similar spur in the jaws of carnivora.

THE HYOID BONE

The **hyoid bone** [os hyoideum] or os linguæ (fig. 186), situated in the anterior part of the neck between the chin and the thyroid cartilage, supports the tongue and gives attachment to numerous muscles. It is suspended from the lower extremities of the styloid processes of the temporal bones by two slender bands known as the **stylohyoid ligaments,** and is divisible into a **body** and two pairs of processes, the **greater** and **lesser cornua.**

The **body,** constituting the central portion of the bone, is transversely placed and quadrilateral in form. It is compressed from before backward and lies obliquely so that the anterior surface looks upward and forward and the posterior surface in the opposite direction.

FIG. 186.—THE HYOID BONE. A, MALE; B, FEMALE. (Natural Size.)



The **anterior surface** is convex and divided by a horizontal ridge into a superior and an inferior portion. Frequently it also presents a vertical ridge crossing the former at right angles, and just above the point of intersection is the **glossohyal** process, the vestige of a well-developed process is to be found in this situation in the hyoid bone of some of the lower animals. In this way four spaces or depressions for muscular attachments are marked off, two on either side of the middle line. The **posterior surface** is deeply concave and separated from the epiglottis by the thyrohyoid membrane, and by some loose areolar tissue. The membrane passes upward from the thyroid cartilage to be attached to the **superior border,** and interposed between it and the concavity on the back of the body is a small synovial bursa. The **inferior border,** thicker than the upper, gives insertion to muscles. The **lateral borders** are partly in relation with the greater cornua, with which they are connected, up to middle life, by synchrondrosis, but after this period, usually by bone.

The **greater cornua** projects upward and backward from the sides of the body. They are flattened from above downward, thicker near their origin, and terminate posteriorly in a rounded tubercle to which the thyrohyoid ligament is attached.

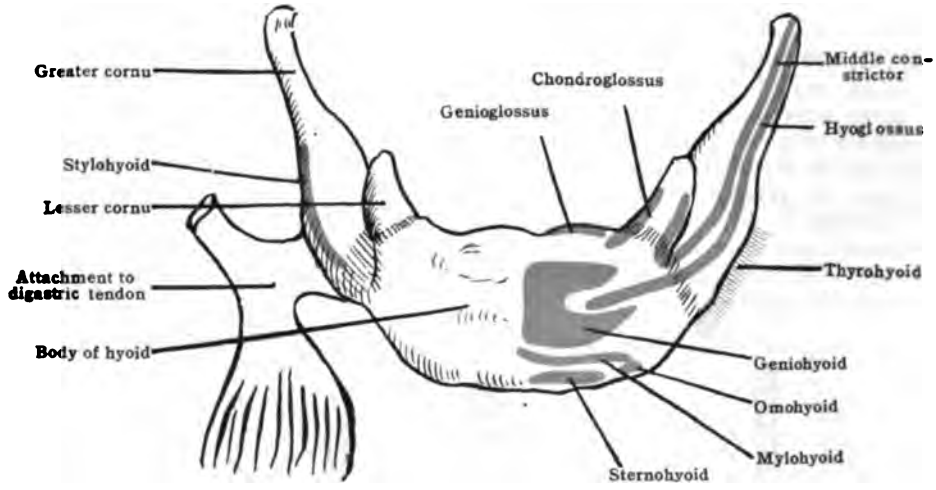
The **lesser cornua** are small conical processes projecting upward and backward opposite the lines of junction between the body and the greater cornua, and by their apices give attachment to the stylohyoid ligaments; they are connected to the body by fibrous tissue. Professor Parsons has shown that a joint with a synovial cavity is common between the smaller and greater cornua. The lesser cornua are sometimes partly or completely cartilaginous in the adult.

The **muscles** attached to each half of the hyoid bone may be enumerated as follows:—

Body.....Geniohyoid, genioglossus, mylohyoid, sternohyoid, omohyoid, stylohyoid, thyrohyoid and hyoglossus.
Greater cornu.....Thyrohyoid, middle constrictor, hyoglossus, and digastric.
Lesser cornu.....Chondroglossus, and middle constrictor.

Ossification.—In the early months of intrauterine life the hyoid bone is composed of hyaline cartilage and is directly continuous with the styloid processes of the temporal bones. Ossification takes place from six centers, of which two appear in the central piece of cartilage, one on either side of the middle line, either just before or just after birth; soon after their appearance, however, they coalesce to form the body of the bone (basihyal). The center for each of the greater cornua (thyreohyals) appears just about the time of birth, and for each of the lesser cornua (ceratohyals) some years after birth, even as late as puberty. (F. G. Parsons.) The greater cornua and the body unite in middle life; the lesser cornua rarely ankylose with the body and only in advanced age. Parsons has shown, however, that the lesser cornua more frequently unite with the greater cornua.

FIG. 187.—HYOID BONE ENLARGED TO SHOW MUSCULAR ATTACHMENTS. (After F. G. Parsons.)



THE MORPHOLOGY OF THE SKULL

In man the skull during development passes through three stages. At first the brain vesicles are enclosed in a sac of indifferent tissue which ultimately becomes tough and fibrous to form the **membranous cranium.** This, in turn, is partly converted into the membrane or roof bones of the cranium, whilst the remainder is represented in the adult by the dura mater. At the sides and base of the membranous cranium, however, cartilage is deposited, **chondrocranium,** in which as well as in the membranous tracts, osseous tissue appears in due course. Eventually, an **osseous box** is formed, consisting of membrane bones and cartilage bones intricately interwoven. For early stages and figure of the chondrocranium, see p. 28.

A study of the skull in the chondral stage is very instructive. It consists of two parts: (1) The skull proper and (2) the appendicular elements.

(1) The **skull proper** consists of three regions:—

(*a*) The **notochordal** region, which ultimately gives rise to the chief parts of the occipital bone and a part of the sphenoid. It is named notochordal because the notochord runs in it as far as the anterior extremity, i.e., the level of the fossa hypophyseos (sella turcica).

(*b*) Anterior to the notochordal is the **trabecular region,** from which the remainder of the sphenoid is developed.

(*c*) The most anterior part of the prechordal portion of the base is the **ethmovomerine region,** from which the nasal septum and its cartilages arise. These three parts continue forward the line of the vertebral axis, and constitute a *craniofacial axis* terminating, in front, in the premaxillæ. Finally, wedged in on each side, between the notochordal and trabecular regions, is the complicated **periotic** (auditory) capsule.

(2) The **appendicular elements** of the skull are a number of cartilaginous rods surrounding the visceral cavity—i. e., nose, mouth, and pharynx—which undergo a remarkable metamorphosis, and are represented in the adult by the *ear-bones*, the *styloid process*, and the *hyoid bone*. These rods of cartilage are named, from before backward, the **mandibular, hyoid,** and **thyroid** bars. They may with care be easily dissected in the fetus between the third and fourth months. For description of their metamorphosis, see p. 29.

In addition to these structures ossifications occur in the connective tissue of the maxillary process, a structure which may be regarded as forming the anterior part of the first branchial arch, and in the medial nasal process. The ossifications in the maxillary process give rise to the pterygoid (medial pterygoid process of the sphenoid), the palate, the maxilla, and the zygomatic, while that in the medial nasal process forms the premaxilla.

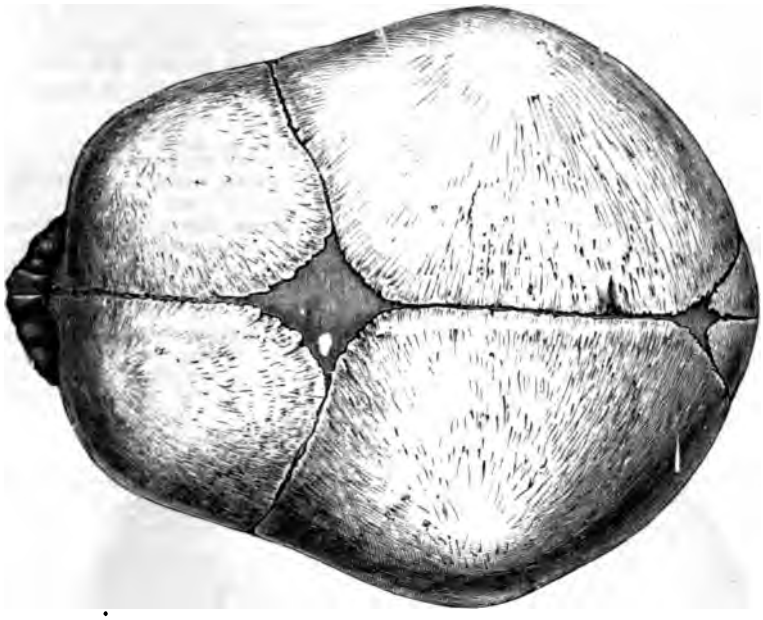
The Skull at Birth

The skull at birth presents, when compared with the adult skull, several important and interesting features. Its peculiarities may be considered under three headings:—The peculiarities of the fetal skull as a whole; the construction of the individual bones; the remnants of the chondral skull.

(1) *The General Characters of the Fetal Skull* (Figs. 188–190)

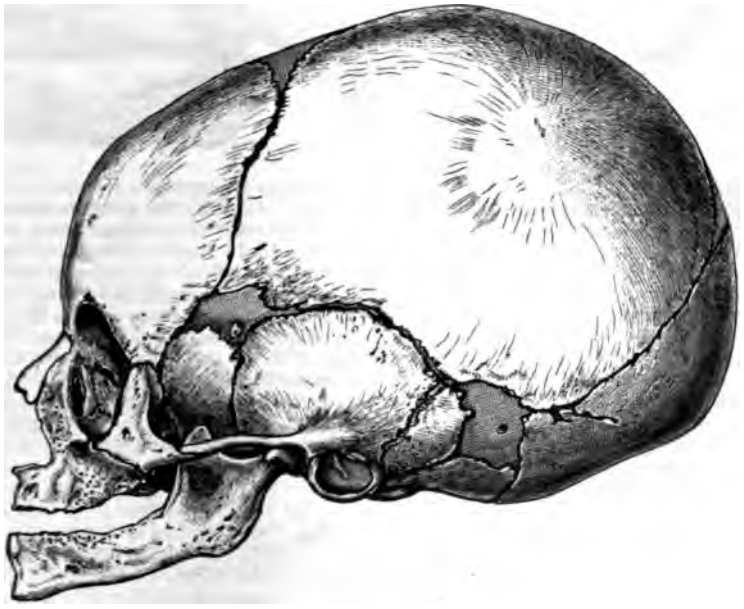
The most striking features of the skull at birth are, its relatively large size in comparison with the body, and the predominance of the cranial over the facial portion of the skull (8 to 1). The frontal and parietal eminences are large and conspicuous; the sutures are absent; the adjacent margins of the bones of the vault are separated by septa of fibrous tissue continuous

FIG. 188.—THE CRANIUM AT BIRTH. (Viewed from above.)



with the dura mater internally and the pericranium externally; hence it is difficult to separate the roof bones from the underlying dura mater, each being lodged, as it were, in a dense membranous sac. The bones of the vault consist of a single layer without any diploë, and their cranial surfaces present no digital impressions. Six membranous spaces exist, named fonta-

FIG. 189.—THE CRANIUM AT BIRTH. (Lateral view.)



nelles: two are median, the frontal [fonticulus frontalis; major] being anterior and the occipital [fonticulus occipitalis; minor] posterior. Two exist on each side, termed anterior [fonticulus sphenoidalis] and posterior [fonticulus mastoideus] lateral fontanelles. Each angle of the parietal bones is in relation with a fontanelle. The anterior fontanelle is lozenge-shaped, the poste-

rior triangular. The lateral fontanelles are irregular in outline. The lateral fontanelles close soon after birth; the occipital fontanelle closes in the first year, and the frontal during the second year. For further details on the fontanelles, see p. 29.

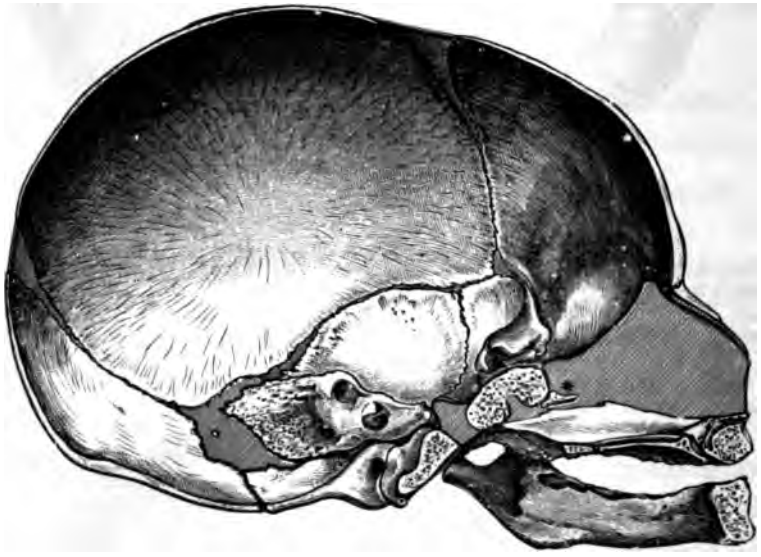
Turning to the base of the skull, the most striking points are the absence of the mastoid processes, and the large angle which the pterygoid plates form with the skull-base, whereas in the adult it is almost a right angle. The base of the skull is relatively short, and the lower border of the mental symphysis is on a level with the occipital condyles.

The **facial skeleton** is relatively small in consequence of the small size of the nasal fossæ, the small size of the maxillary sinus, and the rudimentary condition of the alveolar borders of the maxillæ and mandible; the nasal fossæ are as wide as they are high, and are almost filled with the conchæ. Growth takes place rapidly in the first seven years after birth. There is a second period of rapid growth at puberty, when the air-sinuses develop, and this affects especially the face and frontal portion of the cranium. For further details on the growth of the skull, see p. 29.

(2) *The Peculiarity of Individual Bones at Birth*

The **occipital bone** (fig. 134) consists of four distinct parts, which have already been described. Compared with the adult bone, the following are the most important points of distinction:—There is no **pharyngeal tubercle** or **jugular process**; the squamous portion presents two deep fissures separating the interparietal from the supraoccipital portion and extending medially as far as the occipital protuberance. The grooves for the transverse (lateral) sinuses are absent.

FIG. 190.—THE CRANIUM AT BIRTH IN SAGITTAL SECTION. (Sphenoidal concha indicated by a *.)



The **sphenoid** (see fig. 146) in a macerated fetal skull falls into three pieces: (1) united pre- and post-sphenoids, orbitosphenoids, and linguläe, and (2 and 3) the **alisphenoids**. The presphenoid is quite solid and connected with the ethmovomerine cartilage, and presents but traces of the air-sinus which occupy this part in the adult skull. The presphenoid by its upper surface forms part of the anterior cranial fossa, from which it is subsequently excluded by the growth of the orbitosphenoids. The optic foramina are large and triangular in shape. The **linguläe** stand out from the basisphenoid as two lateral buttresses, and at the tuberculum sellæ is the **basipharyngeal canal**, which in the recent bone is occupied by fibrous tissue. The **dorsum sellæ** is still cartilaginous. The **alisphenoids** with the pterygoid processes are separated from the rest of the bone by cartilage. The foramen rotundum is complete, but the future foramen ovale is merely a deep notch in the posterior border of the great wing, and there is no foramen spinosum. The pterygoid processes are short, and each medial pterygoid plate presents a broad surface for articulation with the lingula. The **pterygoid canal** is a groove between the medial pterygoid plate, the lingula, and great wing.

The **temporal bone** at birth (figs. 151–153, 161) consists of three elements, the **petrosal**, **squamosal**, and **tympanic**. The **petrosal** presents a large and conspicuous floccular (subarcuate) fossa; the hiatus canalis facialis (Fallopii) is a shallow bay lodging the geniculate ganglion of the facial nerve. There is a relatively large mastoid antrum, but no mastoid process. The styloid process is unossified, but the **tympanohyal** may be detected as a minute rounded nodule of bone near the stylomastoid foramen.

The **squamosal** has a very shallow mandibular fossa and a relatively large postglenoid tubercle. The posterior part of the inferior border is prolonged downward into an uncinate process (*postauditory process*) which closes the mastoid antrum laterally.

The **tympanic** bone or annulus is a delicate, horseshoe-shaped ossicle, attached by its anterior and posterior extremities to the inferior border of the squamosal.

The **ear-bones** are chiefly of interest from their size, for they are as large at birth as in the adult. The anterior (Folian) process may be 2 cm. in length.

The **frontal** (fig. 140) consists of two bones separated by a median vertical (metopic) suture. The frontal eminence is very pronounced, but the superciliary arches and frontal sinuses are wanting. The frontal spine, which later becomes one of the most conspicuous features of this bone, is absent. There is no temporal line.

The **parietal** (figs. 188–189) is simply a quadrilateral lamina of bone, concave on its inner and convex on the outer surface. The parietal eminence, which indicates the point at which the ossification of the bone commenced, is large and prominent. The grooves for blood-sinuses, as in other cranial bones, are absent. Each angle of the parietal is in relation with a fontanelle. As in the adult, the anterior inferior angle of the bone is prolonged downward toward the alisphenoid.

The **ethmoid** consists of two lateral portions separated by the still cartilaginous ethmovomerine plate. The ethmoid cells are represented by shallow depressions, and the uncinate process is undeveloped.

The **sphenoidal conchæ** are two small triangular pieces of bone lying in the perichondrium on each side of the ethmovomerine plate near its junction with the presphenoid. (Indicated by the * in fig. 190.)

The **maxilla** (fig. 176) presents the following characters:—The incisive suture is visible on the palatine aspect of the bone. The alveolar border presents five sockets for teeth. The infraorbital foramen communicates with the floor of the orbit by a deep fissure; this fissure sometimes persists in the adult. The sinus is a shallow depression.

The **mandible** at birth (figs. 184, 189, 190) consists of two halves united by fibrous tissue in the line of the future symphysis. Each half is a bony trough lodging teeth. The trough is divided by thin osseous partitions into five compartments: of these, the fifth is the largest, and is often subdivided by a ridge of bone. The floor is traversed by a furrow as far forward as the fourth socket (that for the first milk molar), where it turns outward at the mental foramen. This furrow lodges the inferior alveolar nerve and artery, which enter by the large mandibular foramen. The condyle is on a level with the upper border of the anterior extremity of the bone.

The **palate bones** differ mainly from those in the adult in that the vertical and horizontal plates are of the same length; thus the nasal fossæ in the fetus are as wide as they are high, whereas in the adult the height of each nasal fossa greatly exceeds the width.

Concerning the remaining bones little need be said. The **vomer** (fig. 190) is a delicate trough of bone for the reception of the inferior border of the ethmovomerine plate; its inferior border, which rests upon the hard palate, is broad, and the bone presents quite a different appearance from that in the adult. The **nasal bones** are short and broad; the **zygomatics** and **inferior conchæ** are relatively very large; and the **lacrimals** are thin, frail, and delicate lamellæ.

The **hyoid** consists of five parts. There is a median nucleus for the basihyal, and one on each side for the greater cornua (thyrohyals). The lesser cornua are cartilaginous.

(3) *Remnants of the Cartilaginous Cranium*

It has already been pointed out that at an early date the base of the skull and the face are represented by hyaline cartilage, which for the most part is replaced by bone before birth. Even at birth remnants of this primitive chondral skull are abundant. In the cranium, cartilaginous tracts exist between the various portions of the occipital bone, as well as at the line of junction of the occipital with the petrosal and sphenoid. The dorsum sellæ is entirely cartilaginous at birth, and the last portion of this cartilage disappears with the ankylosis of the basioccipital and basisphenoid about the twentieth year. A strip of cartilage unites the alisphenoids with the lingulæ, and for at least a year after birth this cartilage is continuous with that which throughout life occupies the foramen lacerum. A strip of cartilage exists along the posterior border of the orbitosphenoid, and not infrequently extends lateralward to the pterion. In the adult skull it is replaced by ligamentous tissue.

The **ethmovomerine plate** (fig. 190 is entirely cartilaginous, and near the end of the nose supports the lateral nasal cartilages, remnants of the frontonasal plate. The fate of the ethmovomerine pla e is instructive. The upper part is ossified to form the mesethmoid; the lower part atrophies from the pressure exerted by the vomer; the anterior end remains as the septal cartilage. The lateral snout-like extremities of the frontonasal plate persist as the lateral cartilages of the nose. Among the appendicular elements of the skull, the styloid process and a large portion of the hyoid are cartilaginous at birth.

The Nerve-foramina of the Skull

The various foramina and canals in the skull which give passage to nerves may be arranged in two groups, **primary** and **secondary**. **Primary** foramina indicate the places where the nerves leave the general cavity of the dura mater, and as this membrane indicates the limit of the primitive cranium, a cranial nerve, in a morphological sense, becomes extracranial at the point where it pierces this membrane. The primary foramina are the formen magnum, the hypoglossal, jugular, auditory, trigeminal, petrosphenoidal and optic foramina. In consequence of the complicated and extraordinary modifications the vertebrate skull has undergone, many nerves traverse, in the adult skull, bony tunnels and canals which are not represented in the less complex skulls of low vertebrates, such as sharks and rays. To such foramina and canals the terms **secondary** or **adventitious** may be applied. These include the superior orbital fissure, foramen rotundum, foramen ovale, ethmoidal canals, infraorbital canal, zygomaticotemporal foramen, zygomaticofacial canals, sphenopalatine foramen, Scarpa's foramen, pharyngeal foramen, pterygoid (Vidian) canal, posterior palatine canal, mandibular (inferior dental) canal, stylomastoid foramen, iter chordæ posterius, iter chordæ anterius, petrotympanic fissure, and inferior orbital fissure.

CRANIOMETRY

Among normal human individuals of all races the **capacity of the cranial cavity**, which is used in calculating the size of the brain, is between 1000 and 1800 c.c. with an average of 1400 c.c. Crania having a capacity below 1350 are *microcephalic;* those exceeding 1450, *megacephalic;* ranging between these figures, *mesocephalic.* The capacity is found by carefully filling the cranial cavity with shot and then measuring the latter.

The greatest **length of the cranium** is measured between the glabella and the point in the midline of the occiput furthest removed—the *occipital point.* The **breadth of the cranium** is the greatest transverse diameter above the level of the supramastoid ridges. The **cephalic index** is obtained by finding the proportion between the maximum length and breadth. $\frac{100 \times \text{breadth}}{\text{length}}$. Skulls having a cephalic index between 75 and 80 are *mesaticephalic;* above 80, *brachycephalic;* below 75, *dolichocephalic.*

The horizontal **circumference of the cranium** is measured passing around the skull through the glabella and occipital point.

The *basibregmatic height* (from basion to bregma) is used in determinations of the **height of the cranium**: $\frac{100 \times \text{length}}{\text{height}}$ = *index of height:* 70–75, *metriocephalic;* below 70, *tapeinocephalic* above 75, *akrocephalic.*

The degree of facial prominence is indicated by the **facial angle**, made with the horizontal by a line from the frontal prominence to the anterior nasal spine. Since the prominence of the face is almost purely prominence of the jaws, the modern method of measuring is by a **gnathic (jaw) index;** that proposed by Flower is a comparison of the basialveolar (basion to alveolar point) with the basinasal length (basion to nasion). When the gnathic index is below 98, the skull is *orthognathous;* above 103, *prognathous;* between 98 and 103, *mesognathous.*

The **form of the face** is determined by comparing the height and breadth (nasio-mental height and bizygomatic breadth); the face is *leptoprosopic* when the index is 90.1 or above; *chameprosopic,* below 90.1.

The **orbital index** is obtained by comparing the vertical height of the aditus orbitæ to its transverse breadth: index between 89–84 is *mesoseme;* below 84, *microseme;* above 89, *megaseme.*

The **nasal index** is derived by comparing the height of the nose (nasion to subnasal point) with the maximum width of the pyriform aperture. A skull having a nasal index under 48 is *leptorhine;* above 53, *platyrhine;* between 48 and 53, *mesorhine.*

Size of the teeth varies considerably among the races, with tendency to be larger in savage peoples. The **dental index** of Flower is; dental length (distance between anterior surface of first premolar and posterior surface of third molar), compared with the basinasal length. Teeth are *mesodont* when the index is between 42 and 44; *microdont,* below 42; *megodont,* above 44.

C. THE THORAX

The **thorax** is a bony cage (figs. 203, 204) formed by the thoracic vertebræ already described, the ribs with their costal cartilages, and the sternum. It serves to protect and support the thoracic viscera and in connection with the musculature of the ribs performs important respiratory functions. The red marrow of the cancellous tissue of the ribs and sternum is one of the chief seats of the red blood-corpuscle formation.

THE RIBS

The **ribs** [costæ] (figs. 191, 192) twelve in number on each side, constitute a series of narrow, flattened bones, extending from the sides of the thoracic vertebræ toward the median line on the anterior aspect of the trunk. The anterior ends of the first seven pairs are connected, by means of their costal cartilages, with the sides of the sternum, and on this account the first seven ribs on each side are termed **true** or sternal ribs. The remaining five pairs, known as **false** or asternal ribs, may be arranged in two sets:—one, including the eighth, ninth, and tenth ribs, in which the cartilages of the anterior extremities are connected together, and the other, including the eleventh and twelfth, in which the anterior extremities, tipped with cartilage, are free. The eleventh and twelfth are known, in consequence, as the **floating** ribs. Thus, the first seven are **vertebrosternal;** the eighth, ninth, and tenth, **vertebrochondral;** the eleventh and twelfth, **vertebral** ribs.

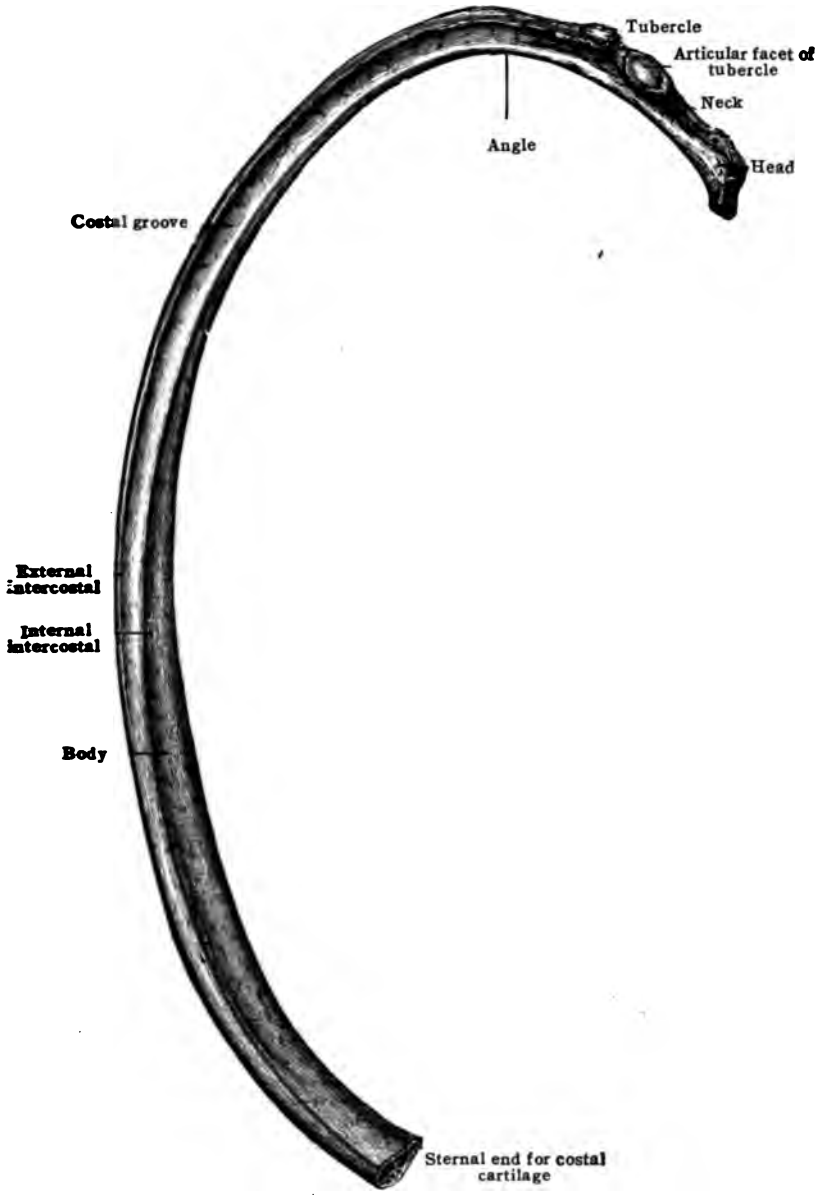
The ribs increase in length from the first to the seventh, and decrease from the seventh to the twelfth. They also vary in their direction, the upper ones being less oblique than the lower. The obliquity is greatest at the ninth rib and gradually decreases from the ninth to the twelfth.

Typical characters of a rib (fig. 191).—The seventh is regarded as the most typical rib. It presents a vertebral extremity or **head**; a narrow portion or **neck**; a **sternal** extremity; and an intermediate portion, the **body** or **shaft.**

The **head** [capitulum costæ] presents an **articular surface** made up of two articular facets separated by a horizontal **crest** [crista capituli].

The crest is connected by an interarticular ligament with an intervertebral disk, and the facets articulate with the costal pits on the sides of the bodies of two vertebræ (sixth and

FIG. 191.—THE SEVENTH RIB OF THE LEFT SIDE. (Seen from below.)



seventh). As a rule, the lower facet is the larger, and articulates with the thoracic vertebra, to which the rib corresponds in number. This is the p imary facet, and is the one represented in those ribs which possess only a single facet on the rib-head. The anterior margin is lipped for the attachment of the radiate ligament.

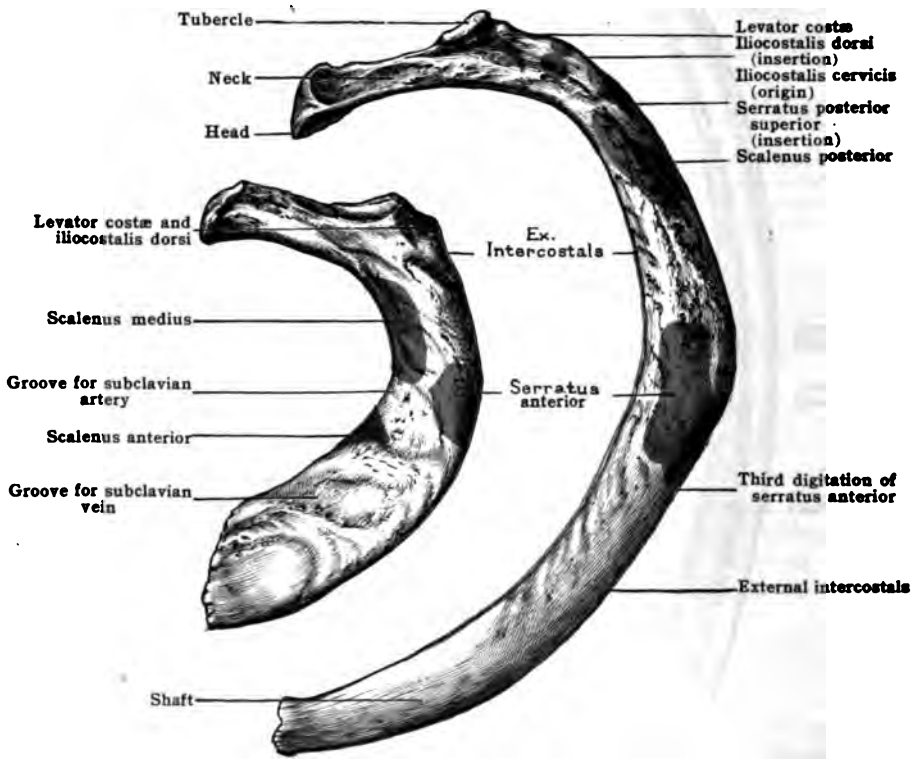
The **neck** [collum costæ] is that portion of the rib extending from the head to the **tubercle.** It is flattened from before backward and is in relation posteriorly with the transverse process of the lower of the two vertebræ with which the head articulates; it forms the anterior boundary of the **costotransverse foramen.**

It is rough where it is attached to the neck ligament [lig. colli costæ]. The anterior surface is flat and smooth. The superior border of the neck, continuous with the corresponding border of the shaft, presents a rough crest [crista colli] for the anterior costotransverse ligament. The inferior border of the neck is rounded and continuous with the ridge of the **costal groove.**

The **tubercle,** situated behind at the junction of the neck with the shaft, consists of an upper and lateral part, rough for the attachment of the posterior costotransverse ligament, and a lower and medial part, bearing a facet for articulation with a pit near the tip of the transverse process. The tubercle projects below the lower edge of the rib to form a crest, marking the beginning of the costal groove.

The **body** is strongly curved and presents two surfaces and two borders. At first the curve is in the same plane as the neck, but it quickly turns forward at a point on the posterior surface of the shaft known as the **angle,** where it gives attachment to the *iliocostalis* muscle and some of its subdivisions. The rib has also a second or upward curve, beginning at the angle. These curves are expressed by describing the main curve as disposed around a vertical, and the second or upward curve around a second transverse axis.

FIG. 192.—FIRST AND SECOND RIBS. (Viewed from above.)



Besides the two curves now described, the rib is slightly twisted on itself, so that the surfaces which look medially and laterally behind are placed obliquely in front and look downward as well as medially, and upward as well as laterally.

The **external surface** of the rib is convex, and gives attachment to muscles. Near its anterior extremity it forms a somewhat abrupt curve, indicated by a ridge on the bone, which gives attachment to the *serratus anterior* (*magnus*) muscle, and is sometimes called the **anterior angle**

The **internal surface** is concave and presents near its inferior border the **costal groove** [sulcus costæ]. The groove is best marked near the angle, and gradually becomes shallower toward the anterior extremity of the rib, where it is finally lost; it lodges the intercostal vessels and nerve. The ridge limiting the groove above is continuous with the inferior border of the neck of the rib, and gives attachment to the *internal intercostal* muscle.

The **superior border** is rounded, and affords attachment to the *internal* and ***external intercostal*** muscles. The **inferior border** commences abruptly near the angle, and gives attachment to the *external intercostal* muscle.

The **sternal** end of the shaft is cupped for the reception of the costal cartilage.

Blood-supply.—The ribs are very vascular and derive numerous branches from the intercostal arteries. The branches in the shaft run toward the vertebral end, whilst those in the head and neck run, as a rule, toward the shaft. In the neighborhood of the tuberosity the vessels do not seem to have any constant arrangement.

Peculiar ribs (figs. 192, 193).—Several ribs present certain peculiarities and differ in many particulars from the general description given above. These are the first, second, tenth, eleventh and twelfth.

The **first rib** (fig. 192) is the broadest, shortest, and most curved of all the series. It is not twisted, and is so placed that its superior surface looks forward as well as upward, and its inferior surface backward as well as downward. The head is small, and as a rule is furnished with only one articular facet. The neck, longer than that of most of the ribs, is slender and rounded. The tubercle is large and prominent. The shaft lies for its whole extent nearly in one plane, has no angle, and is curved in one direction only, i. e., around a vertical axis. The superior surface presents two shallow grooves, separated near the inner border by a rough surface (**scalene tubercle** or tubercle of Lisfranc) for the *scalenus anterior* muscle. The groove in front of this surface is for the subclavian vein and the groove behind it is for the subclavian artery and a nerve trunk passing to the brachial plexus. Between the groove for the artery and the tubercle is a rough surface for the insertion of the *scalenus medius*, and between the groove and the outer margin is an area for the origin of the *serratus anterior* (*magnus*). The inferior surface is uniformly flat and lacks a subcostal groove. By the lateral portion, which is rough,

XII

it gives attachment to the internal intercostal muscle; the remainder of the inferior surface is in relation to pleura and lung. The lateral border is thick and rounded, and gives attachment to the *external intercostal* muscle, whilst the medial border, thin, sharp, and concave, receives the attachment of the fascia (Sibson's) covering the dome of the pleura. The anterior extremity is thick and broad, and its upper margin, as well as the cartilage to which it is joined, afford attachment to the costoclavicular ligament and the *subclavius* muscle. The costal cartilage of this rib is directly united to the manubrium sterni, and occasionally the cartilage and the adjoining part of the anterior extremity of the rib are replaced by fibrous tissue. The rib derives its nutrition mainly from the superior intercostal branch of the subclavian artery.

The **second rib** (fig. 192) is much longer than the first, and although like it in being strongly curved round a vertical axis, in its form and general character there is a closer resemblance to the ribs lower down in the series. The head is round and present two facets, the costal groove is present, though faintly marked, and an angle is situated near the tubercle. The specially distinguishing feature of the rib, however, is a well-marked tuberosity on its outer surface somewhat near the middle, for the origin of a part of the first digitation, and the whole of the second digitation of the *serratus anterior* (*magnus*). Between the tuberosity and the tubercle the outer surface is smooth and rounded and gives attach ent to the *scalenus posterior*, the *serratus posterior superior*, the *iliocostalis cervicis* (*cervicalis ascendens*), and the *liocostalis dorsi* (*accessorius*). The internal surface is smooth and in relation to the pleura. The borders give attachment to the *intercostal* muscles, the upper, to those of the first space, the lower, to those of the second. The shaft of the second rib is not twisted on its own axis, so that both ends can lie flat on the table. The second rib receives vessels from the superior intercostal branch of the subclavian artery and the first aortic intercostal.

The **tenth rib** (fig. 193) is distinguished by a single facet on the head for articulation with

the body of the tenth thoracic vertebra. Occasionally there are two facets, in which case the rib articulates also with the ninth thoracic vertebra. The tenth rib, like the ribs immediately above, is long, curved, presents a deep costal groove, a well-marked tuberosity and an angle. It may be noted, however, that the distance between the tubercle and the angle in this rib is greater than in the ribs above. Speaking generally, the distance between these points increases from above downward.

The **eleventh rib** is peculiar in that it has a single facet on the head, a feebly marked angle some distance from the head, a shallow costal groove, no tubercle, and no neck. The tubercle is sometimes represented by a slight elevation or roughness without any articular facet. The anterior extremity is pointed.

The **twelfth rib** has a large head furnished with one facet for articulation with the root (pedicle) of the twelfth thoracic vertebra. The shaft is narrow and extremely variable in length (3 to 20 cm.). It is usually somewhat longer than the first rib, but it may be shorter. There is no tubercle, no angle, no neck, no costal groove. The anterior extremity is pointed. Posteriorly, the upper border is smooth and rounded; the lower border is sharp and rough.

The **costal cartilages** are bars of hyaline cartilage attached to the anterior extermities of the ribs. Like the shaft of a rib, each cartilage has an outer and inner surface. The outer surfaces give origin and insertion to large muscles, and the inner surfaces, from the second to the

The cartilaginous shaft commences to ossify at the eighth week of intrauterine life

sixth inclusive, are in relation with the *transversus thoracis* (*triangularis sterni*). The upper and lower borders serve for the attachment of the *internal intercostal* muscles. The upper seven cartilages, and occasionally the eighth, are connected with the sternum. Of these, the first fuses with the manubrium sterni and the remaining six are received into small articular concavities, and retained by means of ligaments. The cartilages of the vertebrochondral ribs are united to one another and to the seventh costal cartilage by ligaments (sometimes by short vertical bars of cartilage), while those of the vertebral ribs form no such attachment, but lie between the abdominal muscles. The inner surfaces of the lower six costal cartilages afford attachment to the *diaphragm* and the *transversalis* muscle.

Each of the second, third, fourth, and fifth costal cartilages articulates with the side of the sternum, at a point corresponding to the junction of two sternebræ. The sixth and seventh (and eighth when this reaches the sternum) are arranged irregularly. As a rule, the sixth lies in a recess at the side of the fifth sternebra; the seventh corresponds to the line of junction of the meso- and metasternum; and the eighth articulates with the metasternum (fig. 195).

Blood-supply.—The costal cartilages derive their blood-supply from the terminal twigs of the aortic intercostals and from the internal mammary arteries. They are distributed to the perichondrium. (Blood supply of ribs noted above.)

Ossification.—At the eighth week of intrauterine life the ribs are cartilaginous. About this time a nucleus appears near the angle of each rib, and spreads with great rapidity along the

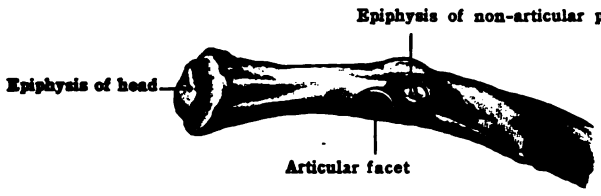
shaft, and by the fourth month reaches as far as the costal cartilage. At this date the length of rib-shaft bears the same proportion to that of the costal cartilage as in adult life. Whilst the ribs are in a cartilaginous condition, the first eight reach to the side of the sternum, and even after ossification has taken place, the costal cartilage of the eighth rib, in many instances, retains its articulation with the sternum up to as late as the eighth month (fig. 195). This relationship may persist through life, but usually the cartilage retrogresses, and is replaced by ligamentous tissue. About the fifteenth year a secondary center appears for the head of each rib, and a little later one makes its appearance for the tubercle, except in the eleventh and twelfth ribs. Frequently epiphyses are developed on both parts of the tubercle (see figs. 196 and 197). The epiphyses fuse with the ribs about the twenty-third year. The rib-shaft increases in length mainly at its line of junction with the costal cartilage.

Variations.—The ribs may be increased in number by addition either at the cervical or lumbar end of the series, but it is extremely rare to find an additional rib or pair of ribs in both the cervical and lumbar regions in the same subject.

FIG. 195.—THE THORAX AT THE EIGHTH FETAL MONTH.
(On the left side eight cartilages reach the sternum.)

Cervical ribs are fairly common; as a rule, they are of small size and rarely extend more than a few mm. beyond the extremity of the transverse process. (For their morphology, see also p. 1365.) Occasionally they exceed such insignificant proportions and reach as far as the sternum; between these two extremes many varieties occur. In one case Turner was able to make a thorough dissection of a specimen in which a complete cervical rib existed. Its head articulated with the body of the seventh cervical vertebra and had a radiate ligament. The tubercle was well developed, and articulated with the transverse process. The costal cartilage blended with that of the first thoracic rib, and gave attachment to the costoclavicular ligament. Between it and the first thoracic rib there was a well-marked intercostal space occupied by intercostal muscles. It received the attachment of the *scalenus anterior* and *medius* muscles, and it was crossed by the subclavian artery and vein. The nerves of the intercostal space were

FIG. 196.—POSTERIOR PORTION OF THE SIXTH RIB IN THE FIFTEENTH YEAR.
(After Toldt.)



supplied by the eighth cervical and first thoracic. The artery of the space was derived from the deep cervical, which, with the superior intercostal, arose from the root of the vertebral. The head of the first thoracic rib in this specimen articulated with the seventh cervical, as well as with the first thoracic vertebra. In this specimen, there was no movable twelfth thoracic rib on the same side as this well-developed cervical rib; the twelfth thoracic vertebra had mammillary and accessory processes, and a strong elongated costal process, and was in linear series with the lumbar transverse processes.

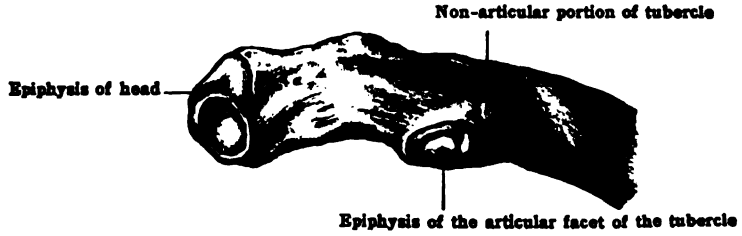
Gruber and Turner, from a careful and elaborate study of this question, summarise the variations in the cervical rib thus:—It may be very short and possess only a head, neck, and tubercle. When it extends beyond the transverse process, its shaft may end freely or join the first thoracic rib: this union may be effected by bone, cartilage, or ligament. In very rare instances it may have a costal cartilage and join the manubrium of the sternum. Not unfrequently a process, or eminence, exists on the first thoracic rib at the spot where it articulates

with a cervical rib. For a recent discussion of the subject of cervical ribs see Todd, Jour. Anat. & Phys., vols. 46 and 47.

Lumbar ribs are of less significance than cervical ribs and rarely attain a great length. Their presence is easily accounted for, as they are the differentiated costal elements of the transverse processes. They are never so complete as the cervical ribs, and articulate only with the transverse processes; the head never reaches as far as the body of the vertebra, and there is no neck or tubercle. An extra *levator costæ* muscle is associated with a lumbar rib.

An interesting variation is that known as the bicipital rib. This condition is seen exclusively in connection with the first thoracic rib. The vertebral end consists of two limbs which lie in different transverse planes. These bicipital ribs have been especially studied in whales and man. This abnormality is due to the fusion of two ribs, either of a cervical rib with the shaft of the first thoracic; or the more common form, the fusion of the first and second true ribs. Among unusual variations of ribs should be mentioned the replacement of the costal cartilage and a portion of the rib-shaft by fibrous tissue, a process which occurs normally in the case of the eighth rib during its development. Sometimes the shafts of two or more ribs may become united by small quadrilateral plates of bone extending across the intercostal spaces.

FIG. 197.—POSTERIOR PORTION OF THE SIXTH RIB IN THE EIGHTEENTH YEAR. (After Toldt.)



THE STERNUM

The **sternum** (figs. 198, 199) is a flat, oblong plate of bone, situated in the anterior wall of the thorax, and divisible into three parts—(1) the **manubrium sterni** (presternum), (2) the **corpus sterni** (mesosternum), constituting the **body** of the bone, and (3) the **xiphoid** (or ensiform) **process** (metasternum). In the young subject it consists of six segments (sternebræ). Of these, the first remains separate throughout life and forms the manubrium; the succeeding four segments fuse together, forming the body; while the lowest segment, also distinct until middle life, is represented by the xiphoid process.

In its natural position the sternum is inclined obliquely from above downward and forward, and corresponds in length to the vertebral column from the third to the ninth thoracic vertebra. It is not of equal width throughout, being broader above at the manubrium and narrow at the junction of this piece with the body. Toward the lower part of the body the sternum again widens, and then suddenly contracts at its junction with the xiphoid process which constitutes the narrowest part.

The **manubrium** or first piece of the sternum forms the broadest and thickest part of the bone, and is of a somewhat triangular form with the base directed upward and the apex downward. It represents two surfaces and four borders. The **anterior surface** [planum sternale] is largely subcutaneous. It is slgihtly convex and directed obliquely upward and forward, is smooth and gives origin on each side to the sternal head of the *sternomastoid* and the *pectoralis major*. The **posterior surface,** almost flat, and directed downward and backward, affords origin near the lateral margins on each side, to the *sternohyoid* muscle above and the *sternothyroid* muscle below. Of the four borders, the **superior** is the longest and much the thickest. In the middle is a curved, non-articular depression, called the **jugular** (interclavicular) **notch,** to which the fibers of the interclavicular ligament are attached, and at either end is an oval **articular surface** [incisura clavicularis], somewhat saddle-shaped and directed upward, backward, and laterâlly for the reception of the medial end of the clavicle. The circumference of the articular surface gives attachment to the sternoclavicular ligaments.

The **lateral borders** of the manubrium slope from above downward and medially and each presents an irregular surface, the **costal notch** [incisura costalis], above the first costal cartilage and a small facet below, which, with an adjoining facet on the body, forms a notch for the second costal cartilage. The two articular surfaces are separated by a narrow curved edge in relation with the *internal intercostal* muscle of the first space. The **lower border is thick**

and short and presents an oval rough surface which articulates with the upper border of the body, forming the **sternal synchondrosis.** The two opposed surfaces are separated by a fibrocartilaginous disk, which may, however, become partially ossified in advanced age, and at the position of the joint there is usually an angle—the **sternal angle** (angulus Ludovici)—which can be felt as a transverse ridge beneath the skin. This is useful in locating the second rib in the living subject.

The **body** [corpus sterni] (gladiolus) or second piece of the sternum is longer, narrower, and thinner than the manubrium. It is widest opposite the notches for the fifth costal cartilages and becomes narrower above and below. The **anterior surface** is flat, directed upward and forward, and marked by three transverse elevations which indicate the lines of junction of its four component parts. It gives attachment on each side to fibers of the *pectoralis major* and is subcutaneous in the midline; it occasionally presents a foramen—the **sternal foramen**—situated at the junction of the third and fourth pieces of the bone. The **posterior surface** is slightly concave, marked by lines corresponding to those on the anterior surface, and below gives attachment on each side to fibers of the *transversus thoracis* (*triangularis sterni*).

The **lateral borders** of the body present four whole costal notches and two half-notches on each side, which articulate with the costal cartilages of the second to the seventh ribs inclusive; the two half-notches are completed by corresponding notches on the manubrium and the xiphoid process. Between the articular depressions the lateral border is curved and in relation to the *internal intercostal* muscles.

In order to appreciate the nature of these articular notches, it is advantageous to study the sternum in a young subject (fig. 202). Each typical **sternebra** presents four angles at each of which is a deminotch. Between every two sternebræ there is an intersternebral disk so that when in position, each notch for a costal cartilage is formed by a sternebra above and below and an intersternebral disk in the middle, thus repeating the relation of the rib-head to the vertebral centrum. Later in life these fuse more or less together, except in the case of the first and second sternebræ, which usually remain separate to the end of life. The first (presternum) is the most modified of all the sternebræ, and differs from them in the fact that the costal cartilage of the first rib is continuous with it, and in fact that it supports the clavicles.

The **superior border** of the sternal body presents an oval facet for articulation (synchondrosis) with the manubrium. The **inferior border** is short and articulated with the xiphoid process, forming the mesometasternal joint, the two opposed surfaces being separated by a layer of cartilage so long as they are not united by bone.

The **xiphoid** (ensiform) **process** is the thin, elongated process projecting downward between the cartilages of the seventh ribs. It is the least developed part of the sternum and is subject to many variations in form, being sometimes pointed, broad and thin, occasionally bifid or perforated by a foramen, and sometimes bent forward, backward, or deflected to one side. In structure it is cartilaginous in early life, partially ossified in the adult, but in old age it tends to become ossified throughout and to fuse with the body.

The **anterior surface** of the xiphoid process gives attachment to a few fibers of the *rectus abdominis* muscle and the chondroxiphoid ligament; the **posterior surface** to the sternal fibers of the *diaphragm*, and the lowest fibers of the *transversus thoracis* (*triangularis sterni*), while the lateral margins receive the aponeuroses of the abdominal muscles. Its tip is directly continuous with the **linea alba.**

Differences according to sex.—The sternum differs somewhat in the two sexes. The female sternum is relatively shorter, the diminution being confined almost to the body. In the male the body is more than twice as long as the manubrium, whereas in the female it is usually less than twice the length of the first piece.

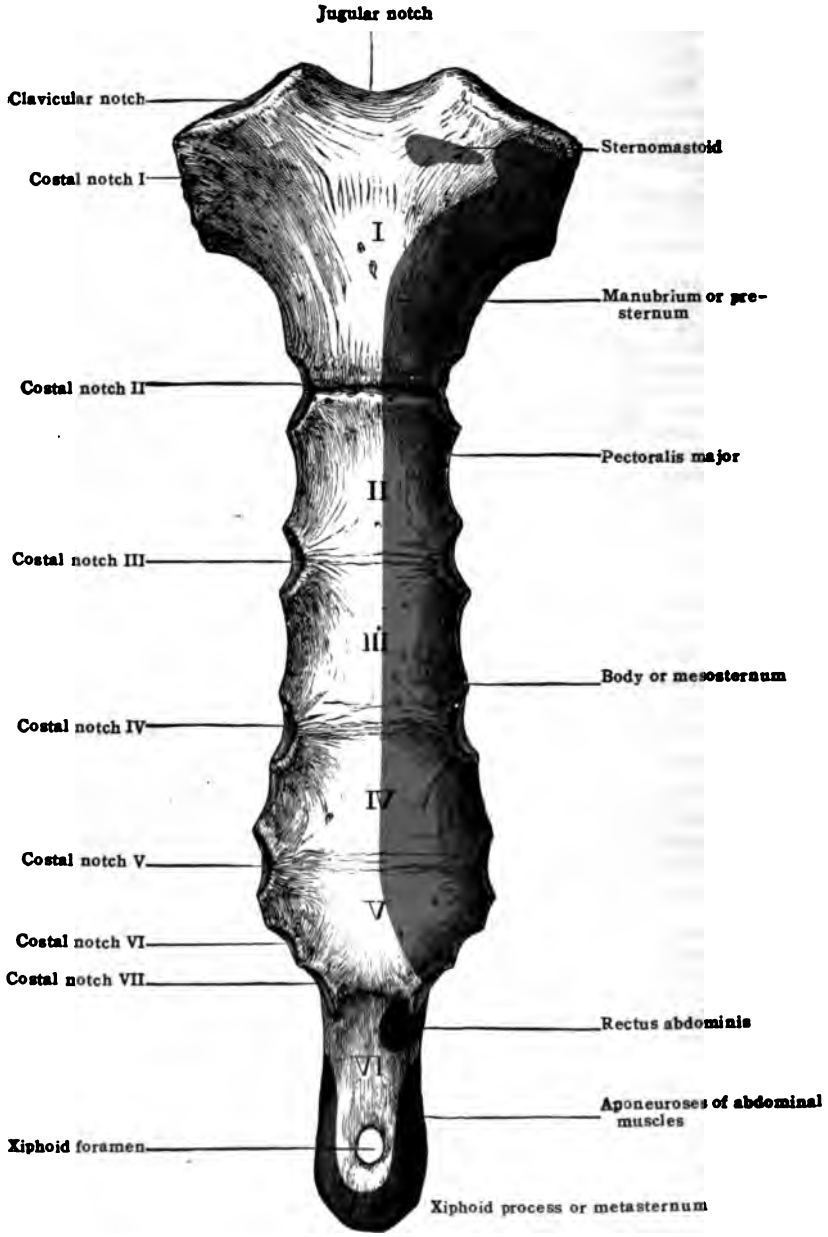
Structurally the sternum is composed of cancellous tissue covered with an outer layer of compact tissue. Its **arterial supply** is derived mainly from the sternal and perforating branches of the internal mammary.

Development of the sternum (figs. 201, 202).—The osseous sternum is preceded by a continuous or non-segmented central sternal cartilage formed in the following way. When the cartilaginous ribs first appear in the embryo, their anterior or ventral ends are united with a tract of mesenchyma, one of a pair of *sternal bands* which are connected with the medial ends of the clavicles and with the mass of tissue between them which has been regarded as the representative of the *episternum.* For some time a median fissure is present, bordered by the two sagittally directed bands which have proceeded to the cartilaginous stage with each of which at first nine ribs are joined. As development proceeds the two bands come into contact in the midline and fuse from before backward to form a median sternal cartilage. The cephalic extremity, *presternum,* is at first connected with the medial ends of the clavicles by mesenchyma in which the sternoclavicular joint and interarticular disk are formed. The latter may be a derivative of the episternum, the remaining part of which is included in the presternum. The eighth costal cartilage generally loses its sternal attachment, although in some cases it remains permanently articulated with the side of the xiphoid process. The ninth costal cartilage be-

comes subdivided, one part remaining attached to the sternum and forming the xiphoid process, while the end still continuous with the rib acquires a new attachment to the eighth cartilage. The ends adherent to the sternum may remain separate and give rise to a bifid xiphoid process, though much more frequently they unite, leaving a small foramen.

At first, therefore, the sternum and costal cartilages are continuous. A joint soon forms between the presternum and mesosternum, and others between the costal cartilages and the

FIG. 198.—THE STERNUM. (Anterior view.)



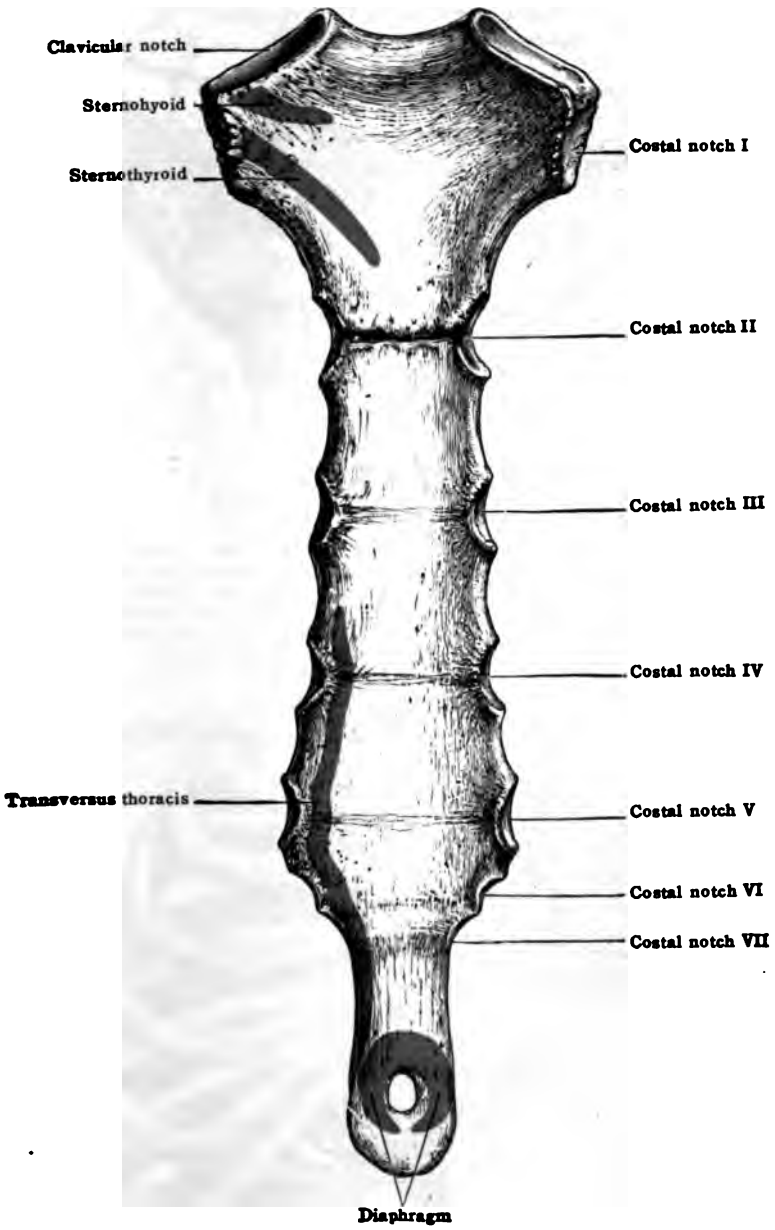
sternum (except in the case of the first) quickly follow. The division of the mesosternum into segments is a still later formation and arises during the process of ossification. On the development of the sternum see Paterson, Jour. Anat. & Phys., vol. 25; Hanson, Am. Jour. Anat., 1919, 26: 41.

Ossification.—The ossification of the sternum is slow and irregular. The process begins in the presternum (manubrium) by a single center about the sixth month of intrauterine life, though occasionally other accessory centers are superadded.

The mesosternum (body) usually ossifies from seven centers. The upper segment ossifies from a single median nucleus about the eighth month, and below this, three pairs of ossific nuclei appear, which may remain for a long time separate. Of these, two pairs for the second and third segments are visible at birth, and those for the lower segment make their appearance

toward the end of the first year. The various lateral centers unite in pairs, so that at the sixth year the sternum consists of six sternebræ, the lowest (metasternum) being cartilaginous. Very often, however, there are only four centers of ossification in the gladiolus, as shown in fig. 202. Gradually the four pieces representing the mesosternum fuse with one another, and at twenty-five they form a single piece, but exhibit, even in advanced life, traces of their original separation. A sternal foramen is usually the result of non-union across the middle line or a defect of ossification.

FIG. 199.—THE STERNUM. (Posterior view.)

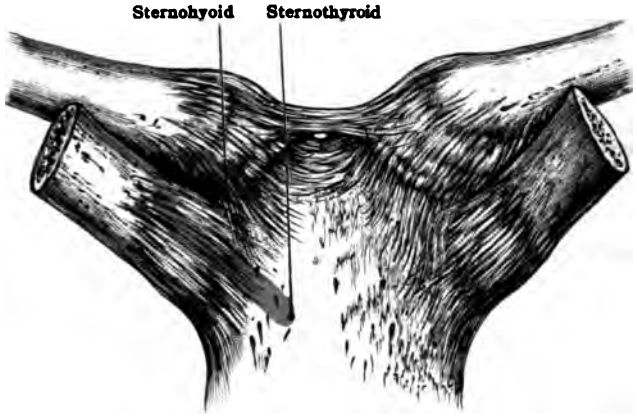


The metasternum is always imperfectly ossified, and does not join with the mesosternum till after middle life. The presternum and mesosternum rarely fuse. The dates given above for the various nuclei, and for the union of the various segments, are merely approximate, hence the sternum affords very uncertain data as to age.

Variations.—The mode of development of the sternum as described above will explain some deviations to which it is occasionally subject. In rare instances the two lateral halves fail to unite, giving rise to the anomaly of a completely cleft sternum (fissura sterni). The union of the two halves may occur in the region of the manubrium and fail below, while in other cases the upper and lower parts have fused but remain separate in the middle. The clefts are in many instances so small as not to be of any moment, and are not even recognised until the skele-

ton is prepared. In a few individuals, however, they have been so extensive as to allow the pulsation of the heart to be perceptible to the hand, and even to the eye, through the skin covering the defect in the bone. A common variation in the sternum is asymmetry of the costal cartilages. Instead of corresponding, the cartilages may articulate with the sternum in an alternating manner. Rarely a pair of cartilaginous nodules or ossicles [ossa suprasternalia] occur at the superior margin of the manubrium; these have been interpreted as vestiges of an *episternum*.

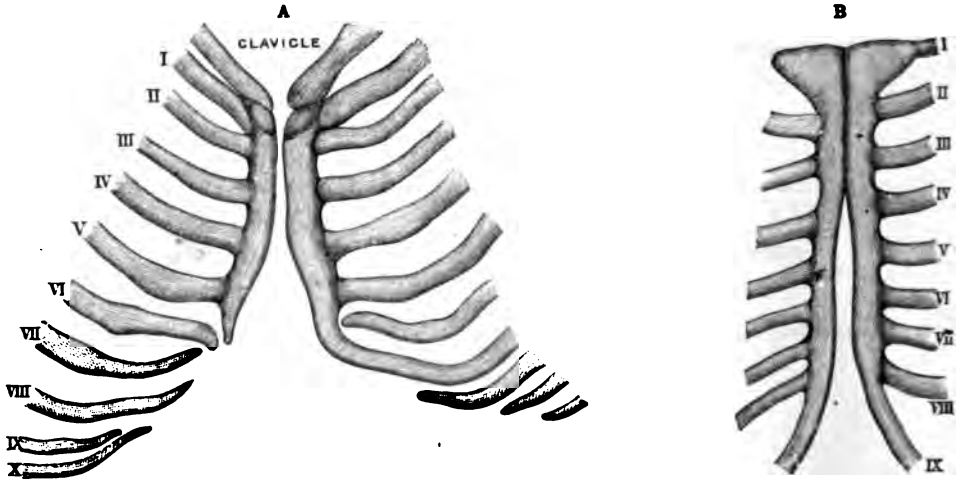
FIG. 200.—POSTERIOR SURFACE OF THE MANUBRIUM, WITH STERNAL ENDS OF CLAVICLES AND THE FIRST COSTAL CARTILAGES.



THE THORAX AS A WHOLE

The bony thorax (figs. 203, 204) is somewhat conical in shape, deeper behind than in front and compressed anteroposteriorly, so that in the adult it measures less in the sagittal than in the transverse axis. The **posterior** wall, formed by the thoracic vertebræ and the ribs as far lateralward as their angles, is convex from above downward, and the backward curve of the ribs produces on each side of the vertebræ a deep furrow, the **costovertebral groove,** in which the *sacrospinalis* (*erector spinæ*) muscle and its subdivisions are lodged. The backward curve of the ribs produces also a deep, broad groove or hollow on each side of the vertebral column

FIG. 201.—TWO STAGES IN THE FORMATION OF THE CARTILAGINOUS STERNUM. (After Ruge.)



within the thorax in which the posterior bulky margin of the lung is contained. **The anterior** wall is formed by the sternum and costal cartilages. It is slightly convex and inclined forward in its lower part, forming an angle of about 20° with the vertical plane. The **lateral** walls are formed by the ribs from the angles to the costal cartilages. The top of the **thorax presents** an elliptical aperture, the **superior thoracic aperture,** which measures on an average 12.5 cm. (5 inches) transversely and 6.2 cm. (2½ inches) in its sagittal axis. It is bounded by the first thoracic vertebra behind, the upper margin of the manubrium sterni in front, and the first rib on each side. As the upper margin of the manubrium sterni is oftenest on a level with the disk between the second and third thoracic vertebræ, it follows that the plane of the opening is directed obliquely upward and forward. The sternal angle is usually opposite the body of

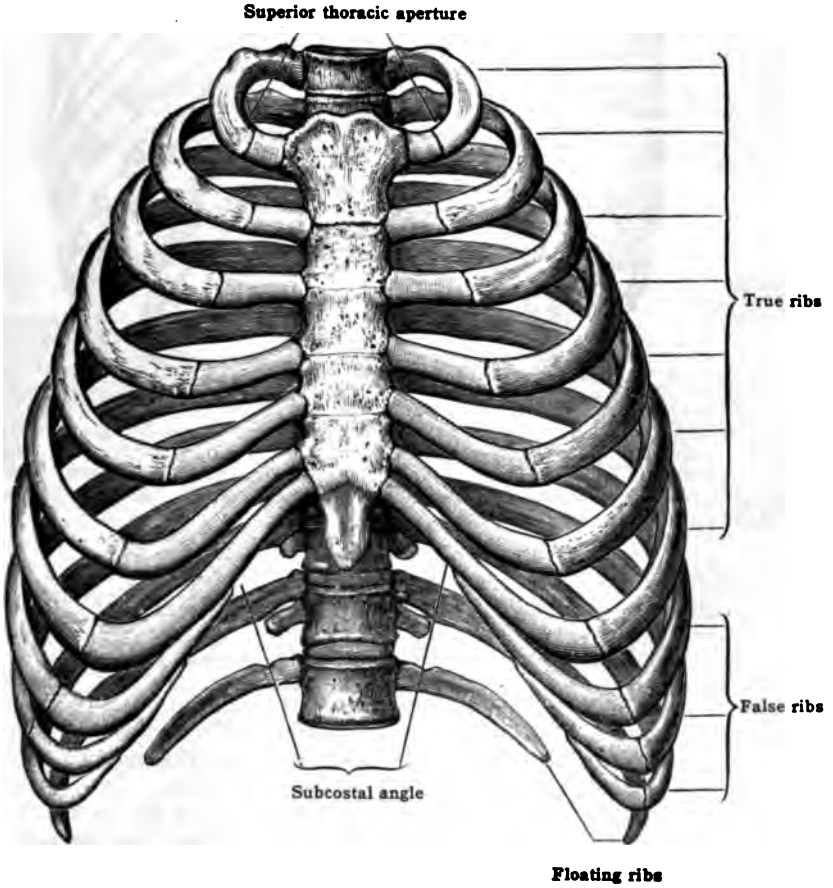
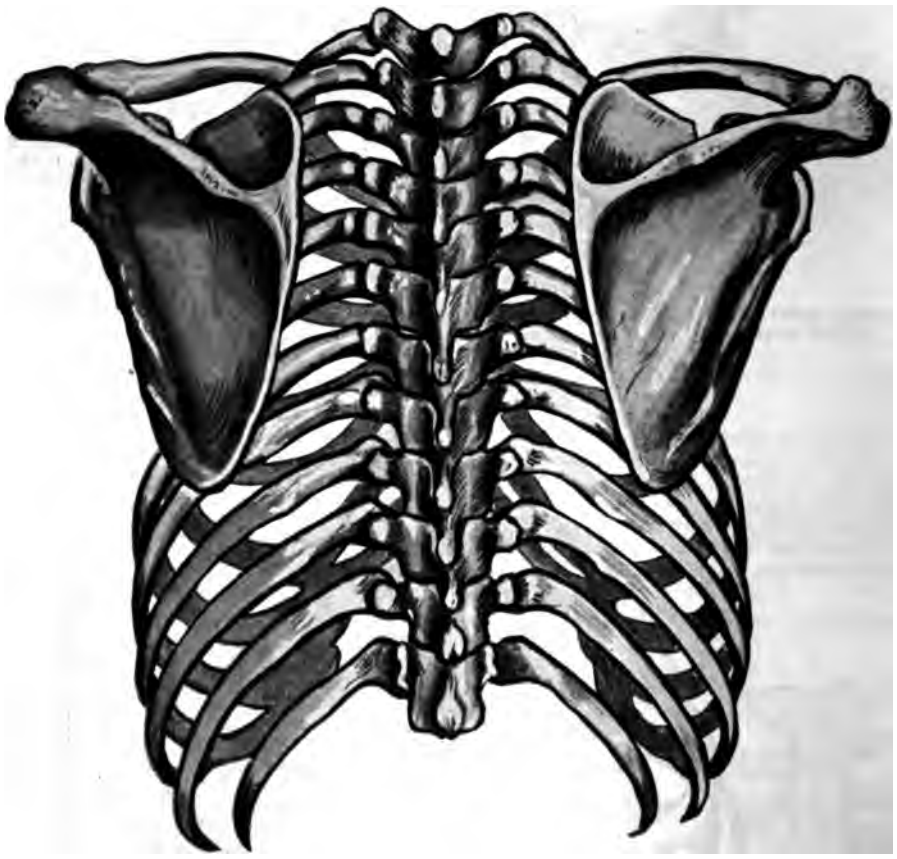
FIG. 203.—THE THORAX. (Front view.)



the fifth thoracic vertebra and the xiphisternal junction corresponds to the disk between the ninth and tenth thoracic vertebræ. The lower aperture of the thorax is very irregular, and is formed by the twelfth thoracic vertebra behind, the twelfth ribs laterally, and in front by two curved lines, ascending one on either side from the last rib, along the costal margin to the lower border of the body. The two borders form the **costal arch**, which in the median line below the sternum forms the **infrasternal angle**. From this angle the xiphoid process projects downward. The intervals between the ribs are the **intercostal spaces**, and are eleven in number on each side.

The ratio of the sagittal and the transverse diameter of the thorax forms the **thoracic index**, which is higher in the female and in children, in whom the thorax is more rounded. In the embryo (p. 17), the index is very much higher, the sagittal diameter being greater than the transverse. In the early embryo, the index is nearly 200; at birth it is about 90. In the adults

FIG. 204.—THE THORAX. (Posterior view.) The scapulæ are drawn from an *X*-ray photograph of a man 33 years old.



it varies from 70 to 75, averaging 2 or 3 per cent. lower in the male than in the female. It is also lower in the negro than in the white race. (Rodes, Zeitschr. f. Morph. u. Anthrop., Bd. 9.) The low thoracic index in man (as compared with quadrupedal mammals) is partly an effect of gravity upon the anterior thoracic wall in the upright posture. Jackson, however, concludes that other factors are predominant.

II. THE APPENDICULAR SKELETON

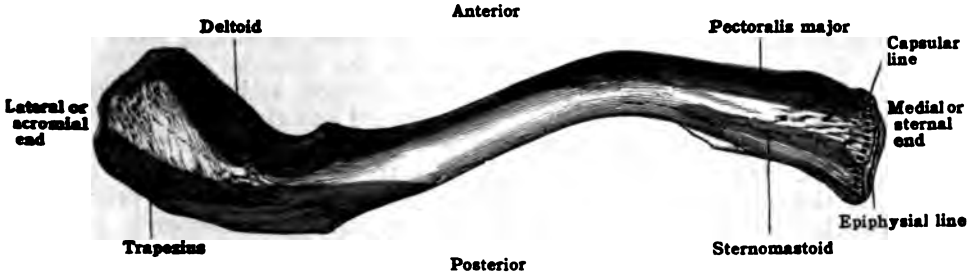
A. BONES OF THE UPPER EXTREMITY

The skeleton of the upper limb is adapted chiefly to the function of prehension which in man is perfected to a high degree. The bones of the upper extremity may be arranged in four groups corresponding to the division of the limb into four segments. In the *shoulder* are the clavicle and the scapula, which together constitute the pectoral or shoulder girdle; in the *arm* is the humerus; in the *forearm* are the radius and ulna; and in the *hand* the carpus, the metacarpus, and the phalanges.

THE CLAVICLE

The **clavicle** [clavicula] or collar bone (figs. 205, 206) is situated immediately above the first rib and extends from the upper border of the manubrium sterni, laterally and backward to the acromion of the scapula. It connects the upper limb with the trunk, and is so situated that while the medial end is securely but flexibly united with the sternum and first costal cartilage, the lateral end is joined with the scapula, supporting it firmly in its various positions and associated with it in all its movements. The clavicle functions chiefly as a prop to the shoulder, putting it away from the side of the body and so establishing conditions for free action of the arm. The clavicle is a long bone, and when

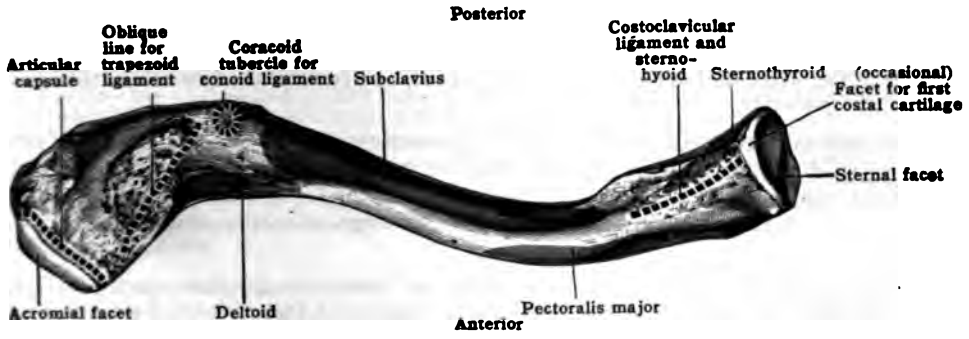
FIG. 205.—THE LEFT CLAVICLE. (Superior surface.)



viewed from above presents a double curvature, so that it somewhat resembles in shape the italic letter *f*, with a medial prismatic portion, convex forward, and a lateral flattened portion, concave forward.

Prismatic portion.—The medial two-thirds of the bone, extending from the sternal extremity to a point opposite the coracoid process of the scapula, has the form of a triangular prism. This portion, however, is subject to considerable variations of form, being more cylindrical in ill-developed specimens and becoming almost quadrangular when associated with great muscular development. In a typical specimen it is marked by three borders separating three surfaces. Of these, the **anterior surface** is convex and divided near the sternal end by a prominent ridge into two parts, a lower, giving origin to the clavicular portion of

FIG. 206.—THE LEFT CLAVICLE. (Inferior surface.)



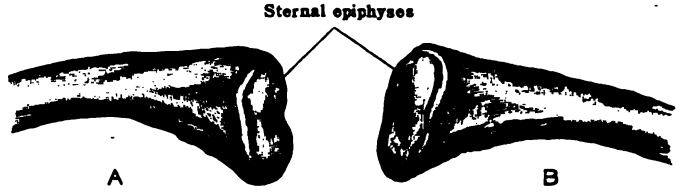
the *pectoralis major;* an upper, for the clavicular portion of the *sternocleidomastoid.* Near the middle of the shaft the ridge disappears, the surface is smooth, and is covered only by the integument, and, the *platysma.* The **posterior surface** is concave, forming an arch over the brachial plexus and the subclavian artery, broadest medially and smooth in its whole extent. It gives origin near the sternal extremity to a part of the *sternohyoid* and occasionally to a few fibers of the *sternothyroid.* Somewhere near the middle of this surface is a small foramen, directed laterally, for the chief nutrient artery of the bone, derived from the transverse scapular (suprascapular) artery. Sometimes the foramen is situated on the inferior surface of the bone, in the subclavian groove. On the **inferior surface** near the sternal end is a rough area, the **costal tuberosity,** about three-quarters of an inch in length, for the attachment of the costoclavic-

ular ligament by which the clavicle is fixed to the cartilage of the first rib. More laterally is a longitudinal groove for the *subclavius*, bordered by two lips, to which the sheath of the muscle is attached. To the posterior of the two lips the layer of deep cervical fascia which binds down the posterior belly of the omohyoid to the clavicle is also attached.

Of the three **borders**, the **superior** separates the anterior and posterior surfaces. Beginning at the sternal end, it is well-marked, becomes rounded and indistinct in the middle, whilst laterally it is continuous with the posterior border of the outer third. The **posterior border** separates the inferior and posterior surfaces and forms the posterior lip of the subclavian groove. It begins at the costal tuberosity and can be traced laterally as far as the coracoid tubercle, an eminence on the under aspect of the bone near the junction of prismatic and flattened portions. The **anterior border** is continuous with the anterior border of the flattened portion and separates the anterior and inferior surface. Medially, it forms the lower boundary of the elliptical area for the origin of the *pectoralis major*, and approaches the posterior border. Near the middle of the bone it coincides with the anterior lip of the subclavian groove.

Flattened portion.—The lateral third of the bone, extending from a point opposite the coracoid process of the scapula to the acromial extremity, is flattened from above downward and presents two surfaces and two borders. The **superior surface** is rough and looks directly upward and gives attachment to the *trapezius* behind and the *deltoid* in front; between the two areas the surface is subcutaneous. On the **inferior surface**, near the posterior border, is a rough elevation, the **coracoid** (conoid) **tubercle**; it overhangs the coracoid process and gives attachment to the conoid ligament. From the coracoid tubercle, a prominent ridge, the **trapezoid** or **oblique line**, runs laterally and forward to near the lateral end of the bone. To it the trapezoid ligament is attached. The conoid and trapezoid ligaments are the two parts of the coracoclavicular ligament which binds the clavicle down to the coracoid process.

FIG. 207.—THE STERNAL ENDS OF TWO CLAVICLES WITH EPIPHYSES.
A, right clavicle from below and behind. B, left clavicle from below and behind.
(From Royal College of Surgeons Museum.)



The **anterior border** is sharp, gives origin to the *deltoid* muscle, and frequently presents near the junction of the flattened and prismatic portions a projection known as the **deltoid tubercle**. The **posterior border** is thick and rounded, and receives the insertion of the upper fibers of the *trapezius*.

The **sternal extremity** of the clavicle presents a triangular articular surface, directed medially, downward, and a little forward, slightly concave from before backward and convex from above downward, which articulates with a facet on the upper border of the manubrium sterni through an interposed interarticular disk.

Of the three angles, one is above and two below. The *posteroinferior angle* is prolonged backward, and so renders this surface considerably larger than that with which it articulates; the *superior angle* receives the attachment of the upper part of the disk. The lower part of the surface is continuous with a facet on the under aspect of the bone, medial to the costal tuberosity, for the first costal cartilage. The circumference of the extremity is rough, and gives attachment to the interclavicular ligament above and the anterior and posterior sternoclavicular ligaments in front and behind.

The **acromial extremity** presents a smooth, oval, articular facet, flattened or convex, directed slightly downward for the acromion; its border is rough, for the attachment of the capsule of the acromioclavicular joint.

Structure.—The clavicle consists externally of a compact layer of bone, much thicker in the middle and thinning out gradually toward the two extremities. There is no true medullary cavity, for the interior is occupied from end to end by cancellous tissue, the amount in the various parts of the bone being in inverse proportion to the thickness of the outer compact shell.

Ossification—From observations made by F. P. Mall, D. C. L. Fitzwilliams, and E. Fawcett it seems almost certain that there are two centers of ossification of the shaft of the clavicle,

at the juncture of the middle and lateral thirds. They appear very early (first ossific center in the body), about the fifth week of embryonic life, and rapidly fuse. The ossific process extends medially and laterally along the shaft toward the medial and lateral extremities, respectively. About the eighteenth year a secondary center appears at the sternal end and forms a small epiphysis which joins the shaft about the twenty-fifth year.

Variations.—Not infrequently the shaft of the clavicle is perforated by a small canal transmitting one of the cutaneous nerves of the cervical plexus. The degree of curvature in the lateral and medial portions of the bone is subject to fluctuation. The most important deviation from the type is a true variation, with a hereditary tendency, namely partial or complete absence of one or both clavicles. This rare condition is the more remarkable because of its constant association with certain defects of the cranium. It has been named *dysostosis cleidocranialis*. For further details, see Hultkranz, Zeitschr. f. Morph. u. Anthropol., 1908, 11: 385.

THE SCAPULA

The **scapula** (figs. 204, 208, 209) is a large flat bone, triangular in shape, situated on the dorsal aspect of the thorax, between the levels of the second and seventh ribs. It is attached to the trunk by means of the clavicle, with which it is articulated, and by various muscles through which a variety of movements are permitted; it articulates with the humerus at the shoulder-joint. The greater part of the scapula consists of a triangular plate known as the *body*, from which two processes are prolonged: one anterior in position, is the *coracoid;* the other, posterior in position, is the *spine*, which is continued laterally into the *acromion*.

The body presents two surfaces, three borders, and three angles. The **costal (anterior) surface,** or venter, looks considerably medialward, is deeply concave, forming the **subscapular fossa.**

The fossa is marked by several oblique lines which commence at the posterior border and pass obliquely upward and laterally; these lines or ridges divide the surface into several shallow grooves, from which the *subscapularis* takes origin, while the ridges give attachment to the tendinous intersections of that muscle. The lateral third of the surface is smooth and overlapped by the subscapularis, while medially are two small flat areas in front of the upper and lower angles respectively, but excluded from the subscapular fossa by fairly definite lines and joined by a ridge which runs close to the vertebral border. The ridge and its terminal areas serve for the insertion of the *serratus anterior (magnus)*.

The **dorsal** (posterior) **surface** is generally convex and divided by a prominent plate of bone—the **spine**—into two unequal parts. The hollow above the spine is the **supraspinous fossa** and lodges the *supraspinatus* muscle. The part below the spine is the **infraspinous fossa;** it is three times as large as the supraspinous fossa, is alternately concave and convex, and gives origin to the *infraspinatus*. The muscle is attached to its medial three-fourths and covers the lateral fourth, without taking origin from it.

The infraspinous fossa does not extend as far as the axillary border, but is limited laterally by a ridge—the oblique line—which runs from the glenoid cavity—the large articular surface for the head of the humerus—downward and backward to join the posterior border a short distance above the inferior angle. This line, which gives attachment to a stout aponeurosis, cuts off an elongated surface, narrow above for the origin of the *teres minor*, and crossed near its middle by a groove for the circumflex (dorsal) artery of the scapula; below, the surface is broader for the origin of the *teres major* and occasionally a few fibers of the *latissimus dorsi*. The two areas are separated by a line which gives attachment to an aponeurotic septum situated between the two teres muscles.

The supra- and infraspinous fossæ communicate through the **great scapular notch** at the lateral border of the spine, and through the notch the suprascapular nerve and transverse scapular artery are transmitted from one fossa to the other.

Borders.—The three borders of the scapula are named superior, vertebral, and axillary. The **superior** is short and thin and extends from the upper angle to the coracoid process. Laterally it presents a deep depression, the **scapular notch,** to the extremities of which the superior transverse ligament is attached.

The notch or foramen transmits the suprascapular nerve, while the transverse scapular artery usually passes over the ligament. From the adjacent margins of the notch and from the ligament the posterior belly of the *omohyoid* takes origin.

The **vertebral border** (sometimes called the base) is the longest, and extends from the upper or medial to the lower angle of the bone.

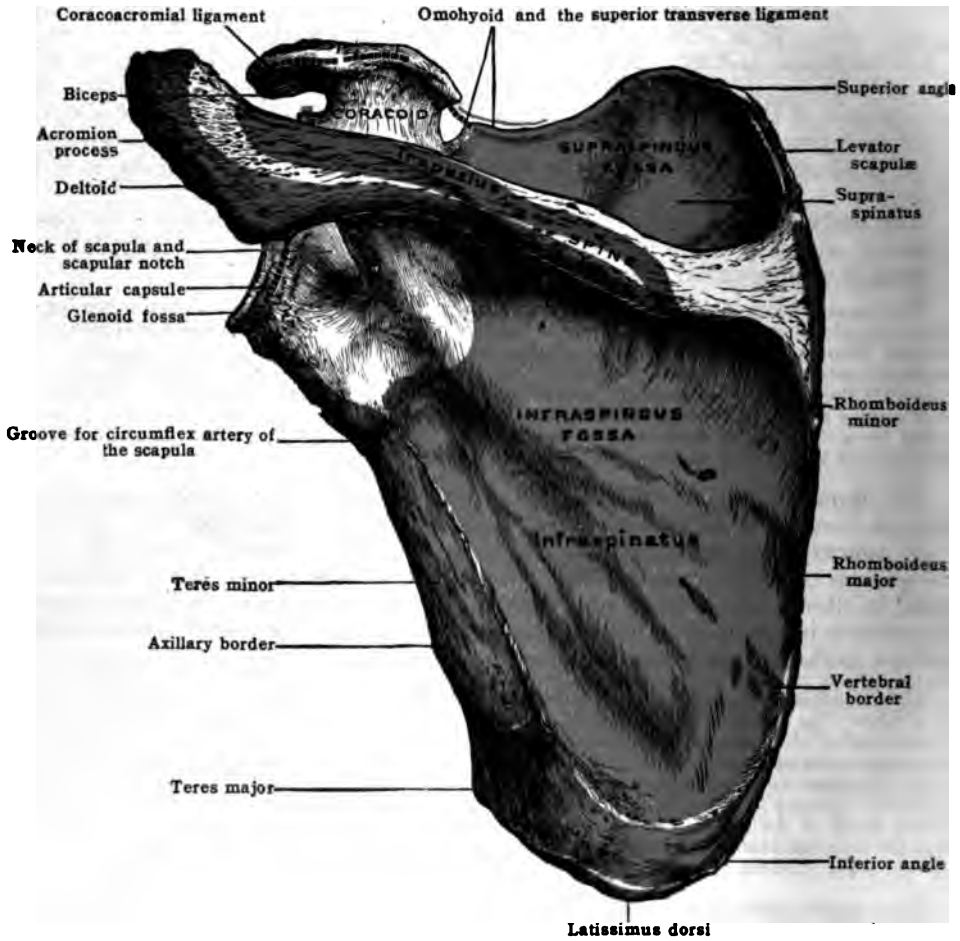
It is divisible into three parts, to each of which a muscle is attached: an upper portion extending from the medial (superior) angle to the spine, for the insertion of the *levator scapulæ;*

a middle portion, opposite the smooth triangular area at the commencement of the spine, for the *rhomboideus minor;* and the lowest and longest portion, extending below this as far as the inferior angle, for the *rhomboideus major*, the attachment of which takes place through the medium of a fibrous arch.

The **axillary border** is the thickest, and extends from the lower margin of the glenoid cavity to the inferior angle of the bone. Near its junction with the glenoid cavity there is a rough surface, about 2.5 cm. (1 in.) in length the **infraglenoid tubercle,** from which the long head of the *triceps* arises, and below the tubercle is the groove for the circumflex (dorsal) artery of the scapula. The upper two-thirds of the border is deeply grooved on the ventral aspect and gives origin to a considerable part of the *subscapularis.*

Angles.—The three angles are named medial, inferior, and lateral.

FIG. 208.—THE LEFT SCAPULA. (Dorsal surface.)



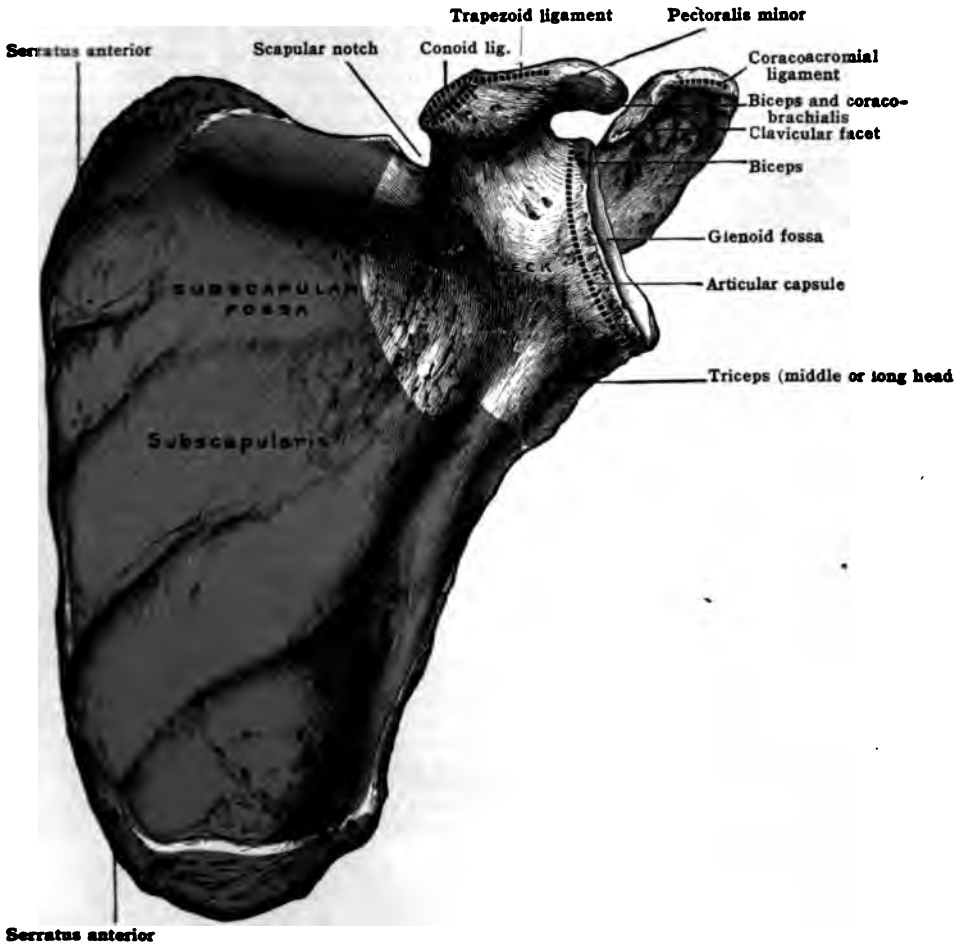
The **medial** (or superior) **angle,** forming the highest part of the body, is thin, smooth, and either rounded or approximating a right angle. It is formed by the junction of the superior and vertebral borders and gives insertion to a few fibers of the *levator scapulæ.* The **inferior angle,** constituting the lowest part of the body, is thick, rounded, and rough. It is formed by the junction of axillary and vertebral borders, gives origin to the *teres major,* and is crossed horizontally by the upper part of the *latissimus dorsi,* the latter occasionally receiving from it a small slip of fleshy fibers.

The **lateral angle** forms the expanded portion of the bone known as the **head,** bearing the **glenoid cavity,** and supported by a somewhat constricted **neck.** The glenoid cavity is a wide, shallow, pyriform, articular surface for the head of the humerus, directed forward and laterally, with the apex above and the broad end below. Its margin is raised, and affords attachment to the glenoid ligament, which deepens its concavity. The margin is not, however, of equal prominence

throughout, being somewhat defective where it is overarched by the acromion, notched anteriorly, and emphasized above to form a small eminence, the **supraglenoid tubercle,** for the origin of the long head of the *biceps*.

The circumference and adjoining part of the neck give attachment to the articular capsule of the shoulder-joint, and the anterior border to the three accessory ligaments of the capsule, known as the superior, middle, and inferior glenohumeral folds. The superior fold (Flood's ligament) is attached above the notch near the upper end; of the two remaining folds, which together constitute Schlemm's ligament, the middle is attached immediately above the notch and the inferior below the notch. In the recent state the glenoid cavity is covered with hyaline cartilage. The neck is more prominent behind than before and below than above, where it supports the coracoid process. It is not separated by any definite boundary from the body.

FIG. 209.—THE LEFT SCAPULA. (Ventral surface.)



Processes.—The **spine** is a strong, triangular plate of bone attached obliquely to the dorsum of the scapula and directed backward and upward. Its apex is situated at the vertebral border; the base, corresponding to the middle of the neck, is free, concave, and gives attachment to the inferior transverse ligament, which arches over the transverse scapular (suprascapular) vessels and suprascapular nerve. Of the two borders, the anterior is joined to the body, while the posterior is free, forming a prominent subcutaneous **crest.** The latter commences at the vertebral border, in a smooth triangular area, over which the tendon of the *trapezius* glides, usually without the intervention of a bursa, as it passes to its insertion into a small tubercle on the crest beyond. Further laterally, this border is rough, and presents two lips—a superior for the insertion of the *trapezius* and an inferior for the origin of the *deltoid*. Laterally the crest is continued into the **acromion.**

The **spine has** two surfaces, the superior, which also looks medialward and

forward, is concave, contributes to the formation of the supraspinous fossa, and gives origin to the *supraspinatus* muscle; the inferior surface, also slightly concave, is directed lateralward and backward, forms part of the infraspinous fossa, and affords origin to the *infraspinatus* muscle. On both surfaces are one or more prominent vascular foramina.

The **acromion,** a process overhanging the glenoid cavity, springs from the angle formed by the junction of the crest with the base of the spine. Somewhat crescentic in shape, it forms the summit of the shoulder and is compressed from above downward so as to present two surfaces, two borders, and two extremities.

The posterior part sometimes terminates laterally in a prominent **acromial angle** (metacromion) and the process then assumes a more or less triangular form. Of the two extremities, the posterior is continuous with the spine, while the anterior forms the free tip. The upper surface, directed upward, backward, and slightly lateralward, is rough and convex, and affords origin at its lateral part to a portion of the *deltoid;* the remaining part of this surface is subcutaneous. The lower surface, directed downward, forward, and slightly medialward, is concave and smooth. The medial border, continuous with the upper lip of the crest, presents, from behind forward, an area for the insertion of the *trapezius;* a small, oval, concave articular facet for the lateral end of the clavicle, the edges of which are rough for the acromioclavicular ligaments; and, beyond this, the anterior extremity or tip, to which is attached the apex of the coracoacromial ligament. The lateral border, continuous with the inferior lip of the crest, is thick, convex, and presents three or four tubercles with intervening depressions; from the tubercles the tendinous septa in the acromial part of the *deltoid* arise, and from the depressions, some fleshy fibers of the same muscle.

Projecting upward from the neck of the scapula is the **coracoid process,** bent finger-like, pointing forward and laterally. It consists of two parts, ascending and horizontal, placed at almost a right angle to each other.

The *ascending part* arises by a wide root, extends upward and medially for a short distance, and is compressed from before backward; it is continuous above with the horizontal part and below with the neck of the scapula; the lateral border lies above the glenoid cavity and gives attachment to the coracohumeral ligament; the medial border, which forms the lateral boundary of the scapular notch, gives attachment to the conoid ligament above and the transverse ligament below. Its anterior and posterior surfaces are in relation with the *subscapularis* and *supraspinatus* respectively. The *horizontal part* of the process runs forward and lateralward; it is compressed from above downward so as to present two borders, two surfaces, and a free extremity. The medial border gives insertion along its anterior half to the *pectoralis minor* and nearer the base to the costocoracoid membrane; the lateral border is rough for the coracoacromial and coracohumeral ligaments; the upper surface is irregular and gives insertion in front to the *pectoralis minor,* and behind to the trapezoid ligament; the inferior surface is smooth and directed toward the glenoid cavity, which it overhangs; the free extremity or apex gives origin to the conjoined *coracobrachialis* and short head of the *biceps.*

Structure and vessels.—The greater part of the body of the scapula and the central parts of the spinous process are thin and transparent. The coracoid and acromion processes, the crest of the spine and inferior angle, the head, neck, and axillary border, are thick and opaque. The young bone consists of two layers of compact tissue with an intervening cancellous layer, but in the transparent parts of the adult bone the middle layer has disappeared. The vascular foramina on the costal surface transmit twigs from the subscapular and transverse scapular (suprascapular) arteries; those in the infraspinous fossa, twigs from the circumflex (dorsal) and transverse scapular (suprascapular) arteries, the latter also giving off vessels which enter the foramina in the supraspinous fossa. The acromion is supplied by branches from the thoracoacromial (acromiothoracic) artery.

The line of attachment of the spinous process to the dorsum of the scapula is known as the **morphological axis,** and the obtuse angle in the subscapular fossa opposite the spine as the *subscapular angle.* From the axis three plates of bone radiate as from a center, the **prescapula** forward, the **mesoscapula** laterally, and the **postscapula** backward, being named in accordance with the long axis of the body in the horizontal position. In the human subject the postscapula is greatly developed, and this is associated with the freedom and versatility of movement possessed by the upper limb.

The **scapular index,** $\frac{100 \times \text{breadth}}{\text{length}}$, is the ratio between the breadth and length of the bone. The index is higher in negroes than in Europeans; it is also higher in infants than in adults.

Ossification.—The scapula is ossified from nine centers. Of these, two (for the body of the scapula and the coracoid) may be considered as primary, and the remainder as secondary. The center for the body appears in a plate of cartilage near the neck of the scapula about the eighth week of intrauterine life, and quickly forms a triangular plate of bone, from which the spine appears as a slight ridge about the middle of the third month. At birth the glenoid fossa and part of the scapular neck, the acromion and coracoid processes, the vertebral border and inferior angle, are cartilaginous. During the first year a nucleus appears for the coracoid, and at the tenth year a second center appears for the base of the coracoid and the upper part of the glenoid cavity (subcoracoid, fig. 210).

During the fifteenth year the coracoid unites with the scapula, and about this time the other secondary centers appear. Two nuclei are deposited in the acromial cartilage, and fuse to form the acromion, which joins the spine at the twentieth year. The union of spine and acromion

may be fibrous, hence the latter is sometimes found separate in macerated specimens. The cartilage along the vertebral border ossifies from two centers, one in the middle, and another at the inferior angle. A thin lamina is added along the upper surface of the coracoid process and occasionally another at the margin of the glenoid cavity. These epiphyses join by the twenty-fifth year.

The occurrence of a special primary center for the coracoid process is of morphological importance in that the process is the representative of what in the lower vertebrates is a distinct *coracoid bone*. This primarily takes part in the formation of the glenoid cavity and extends medially to articulate with the sternum. In man and all the higher mammals only the lateral portion of the bone persists.

Variations.—The scapular notch is sometimes found bridged over by bone converting it into a foramen (normal in some animals). The whole acromion process may fail to unite or a part of it, representing one of the two or three component centers may be separate. Scapulæ with concave vertebral margins (scaphoid type) have been described by Dr. W. W. Graves as of frequent occurrence, generally poorly ossified and with low scapular index.

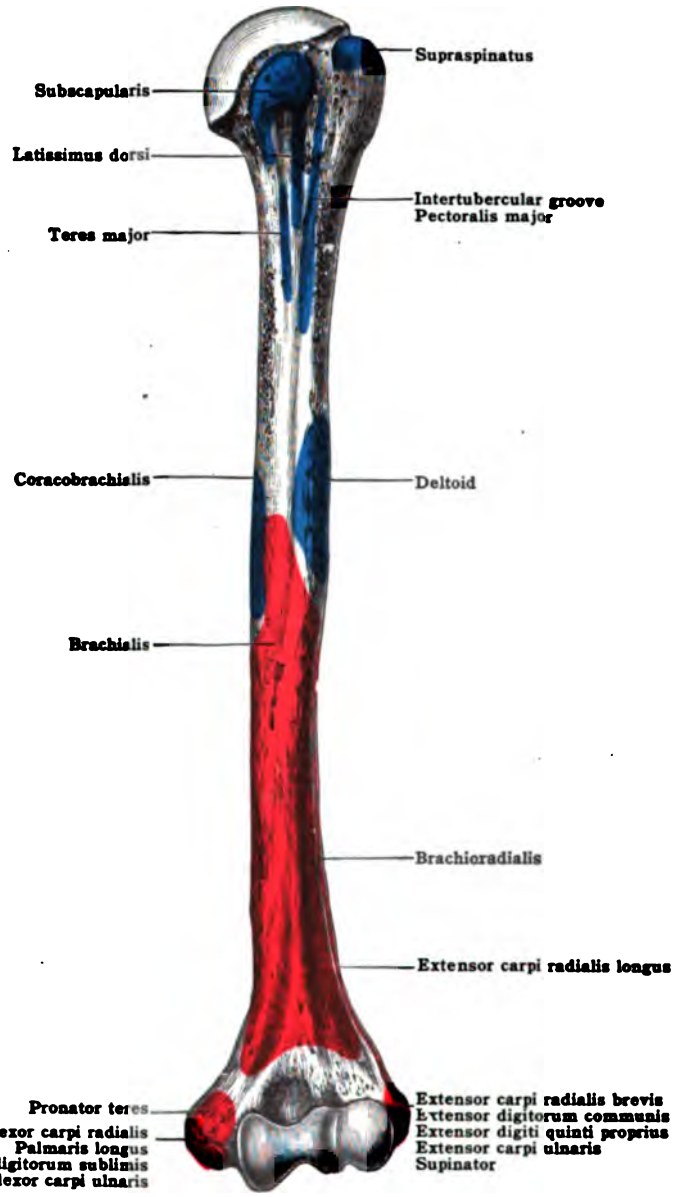
THE HUMERUS

The **humerus** (figs. 211–213) is the longest and largest bone of the upper limb, and extends from the shoulder above, where it articulates with the scapula, to the elbow [cubitus] below, where it articulates with the two bones of the forearm [antibrachium]. It is divisible into a shaft and two extremities; the *upper* extremity includes the head [caput], neck [collum], and two tuberosities—great and small; the *lower* extremity includes the articular surface with the surmounting fossæ in front and behind, and the two epicondyles.

Upper extremity.—The **head** forms a nearly hemispherical articular surface, cartilage-clad in the recent state and directed upward, medially, and backward toward the glenoid cavity. Below the head the bone is rough and somewhat constricted, constituting the **anatomical neck**, best marked superiorly, where it forms a groove separating the articular surface from the two tuberosities. The circumference of the neck gives attachment to the capsule of the shoulder-joint and the glenohumeral ligaments, the upper of which is received into a depression near the top of the intertubercular (bicipital) groove. The lowest part of the

capsule descends upon the humerus some distance from the articular margin. Laterally and in front of the head are the two tuberosities, separated by a deep furrow. The **greater tuberosity** [tuberculum majus], lateral in position and reaching higher than the **lesser tuberosity** [tuberculum minus], is marked by three facets for the insertion of muscles: an upper one for the *supraspinous*, a middle for the *infraspinatus*, and a lower for the *teres minor*. The **lesser tuberosity** is situated in front of the head and is the more prominent of the two; it receives the insertion

FIG. 211.—THE LEFT HUMERUS. (Anterior view.)

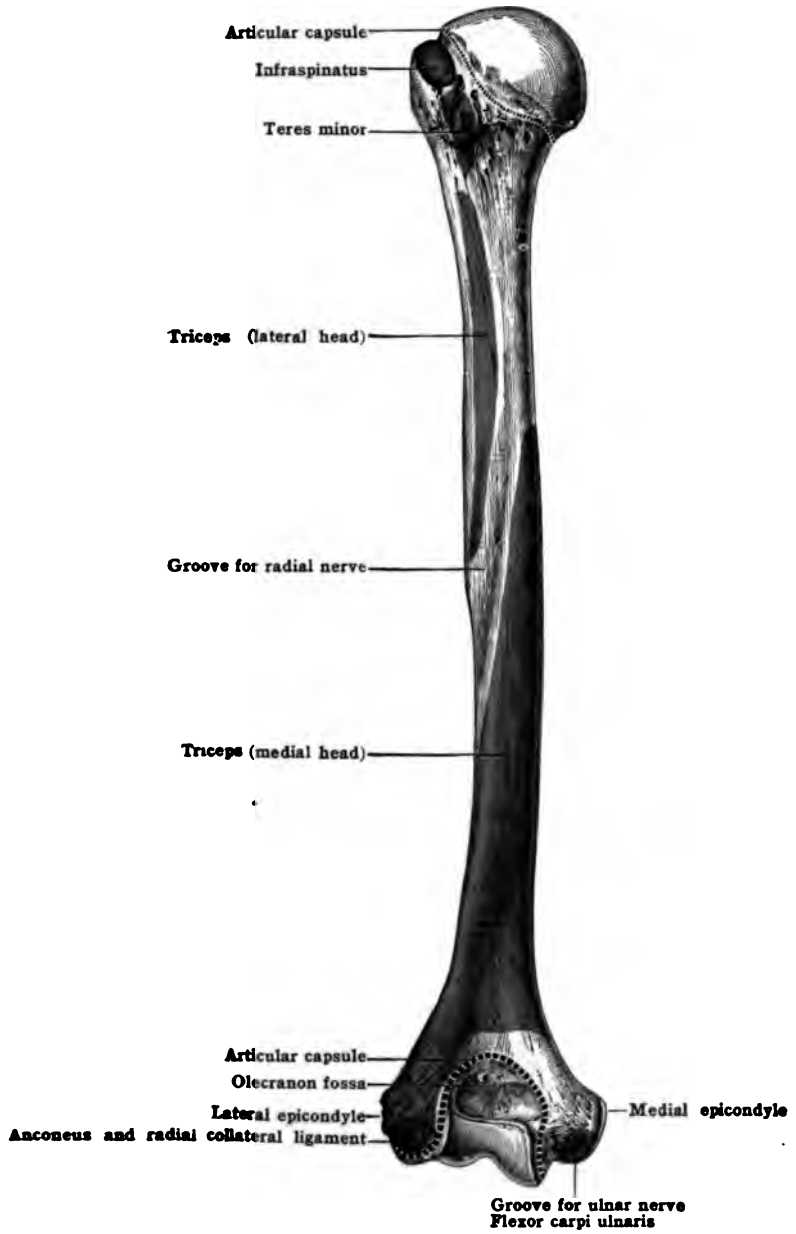


of the *subscapularis*. The furrow between the tuberosities lodges the long tendon of the biceps and forms the commencement of the **intertubercular** (bicipital) **groove,** which extends downward along the shaft of the humerus. Between the tuberosities the transverse humeral ligament converts the upper end of the groove into a canal. In addition to the long tendon of the biceps and its tube of synovial membrane, the groove transmits a branch of the anterior circumflex artery. Immediately below the two tuberosities the bone becomes contracted and forms the **surgical neck.**

The shaft or **body** [corpus humeri] is somewhat cylindrical above, flattened and prismatic below. Three borders and three surfaces may be recognised.

Borders.—The **anterior border** commences above at the greater tuberosity, and its upper part, forming the **crest** of this tuberosity [crista tuberculi majoris] receives the *pectoralis major*. In the middle of the shaft it is rough and prominent and gives insertion to the *deltoid;* below it is smooth and rounded, giving origin

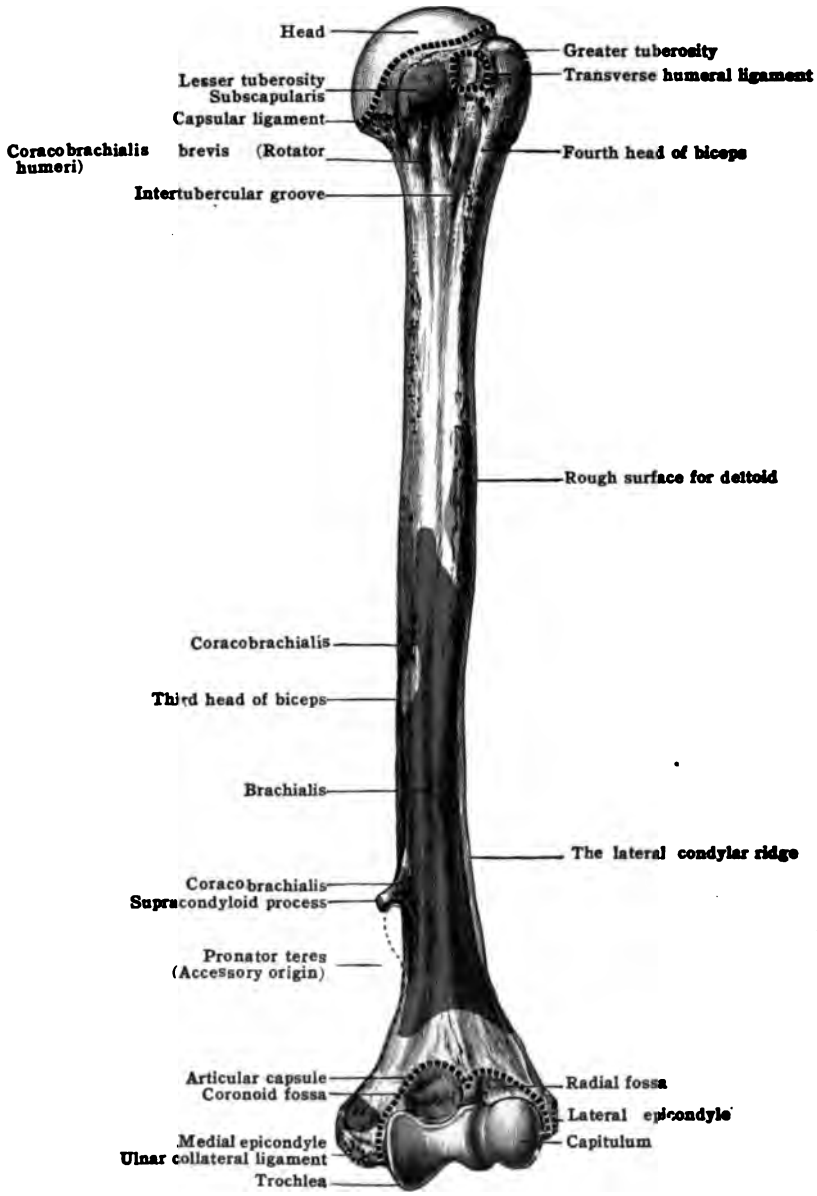
FIG. 212.—THE LEFT HUMERUS. (Posterior view.)



to the *brachialis*, and finally it passes along lateral to the coronoid fossa to become continuous with the ridge separating the capitulum and trochlea. It separates the anteromedial from the anterolateral surface. The **lateral margin** extends from the lower and posterior part of the greater tuberosity to the lateral epicondyle. Smooth and indistinct above, it gives attachment to the *teres minor* and the lateral head of the *triceps;* it is interrupted in the middle by the **groove for the radial nerve** (musculospiral groove), and the lower third becomes prominent and curved

laterally to form the **lateral supracondylar ridge,** which affords origin in front to the *brachioradialis* and the *extensor carpi radialis longus;* behind to the medial head of the *triceps,* and between these muscles in front and behind to the lateral intermuscular septum. It separates the anterolateral from the posterior surface. The **medial border** commences at the lesser tuberosity, forming its **crest** which receives the insertion of the *teres major,* and continuing downward to the medial epicondyle. Near the middle of the shaft it forms a ridge for the insertion of the

FIG. 213.—THE LEFT HUMERUS WITH A SUPRACONDYLOID PROCESS AND SOME IRREGULAR MUSCLE ATTACHMENTS. (Anterior view.)



coracobrachialis and presents a foramen for the nutrient ratery, directed downward toward the elbow-joint. Below it forms a distinct **medial supracondylar ridge,** curved medially, which gives origin to the *brachialis* in front, the medial head of the *triceps* behind, and the medial intermuscular septum in the interval between the muscles. This border separates the anteromedial from the posterior surface.

Surfaces.—The **anterolateral surface** is smooth above, rough in the middle, forming a large impression for the insertion of the *deltoid,* below which is the

termination of the groove for the radial nerve. The lower part of the surface **gives origin** to the lateral part of the *brachialis*. The **anteromedial surface** is **narrow above**, where it forms the floor of the intertubercular (bicipital) groove, **and receives** the insertion of the *latissimus dorsi*. Near the junction of the upper **and middle** thirds of the bone the groove, gradually becoming shallower, widens **out and**, with the exception of a rough impression near the middle of the shaft **for the** *coracobrachialis*, the remaining part of the anteromedial surface is flat **and smooth**, and gives origin to the *brachialis*.

Occasionally, a bony spine of variable size, the **supracondylar process** (fig. 213), projects downward from the medial border about 5 cm. (2 in.) above the medial epicondyle, to which it is joined by a band of fibrous tissue. It occurs in from 1 per cent. (Testut) to 2.7 per cent. (Gruber) of cases; and was found in 8 of 1000 living subjects (Terry). Through the ring thus formed, which corresponds to the supracondylar foramen in many of the lower animals, the median nerve and brachial artery are transmitted, though in some cases it is occupied by the nerve alone. The process gives origin to the *pronator teres*, and may afford insertion to a persistent lower part of the *coracobrachialis*.

The **posterior surface** is obliquely divided by a broad shallow groove, which runs in a spiral direction from behind downward and forward and transmits the radial (musculospiral) nerve and the profunda artery. The lateral part of the surface above the groove gives attachment to the lateral head, and the part below the groove, to the medial head of the *triceps*.

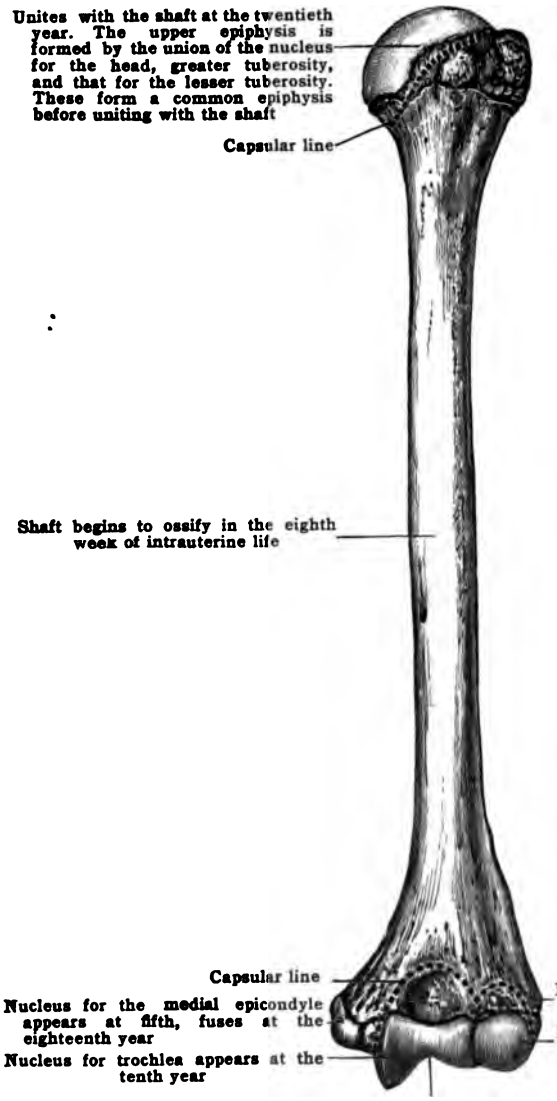
FIG. 214.—A DIAGRAM SHOWING PRESSURE AND TENSION CURVES IN THE HEAD OF THE HUMERUS. (After Wagstaffe.)

The **lower extremity** of the humerus is flattened from before backward, and terminates below in a sloping articular surface, subdivided by a low ridge into the **trochlea and the capitulum.** The **trochlea** is the pulley-like surface which extends over the end of the bone for articulation with the semilunar notch (great sigmoid cavity) of the ulna. It is constricted in the center and expanded laterally to form two prominent edges, the medial of which is thicker, descends lower, and forms a marked projection; the lateral edge is narrow and corresponds to the interval between the ulna and radius. Above the trochlea are two fossæ: on the anterior surface is the **coronoid fossa,** an oval pit which receives the coronoid process of the ulna when the forearm is flexed; on the posterior aspect is the **olecranon fossa,** a deep hollow for the reception of the anterior extremity of the olecranon in extension of the forearm. These fossæ are usually separated by a thin, translucent plate of bone, sometimes merely by fibrous tissue, so that in macerated specimens a perforation, the **supratrochlear foramen,** exists. The **capitulum,** or radial head, is much smaller than the trochlea, somewhat globular in shape, and limited to the anterior and inferior surfaces of the extremity. It articulates with the concavity on the summit of the radius. The **radial fossa** is a slight depression on the front of the bone, immediately above the capitulum, which receives the anterior edge of the head of the radius in complete flexion of the forearm, whilst between the capitulum and the trochlea is a shallow groove occupied by the medial margin of the head of the radius.

In the recent state the inferior articular surface is covered with cartilage, the fossæ are lined by synovial membrane, and their margins give attachment to the capsule of the elbow-joint. Projecting on either side from the lower end of the humerus are the two **epicondyles.** Both epicondyles project beneath the skin and are easily felt in palpating the elbow. The medial

one is large and by far the more prominent of the two, rough in front and below, smooth behind, where there is a shallow groove for the ulnar nerve. The rough area serves for origin of the *pronator teres* above, the common tendon of origin of the *flexor carpi radialis, palmaris longus, flexor digitorum sublimis* and *flexor carpi ulnaris* in the middle, and the ulnar collateral ligament below. The lateral epicondyle is flat and irregular. Above, it gives attachment to a common tendon of origin of the *extensor carpi radialis brevis, extensor digitorum communis, extensor quinti digiti proprius, extensor carpi ulnaris,* and *supinator;* to a depression near the outer margin of the capitulum, the radial collateral ligament is attached, and from an area below and behind, the *anconeus* takes origin.

FIG. 215.—OSSIFICATION OF THE HUMERUS; THE FIGURE ALSO SHOWS THE RELATIONS OF THE EPIPHYSIAL AND CAPSULAR LINES.



Unites with the shaft at the twentieth year. The upper epiphysis is formed by the union of the nucleus for the head, greater tuberosity, and that for the lesser tuberosity. These form a common epiphysis before uniting with the shaft
Capsular line
Shaft begins to ossify in the eighth week of intrauterine life
Capsular line
Nucleus for the medial epicondyle appears at fifth, fuses at the eighteenth year
Nucleus for trochlea appears at the tenth year
Nucleus for lateral epicondyle appears at fourteenth year
Nucleus for capitulum appears in the third year
The centers for the radial epicondyle, trochlea, and capitulum unite together and form an epiphysis which fuses with the shaft at the seventeenth year

The *length* of the humerus is somewhat less than one-fifth the stature of the individual. The principal axes of the upper and lower extremities of the bone lie in planes that cross each other at an angle that varies in size between 12° and 20° in Europeans and is considerably greater in negroes.

The term neck is applied to three parts of the humerus. The *anatomical* neck is the constriction to which the articular capsule is mainly attached. The upper extremity of the humeral shaft, before its union with the epiphysis, terminates in a low three-sided pyramid, the surfaces of which are separated from one another by ridges. The medial of these three surfaces underlies the head of the bone, and the two lateral surfaces underlie the tuberosities. The part sup-

ng the head constitutes the *morphological* neck of the humerus. The *surgical* neck is the inite area below the tuberosities where the bone is liable to fracture.

rchitecture.—The interior of the shaft of the humerus is hollowed out by a large medullary l, whereas the extremities are composed of cancellated tissue invested by a thin compact . The arrangement of the cancellous tissue at the upper end of the humerus is shown g. 214. The lamellæ converge to the axis of the bone and form a series of superimposed es which reach upward as far as the epiphysial line. In the epiphyses the spongy tissue s a fine network, the lamellæ resulting from pressure being directed at right angles to the ular surface of the head and to the great tuberosity.

lood-supply.—The foramina which cluster round the circumference of the head and tuber- es transmit branches from the transverse scapular (suprascapular) and anterior and pos- r circumflex arteries. At the top of the intertubercular groove is a large nutrient foramen branch of the anterior circumflex artery which supplies the head. The nutrient artery of haft is derived from the brachial, and in many cases, an additional branch, derived from profunda artery, enters the foramen in the groove for the radial nerve (musculospiral

re). The lower extremity is nourished by branches derived from the profunda (superior nda), the superior and inferior ulnar collateral (inferior profunda and anastomotic), and ecurrent branches of the radial, ulnar, and interosseous arteries.

ssification.—The humerus is ossified from one primary center (diaphysial) and six second- enters (epiphysial). The center for the shaft appears about the seventh week (forty-second according to Mall) of intrauterine life and grows very rapidly. At birth only the two mities are cartilaginous, and these ossify in the following manner: Single centers appear he head in the first year, for the greater tuberosity in the third year, and for the lesser rosity in the fifth year, though sometimes the latter ossifies by an extension from the greater rosity. These three nuclei coalesce at six years to form a single epiphysis, which joins the t about the twentieth year.

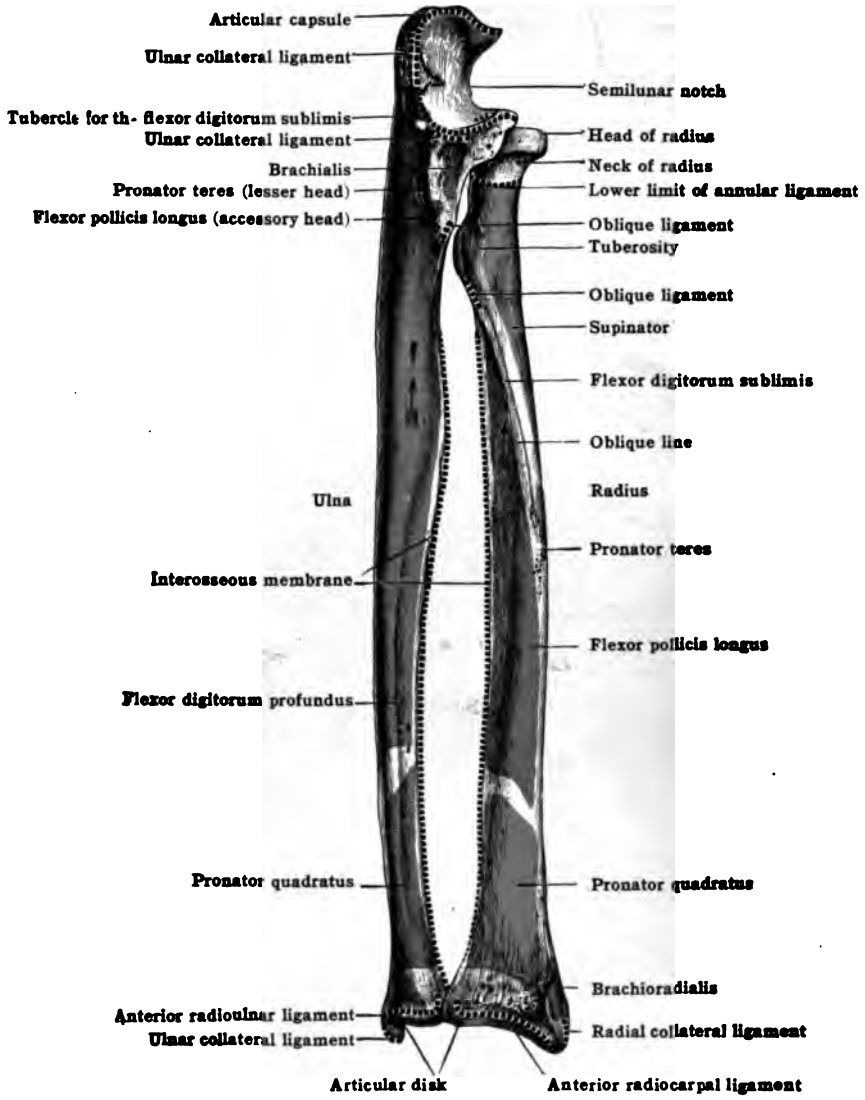
The inferior extremity ossifies from four centers: one for the capitulum appears in the third , a second for the medial epicondyle in the fifth year, a third for the trochlea in the tenth , and a fourth for the lateral epicondyle in the fourteenth year. The nuclei for the capitu- trochlea, and lateral epicondyle coalesce to form a single epiphysis which joins the shaft e seventeenth year (figs. 223, 1121). The nucleus of the medial epicondyle joins the shaft pendently at the age of eighteen years.

THE RADIUS

The **radius** (figs. 2172—22) is the lateral and shorter of the two bones of the forearm. Above, it articulates with the humerus; below, with the carpus; and on the medial side with the ulna. It presents a shaft and two extremities.

The **upper extremity,** smaller than the lower, includes the head, neck, and tuberosity. The **head** [capitulum], covered with cartilage in the recent state, is a circular disk forming the expanded, articular end of the bone. Superiorly it presents the capitular depression [fovea capituli] for the reception of the capitulum

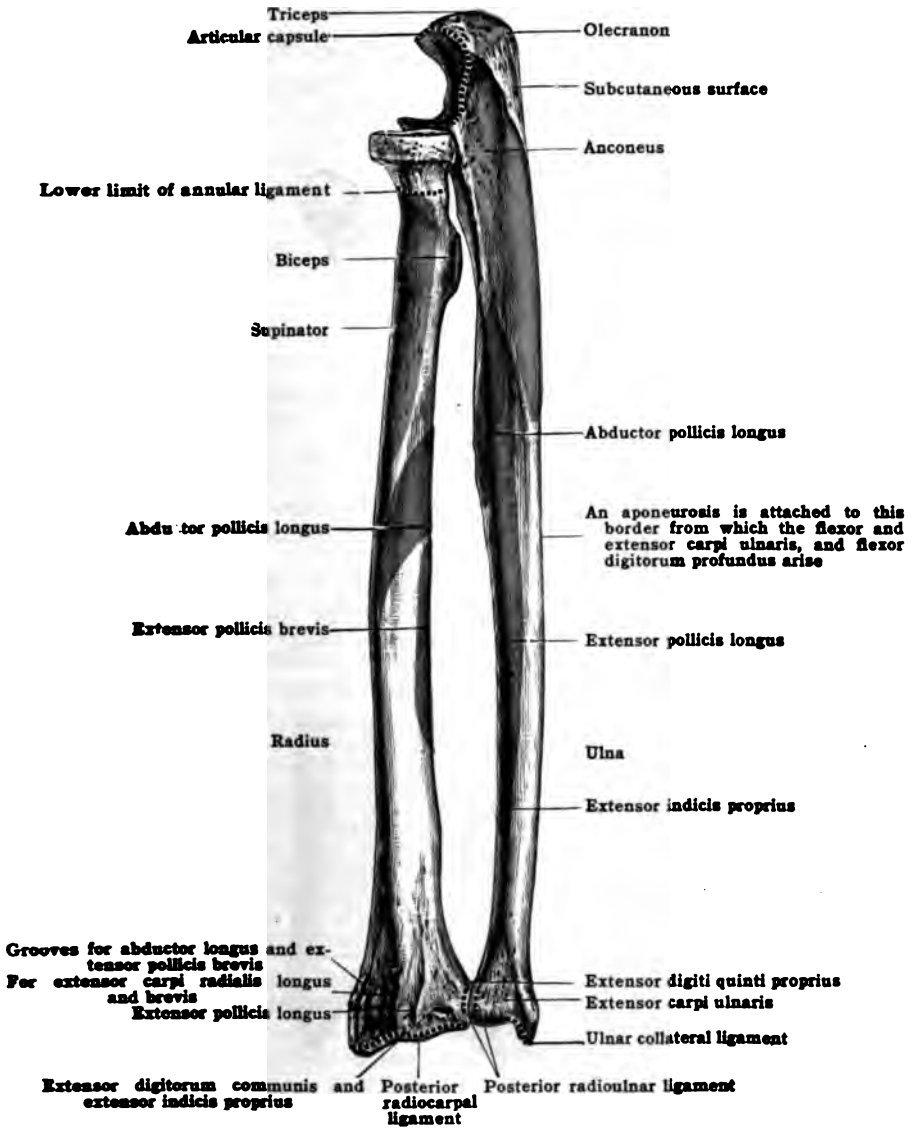
FIG. 217.—THE LEFT ULNA AND RADIUS. (Anteromedial view.)



of the humerus; its *circumference* [circumferentia articularis], deeper on the medial aspect, articulates with the radial notch (lesser sigmoid cavity) of the ulna, and is narrow elsewhere for the annular ligament by which it is embraced. Below the head is a short cylindrical portion of bone, somewhat constricted, and known as the **neck.** The upper part is surrounded by the ligament which embraces the head, and below this it gives insertion anterolaterally to the *supinator.* Below the neck, at the anteromedial aspect of the bone, is an oval eminence, the **radial tuberosity,** divisible into two parts: a rough posterior portion for the insertion of the tendon of the *biceps,* and a smooth anterior surface in relation with a bursa which is situated between the tendon and the tuberosity.

The body [corpus radii] or **shaft** is somewhat prismatic in form, gradually increasing in size from the upper to the lower end, and slightly curved so as to be concave toward the ulna. Three borders and three surfaces may be recognized. Of the borders, the medial or **interosseous crest** [crista interossea] is best marked. Commencing at the posterior edge of the tuberosity, its first part is round and indistinct, and receives the attachment of the oblique cord of the radius; it is continued as a sharp ridge which divides near the lower extremity to become continuous with the anterior and posterior margins of the ulnar notch (sigmoid cavity).

FIG. 218.—THE LEFT ULNA AND RADIUS. (Posterolateral view.)



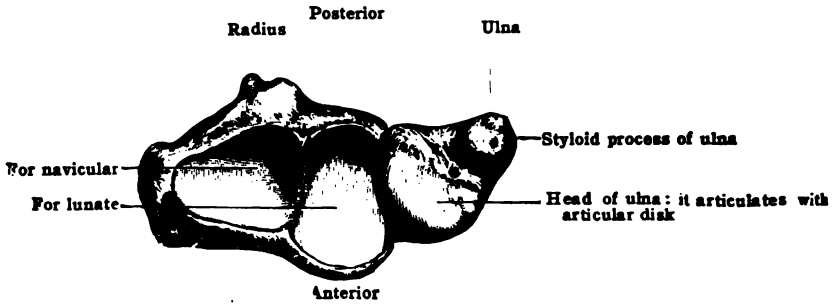
The prominent ridge and the posterior of the two lower lines give attachment to the interosseous membrane, whilst the triangular surface above the ulnar notch receives a part of the *pronator quadratus*. The interosseous crest separates the volar from the dorsal surface.

The volar border [margo volaris] runs from the tuberosity obliquely downward to the lateral side of the bone and then descends vertically to the anterior border of the styloid process. The upper third, constituting the oblique line of the radius, gives origin to the radial head of the *flexor digitorum sublimis*, limits the insertion of the *supinator* above, and the origin of the *flexor pollicis longus* below. The volar border separates the volar from the lateral surface. The dorsal border extends from the back of the tuberosity to the prominent middle tubercle on the

posterior aspect of the lower extremity. Separating the lateral from the dorsal surface, it is well marked in the middle third, but becomes indistinct above and below.

Surfaces.—The **volar** (or anterior) **surface** is narrow and concave above; broad, flat, and smooth below. The upper two-thirds is occupied chiefly by the *flexor pollicis longus* and a little less than the lower third by the *pronator quadratus.* Near the junction of the upper and middle thirds of the volar surface is the nutrient foramen, directed upward toward the proximal end of the bone. It transmits a branch of the volar interosseous artery. The **lateral surface** is convex, rounded above and affords insertion to the *supinator;* marked near the middle by a rough, low, vertical ridge for the *pronator teres;* smooth below, where the tendons of the

FIG. 219.—ARTICULAR FACETS ON THE LOWER END OF LEFT RADIUS AND ULNA.



extensor carpi radialis longus and *brevis* lie upon it, and where it is crossed by the *abductor pollicis longus* and *extensor pollicis brevis.* The **dorsal** (or posterior) **surface,** smooth and rounded above, is covered by the *supinator;* grooved longitudinally in the middle third for the *abductor pollicis longus* and the *extensor pollicis brevis;* the lower third is broad, rounded, and covered by tendons. The line which forms the upper limit of the impression for the *abductor pollicis longus* is known as the **posterior oblique line.**

The **lower extremity** of the radius is quadrilateral; its **carpal surface** [facies articularis carpea] is articular and divided by a ridge into a medial **quadrilateral** portion, concave for articulation with the lunate bone; and a lateral **triangular**

FIG. 220.—DORSAL VIEW OF THE LOWER END OF THE RADIUS AND ULNA.

portion, extending onto the styloid process for articulation with the navicular (scaphoid) bone. The medial surface, also articular, presents the **ulnar notch** (sigmoid cavity) for the reception of the rounded margin of the head of the ulna. To the border separating the ulnar and carpal articular surfaces the base of the articular disk is attached, and to the anterior and posterior borders, the anterior and posterior radioulnar ligaments respectively. The **anterior surface** is raised into a prominent area for the anterior ligament of the wrist-joint. The **lateral surface** is represented by the **styloid process,** a blunt pyramidal eminence, easily palpated beneath the skin; to its base the *brachioradialis* is inserted, whilst the tip serves for the attachment of the radial (external) collateral ligament of the wrist.

Its lateral surface is marked by two shallow furrows for the tendons of the *abductor pollicis longus* and *extensor pollicis brevis*. The **posterior surface** is convex, and marked by three prominent ridges separating three furrows. The posterior annular ligament is attached to these ridges, thus forming with the bone a series of tunnels for the passage of tendons (fig. 220).

The most lateral groove is broad, shallow, and frequently subdivided by a low ridge. The lateral subdivision is for the *extensor carpi radialis longus*, the medial for the *extensor carpi radialis brevis*. The middle groove is narrow and deep for the tendon of the *extensor pollicis longus*. The sharp tubercle which limits this groove laterally can be distinguished by palpation. The most medial is shallow and transmits the *extensor indicis proprius*, the *extensor digitorum communis*, the dorsal branch of the interosseous artery, and the dorsal interosseous nerve. When the radius and ulna are articulated, an additional groove is formed for the tendon of the *extensor digiti quinti proprius*.

Ossification.—The radius is ossified from a center which appears in the middle of the shaft in the eighth week of intrauterine life and from two epiphyseal centers which appear after birth. The nucleus for the lower end appears in the second year, and that for the upper end, which forms simply the disk-shaped head, from the fifth year to the tenth year. According to Pryor the distal epiphysis appears in female children at the eighth month; in males at fifteen months. The head unites with the shaft at the seventeenth year whilst the inferior epiphysis and the shaft join about the twentieth year.

Variations.—Congenital absence of the radius has frequently been observed; absence of the thumb has been noted in association with this variation in a number of cases. A sesamoid develops rarely in the tendon of the biceps over the tuberosity of the radius.

THE ULNA

The **ulna** (figs. 217, 218, 221, 224) is a long prismatic bone, thicker above than below, on the medial side of the forearm and parallel with the radius, which it exceeds in length by the extent of the olecranon process. It articulates at the upper end with the humerus, at the lower end indirectly with the carpus, and on the lateral side with the radius. It is divisible into a shaft and two extremities.

The upper extremity is of irreeular shape and forms the thickest and strongest part of the bone. The superior articular surface is concave from above downward, convex from side to side, and transversely constricted near the middle. It belongs partly to the **olecranon,** the thick upward projection from the shaft, and partly to the **coronoid process,** which projects horizontally forward from the front of the ulna. This semilunar excavation forms the **semilunar notch** (greater sinmoid cavity) and articulates with the trochlear surface of the humerus. The **olecranon** is the large curved eminence forming the highest part of the bone.

The superior surface of the olecranon, uneven and somewhat quadrilateral in shape, receives behind, where there is a rough impression, the insertion of the *triceps*, and along the anterior margin the articular capsule of the elbow-joint. The posterior surface, smooth and triangular in outline, is separated from the skin by a bursa and can be readily palpated. The anterior surface, covered with cartilage in the recent state, is directed downward and forward, and its margins give attachment to the articular capsule of the elbow-joint. This surface, as already noticed, forms the upper and back part of the semilunar notch. On the medial surface of the olecranon is a tubercle for the origin of the ulnar head of the *flexor carpi ulnaris*, and in front of this a fasciculus of the ulnar collateral ligament of the elbow-joint is attached to the bone; the lateral surface is rough, concave, and gives insertion to a part of the *anconeus*. The extremity of the olecranon lies during extension of the elbow in the olecranon fossa of the humerus.

The **coronoid process,** forming the lower and anterior part of the semilunar notch, has a superior articular surface continuous with the anterior surface of the olecranon, and, like it, covered with cartilage. The inferior aspect is rough and concave, and gives insertion to the *brachialis*.

It is continuous with the volar surface of the shaft, and near the junction of the two is a rough eminence named the **tuberosity of the ulna,** which receives the attachment of the oblique cord of the radius and the insertion of the *brachialis*. The medial side presents above a smooth tubercle for the origin of the ulnar portion of the *flexor digitorum sublimis*, and a ridge below for the lesser head of the *pronator teres* and the rounded accessory bundle of the *flexor pollicis longus*, whilst immediately behind the sublimis tubercle there is a triangular depressed surface for the upper fibers of the *flexor digitorum profundus*.

On the lateral surface is the **radial notch** (lesser sigmoid cavity), an oblong articular surface which articulates with the circumference of the head of the radius, the anterior and posterior margins of which afford attachment to the annular ligament and the radial collateral ligament of the elbow-joint. In flexion of the elbow the tip of the process is received into the coronoid fossa of the humerus.

Capsular line

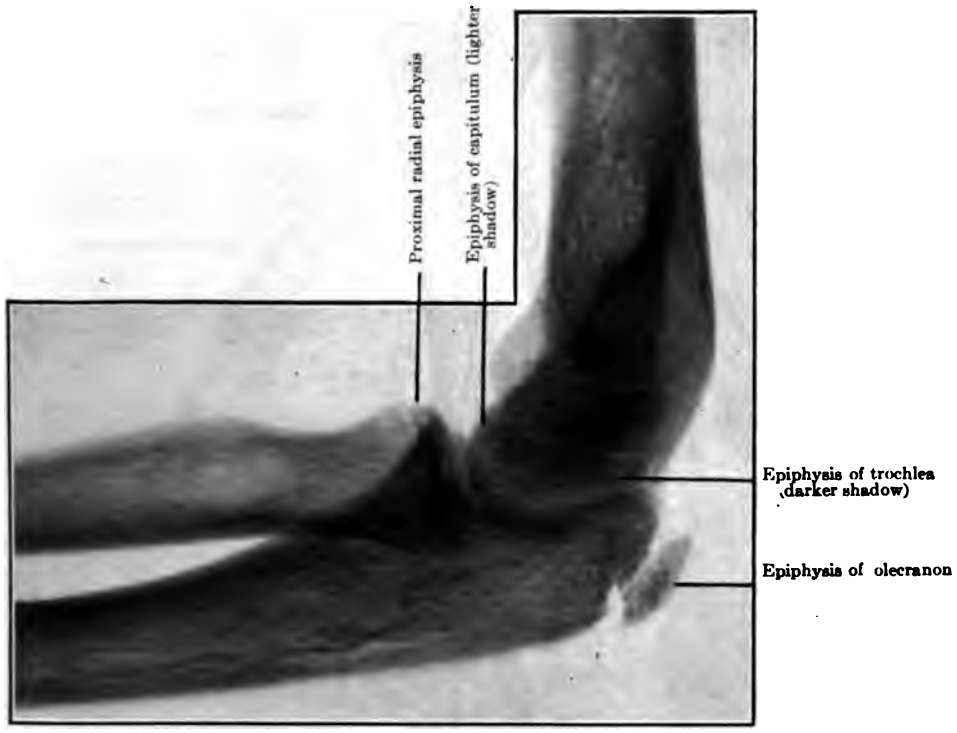
The **body** [corpus ulnæ] or **shaft** throughout the greater part of its extent is three-sided, but tapers toward the lower extremity, where it becomes smooth and rounded. It has three borders and three surfaces. Of the three borders, the **lateral,** the **interosseous crest,** is best marked. In the middle three-fifths of the shaft it is sharp and prominent, but becomes indistinct below; above it is continued by two lines which pass to the anterior and posterior extremities of the radial notch and enclose a depressed triangular area (bicipital hollow), the fore part of which lodges the tuberosity of the radius and the insertion of the biceps tendon during pronation of the hand, while from the posterior part the *supinator* takes origin. The **interosseous crest** separates the volar from the dorsal surface and gives attachment by the lower four-fifths of its extent to the interosseous membrane. The **volar border** is directly continuous with the medial edge of the rough surface for the brachialis and terminates inferiorly in front of the styloid process. Throughout the greater part of its extent it is smooth and rounded, and affords origin to the *flexor digitorum profundus* and the *pronator quadratus.* It separates

FIG. 223.—RIGHT ELBOW-JOINT OF A BOY AGED SIXTEEN. From an *X*-ray Plate by Dr. Sherwood Moore, Washington University. (Cf. Fig. 1121.)



Proximal radial epiphysis

Epiphysis of trochlea (darker shadow)
Epiphysis of olecranon

the volar from the medial surface. The **dorsal border** commences above at the apex of the triangular subcutaneous area on the back of the olecranon, and takes a sinuous course to the back part of the styloid process. The upper three-fourths gives attachment to an aponeurosis common to three muscles, viz., the *flexor* and *extensor carpi ulnaris* and the *flexor digitorum profundus.* This border separates the medial from the dorsal surface, and is easily palpated throughout.

Surfaces.—The **volar** (or anterior) **surface** is grooved in the upper three-fourths of its extent for the origin of the *flexor digitorum profundus,* narrow and convex below, for the origin of the *pronator quadratus.* The upper limit of the area for the latter muscle is sometimes indicated by an oblique line—the **pronator ridge.** Near the junction of the upper and middle thirds of the anterior surface is the nutrient foramen, directed upward toward the proximal end of the bone. It transmits a branch of the volar interosseous artery. The **medial surface,** smooth and rounded, gives attachment, on the upper two-thirds, to the *flexor digitorum profundus,* whereas the lower third is subcutaneous. The **dorsal** (or posterior) **surface,** directed laterally as well as backward, presents at its upper part the

oblique line of the ulna running from the posterior extremity of the radial notch to the dorsal border.

The oblique line gives attachment to a few fibers of the *supinator* and marks off the posterior surface into two unequal parts. That above the line, much the smaller of the two, receives the insertion of the *anconeus*. The more extensive part below is subdivided by a vertical ridge into a medial portion, smooth, and covered by the *extensor carpi ulnaris*, and a lateral portion which gives origin to three muscles, viz., the *abductor pollicis longus*, the *extensor pollicis longus* and the *extensor indicis proprius*, from above downward.

The **lower extremity** of the ulna is of small size and consists of two parts, the **head** and the **styloid process**, separated from each other on the inferior surface by a groove into which the apex of the articular disk is inserted. That part of the head adjacent to the groove is semilunar in shape and plays upon the articular disk which thus excludes the ulna from the radiocarpal or wrist-joint. The mar-

FIG. 224.—THE LEFT RADIUS AND ULNA IN PRONATION. (Anterior view.)

gin of the head is also semilunar, and is received into the ulnar notch of the radius. In pronation the head of the ulna makes the rounded prominence on the dorsal side of the wrist. The **styloid process** projects from the medial and back part of the bone, and appears as a continuation of the dorsal border. To its rounded summit the ulnar collateral ligament of the wrist-joint is attached, and its dorsal surface is grooved for the passage of the tendon of the *extensor carpi ulnaris*. Immediately above the articular margin of the head the anterior and posterior radioulnar ligaments are attached in front and behind.

In contrast to the poor adaptation of the articular surfaces of the humerus and radius for security in the hinge-movements of the elbow is the perfect locking of the semilunar notch of the ulna with the trochlea of the humerus. The inferior extremity of the bone is adapted mainly to the radius in the pivotal movements of pronation and supination, and has undergone regression in those mammals in which the antibrachium is permanently fixed in pronation, as, for example, in the horse and ox.

The ratio between the lengths of the forearm and the arm is expressed by the ***humero-radial***

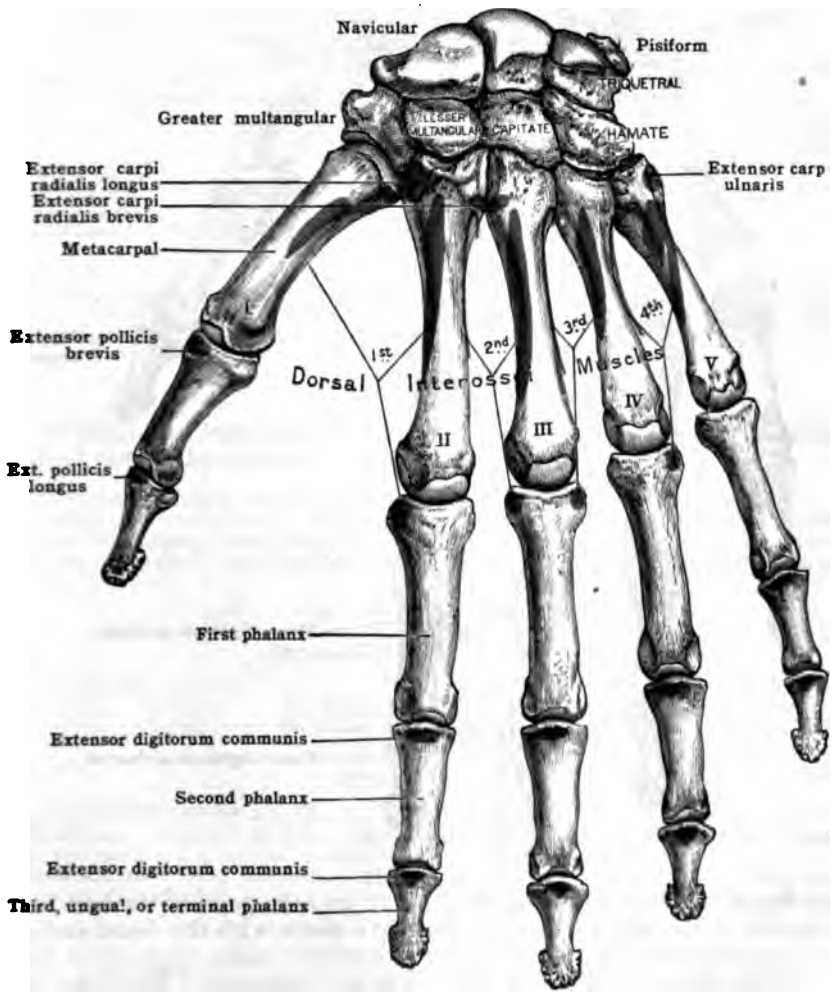
index, $\frac{\text{length of radius} \times 100}{\text{length of humerus}}$. The index is higher in the infant than in the adult; higher in women than in men. In Europeans the index has been found to be 74; in the negro, 79; in Andamanese 81. In the anthropoid apes, the gorilla has an index of 90; the orang, 100.

Ossification.—The ulna is ossified from three centers. The primary nucleus appears near the middle of the shaft in the eighth week of intrauterine life. At birth the inferior extremity and the greater portion of the olecranon are cartilaginous. The nucleus for the lower end appears during the sixth year (sixth to seventh year in girls; eighth to ninth in boys. Pryor) and the epiphysis joins with the shaft from the eighteenth to the twentieth year (fig. 241). The greater part of the olecranon is ossified from the shaft, but an epiphysis is subsequently formed from a nucleus which appears in the tenth year.

The epiphysis varies in size, and may be either scale-like and form a thin plate on the summit, or involve the upper fourth of the olecranon and the corresponding articular surface. In the latter case the epiphysis is probably composed of two parts fused together: (1) The scale on the summit of the olecranon process, and (2) the beak center which enters into the formation of the upper end of the semilunar notch. The epiphysis unites to the shaft in the sixteenth or seventeenth year.

Variations.—A sesamoid bone above the olecranon and lodged in the tendon of the triceps occurs rarely. Total absence of the ulna has been recorded.

FIG. 225.—BONES OF THE LEFT HAND. (Dorsal surface.)



THE CARPUS

The carpus (figs. 225, 226) consists of eight bones, arranged in two rows, four bones in each row. Enumerated from the radial to the ulnar side, the bones of the proximal row are named **navicular** (scaphoid), **lunate** (semilunar), **triquetral (cuneiform), and pisiform**; those of the distal row, **greater multangular** (trape-

zium), **lesser multangular** (trapezoid), **capitate** (os magnum), **and hamate** (unciform).

When the bones of the carpus are articulated, they form a mass somewhat quadrangular in outline, wider below than above, and with the long diameter transverse. The dorsal surface is convex and the volar surface concave from side to side. The concavity is increased by four prominences, which project forward, one from each extremity of each row. On the radial side are the tuberosity of the navicular and the ridge of the greater multangular; on the ulnar side, the pisiform and the hook of the hamate. Stretched transversely between these prominences, in the recent state, is the transverse carpal ligament forming a canal for the pas-

sage of the flexor tendons and the median nerve into the palm of the hand. The proximal border of the carpus is convex and articulates with the distal end of the radius and the articular disk. The pisiform, however, takes no share in this articulation, being attached to the volar surface of the triquetral. The distal border forms an undulating articular surface for the bases of the metacarpal bones. The line of articulation between the two rows of the carpus is concavoconvex from side to side, the lateral part of the navicular being received into the concavity formed by the greater multangular, lesser multangular, and capitate, and the capitate and hamate into that formed by the navicular, lunate, and triquetral bones.

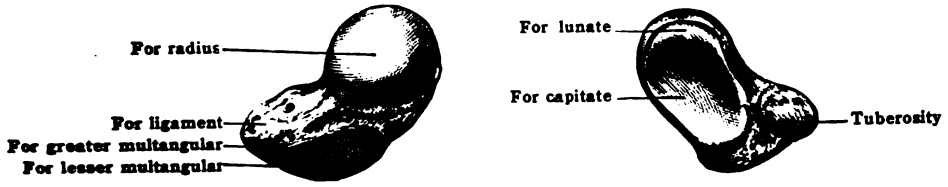
The individual carpal bones have several points of resemblance. Each bone (excepting the pisiform) has six surfaces, of which the anterior or volar and poste-

rior or dorsal are rough for the attachment of ligaments, the volar surface being the broader in the proximal row, the dorsal surface in the distal row. The superior and inferior surfaces are articular, the former being generally convex and the latter concave. The lateral surfaces, when in contact with adjacent bones, are also articular, but otherwise rough for the attachment of ligaments. Further, the whole of the carpus is cartilaginous at birth and each bone is ossified from a single center.

The Navicular

The **navicular** [os naviculare] or scaphoid (fig. 227) is the largest bone of the proximal row, and so disposed that its long axis runs obliquely downward and lateralward.

Fig. 227.—The Left Navicular.



The **superior surface** is convex and somewhat triangular in shape for articulation with the lateral facet on the distal end of the radius. The **inferior surface**, smooth and convex, is divided into two parts by a ridge running from before backward. The lateral part articulates with the greater multangular, the medial with the lesser multangular. The **volar surface**, rough and concave above, is elevated below into a prominent tubercle for the attachment of the transverse carpal ligament and the *abductor pollicis brevis*. The **dorsal surface** is narrow, being reduced to a groove running the whole length of the bone; it is rough and serves for the attachment of the dorsal radiocarpal ligament. The **medial surface** is occupied by two articular facets, of which the upper is crescentic in shape for the lunate bone, whilst the lower is deeply concave for the reception of the head of the capitate. The **lateral surface** is narrow and rough for the attachment of the radial collateral ligament of the wrist-joint.

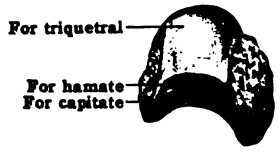
Articulations.—With the radius above, greater and lesser multangular below, lunate and capitate medially.

The Lunate

The **lunate** [os lunatum] or semilunar (fig. 228), placed in the middle of the proximal row of the carpus, is markedly crescentic in outline.

The **superior surface** is smooth and convex and articulates with the medial of the two facets on the distal end of the radius. The **inferior surface** presents a deep concavity divided into two parts by a line running from before backward. Of these, the lateral and larger articulates with the capitate; the medial and smaller with the hamate. The **volar surface** is large and convex,

Fig. 228.—The Left Lunate.



the **dorsal surface** narrow and flat, and both are rough for the attachment of ligaments. The **medial surface** is marked by a smooth quadrilateral facet for the base of the triquetral. The **lateral surface** forms a narrow crescentic articular surface for the lunate.

Articulations.—With the radius above, capitate and hamate below, navicular laterally and triquetral medially.

The Triquetral

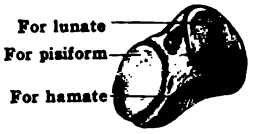
The **triquetral** [os triquetrum] or cuneiform (fig. 229) is pyramidal in shape and placed obliquely, so that its base looks upward and laterally and the apex downward and medially.

The **superior surface** presents laterally near the base a small, convex articular facet which plays upon the articular disk interposed between it and the distal end of the ulna, and medially a rough non-articular portion for ligaments. The **inferior surface** forms a large, triangular undulating facet for articulation with the hamate. The **volar surface** can be readily recognized by the conspicuous oval facet near the apex for the pisiform bone. The **dorsal surface** is rough for the attachment of ligaments. The **medial** and **lateral surfaces** are represented by the base

and the apex of the pyramid. The base is marked by a flat quadrilateral facet for the lunate. The apex forms the lowest part of the bone and is roughened for the attachment of the ulnar collateral ligament of the wrist.

Articulations.—With the pisiform in front, lunate laterally, hamate below, articular disk above.

FIG. 229.—THE LEFT TRIQUETRAL.



THE PISIFORM

The **pisiform** [os pisiforme] (fig. 230), the smallest of the carpal bones, is in many of its characters a complete contrast to the rest of the series. It deviates from the general type in its shape, size, position, use, and development. Forming a rounded bony nodule with the long axis directed vertically, it is situated on a plane in front of the other bones of the carpus.

On the **dorsal surface** is a single articular facet for the triquetral which reaches to the upper end of the bone, but leaves a free non-articular portion below. The **volar surface, rough** and rounded, gives attachment to the transverse carpal ligament, the *flexor carpi ulnaris*, the *ab-*

FIG. 230.—THE LEFT PISIFORM.

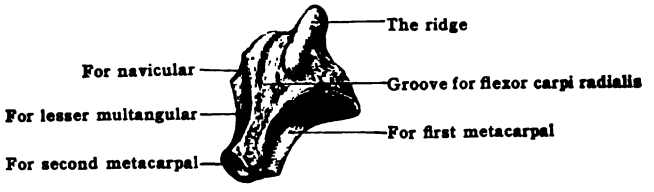
ductor digiti quinti, the pisometacarpal and the pisohamate ligaments. The **medial and lateral** surfaces are also rough and the lateral presents a shallow groove for the ulnar artery. It is usually considered that the pisiform is a sesamoid bone developed in the tendon of the *flexor carpi ulnaris*, though by some writers it is regarded as part of a rudimentary digit.

THE GREATER MULTANGULAR

The **greater multangular** [os multangulum majus] or **trapezium (fig. 231)**, situated between the navicular and first metacarpal, is oblong in form with the lower angle prolonged downward and medially.

The superior surface is concave and directed upward and medially for articulation with the lateral of the two facets on the distal surface of the navicular, and on the **inferior surface is a** saddle-shaped facet for the base of the first metacarpal. The **volar surface presents a prominent** ridge with a deep groove on its medial side which transmits the tendon of the *flexor carpi radialis*.

FIG. 231.—THE LEFT GREATER MULTANGULAR.



The **ridge** gives attachment to the transverse carpal ligament, the *abductor pollicis brevis*, the *opponens pollicis*, and occasionally a tendinous slip of insertion of the *abductor pollicis longus*. The **dorsal** and **lateral surfaces** are rough for ligaments. The **medial surface is** divided into two parts by a horizontal ridge. The upper and larger portion is concave and articulates with the lesser multangular; the lower—a small flat facet on the projecting lower **angle—articulates** with the base of the second metacarpal.

Articulations.—With the navicular above, first metacarpal below, the **lesser multangular** and second metacarpal on the medial side.

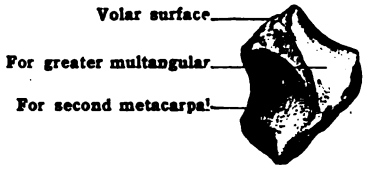
THE LESSER MULTANGULAR

The **lesser multangular** [os multangulum minus] or trapezoid **(fig. 232)**, the smallest of the bones in the distal row, is somewhat wedge-shaped, with the broader end dorsally and the narrow end ventrally.

The superior surface is marked by a small, quadrilateral, concave facet, for the medial f the two facets on the lower surface of the navicular. The **inferior suiface** is convex from side o side and concave from before backward, forming a saddle-shaped articular surface for the ase of the second metacarpal. Of the **volar** and **dorsal surfaces,** the former is narrow and ough, the latter broad and rounded, constituting the widest surface of the bone, and both are ough for the attachment of ligaments. The **lateral surface** slopes downward and medially and convex for articulation with the corresponding surface of the greater multangular. On the **iedial surface** in front is a smooth flat facet for the capitate; elsewhere it is rough for ligaments.

Articulations.—With the navicular above, second metacarpal below, greater multangular terally, and the capitate medially.

FIG. 232.—THE LEFT LESSER MULTANGULAR.

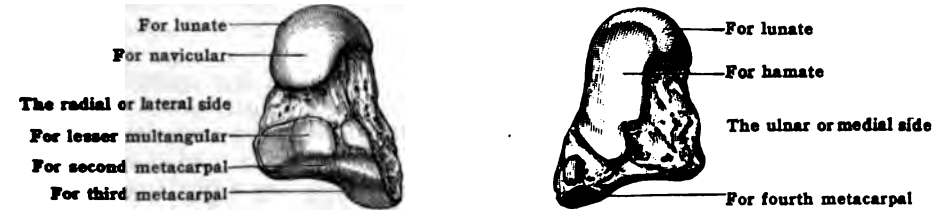


THE CAPITATE

The **capitate** [os capitatum] or os magnum (fig. 233) is the largest bone of the arpus. Situated in the center of the wrist, the upper expanded portion, globular n shape and known as the **head,** is received into the concavity formed above by he navicular and lunate. The cubical portion below forms the **body,** whilst the ntermediate constricted part is distinguished as the **neck.**

Of the six surfaces, the **superior** is smooth and convex, elongated from before backward or articulation with the concavity of the lunate bone. The **inferior surface** is divided into hree unequal parts by two ridges. The middle portion, much the larger, articulates with the ase of the third metacarpal; the lateral, narrow and concave, looks laterally as well as downward o articulate with the second metacarpal, whilst the medial portion is a small facet, placed on the

FIG. 233.—THE LEFT CAPITATE.



projecting angle of the bone dorsally, for the fourth metacarpal bone. The **volar surface** is convex and rough, giving origin to fibers of the oblique *abductor pollicis;* the **dorsal surface** is broad and deeply concave. The **lateral surface** presents, from above downward:—(1) a smooth convex surface, forming the outer aspect of the head, with the superior surface of which it is continuous, for articulation with the navicular; (2) a groove representing the neck, indented or ligaments; (3) a small facet, flat and smooth, for articulation with the lesser multangular. Behind this facet is a rough area for attachment of an interosseous ligament. The **medial surface** has extending along its whole hinder margin an oblong articular surface for the hamate; he lower part of this smooth area sometimes forms a detached facet. The volar part of the urface is rough for an interosseous ligament.

Articulations.—With the lunate and navicular above, second, third, and fourth meta-carpals below, lesser multangular laterally, and hamate medially.

THE HAMATE

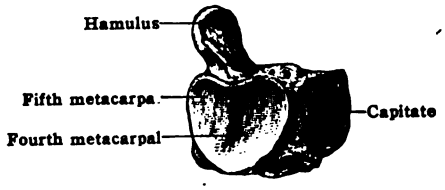
The **hamate** [os hamatum] or unciform (fig. 234) is a large wedge-shaped bone, bearing a hook-like process, situated between the capitate and triquetral, with the base directed downward and resting on the two medial metacarpals.

The apex of the wedge forms the narrow **superior surface,** directed upward and laterally or articulation with the lunate. The **inferior surface** or base is divided by a ridge into two quadrilateral facets for the fourth and fifth metacarpal bones. The **volar surface** is triangular n outline and presents at its lower part a prominent **hamulus** (unciform process), a hook-like minence, projecting forward and curved toward the carpal canal. It is flattened from side o side so as to present two surfaces, two borders, and a free extremity. To the latter the trans-verse carpal ligament and the *flexor carpi ulnaris* (by means of the pisohamate ligament) are ttached, whilst the medial surface affords origin to the *flexor brevis* and the *opponens digiti minimi.* The **lateral surface** is concave and in relation to the flexor tendons. The **dorsal surface**

is triangular and rough for ligaments. The **lateral surface** has extending along its upper and hinder edges a long flat surface, wider above than below, for articulation with the capitate. In front of this articular facet the surface is rough for the attachment of an interosseous ligament. The **medial surface** is oblong and undulating, *i. e.*, concavoconvex from base to apex, for articulation with the triquetral.

Articulations.—With the triquetral, lunate, capitate, and the fourth and fifth metacarpal bones.

FIG. 234.—THE LEFT HAMATE.



OSSIFICATION OF THE CARPAL BONES

Capitate	first year	Greater multangular	fifth year
Hamate	second year	Navicular	sixth year
Triquetral	third year	Lesser multangular	eighth year
Lunate	fourth year	Pisiform	twelfth year

According to the investigations of Pryor the centers of ossification of the carpal bones appear earlier in the female than in the male.

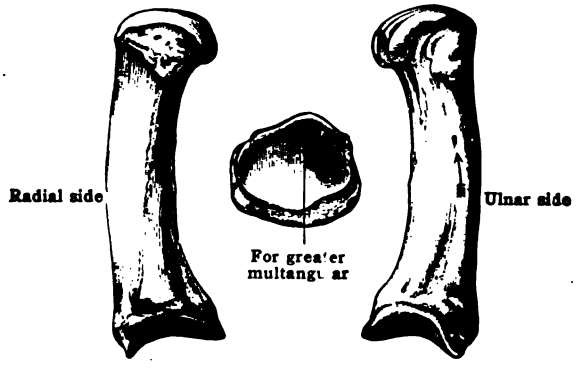
Variations.—Additional carpal elements are occasionally met with. The **os centrale** occurs normally in the carpus of many mammals, and in the human fœtus of two months it is present as a small cartilaginous nodule which soon becomes fused with the cartilage of the navicular. Failure of fusion, with subsequent ossification of the nodule, leads to the formation of an os centrale in the human carpus which is then found on the dorsal aspect, between the navicular, capitate and lesser multangular. In most individuals, however, it coalesces with the navicular or undergoes suppression.

An additional center of ossification, leading to the formation of an accessory carpal element, occasionally appears in connection with the greater multangular and the hamate. An accessory element (*os Vesalianum*) also occurs occasionally in the angle between the hamate and the fifth metacarpal, and others occur between the second and third metacarpals and the lesser multangular and capitate.

THE METACARPALS

The **metacarpus** (figs. 225, 226) consists of a series of five cylindrical bones [ossa metacarpalia], well described as 'long bones in miniature.' Articulated with the carpus above, they descend, slightly diverging from each other, to support the fingers, and are numbered from the lateral to the medial side. With the exception of the first, which in some respects resembles a phalanx, they conform to a general type.

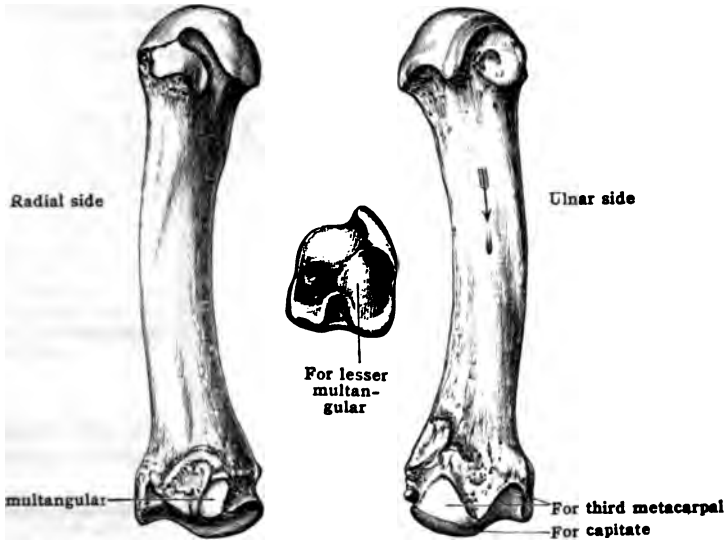
FIG. 235.—THE FIRST (LEFT) METACARPAL.



A typical metacarpal bone presents a shaft and two extremities. **The body or shaft** is prismatic and curved so as to be slightly convex toward the back of the hand. Of the three surfaces, two are **lateral** in position, separated in the middle part of the shaft by a prominent palmar ridge, and concave for the attachment of *interosseous* muscles. The third or **dorsal surface** presents a large, smooth, triangular area with the base below and apex above, covered in the recent state by the extensor tendons of the fingers, and two sloping areas, near the carpal ex-

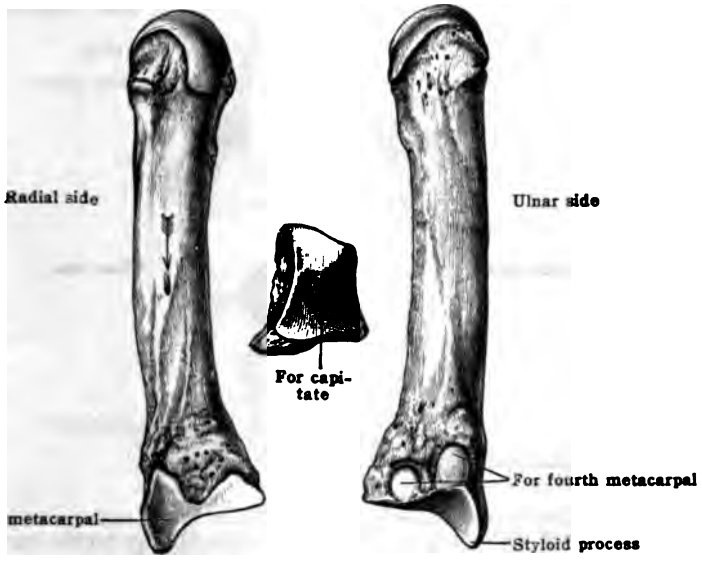
tremity, also for *interosseous* muscles. The triangular area is bounded by two lines, which commence below in two dorsal tubercles, and, passing upward, converge to form a median ridge situated between the sloping areas on either side. A little above or below the middle of the shaft, and near the volar border, is the medullary foramen, entering the bone obliquely upward. The **base** or carpal extremity, broader behind than in front, is quadrilateral, and both palmar and

FIG. 236.—THE SECOND (LEFT) METACARPAL.



dorsal surfaces are rough for ligaments; it articulates above with the carpus and on each side with the adjacent metacarpal bones. The **head** [capitulum] or digital extremity presents a large rounded articular surface, extending further on the palmar than on the dorsal aspect, for articulation with the base of the first phalanx. The volar surface is grooved for the flexor tendons and raised on each

FIG. 237.—THE THIRD (LEFT) METACARPAL.

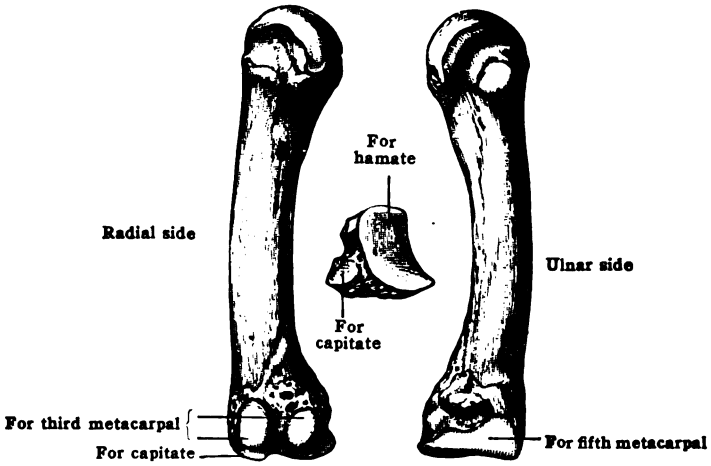


side into an articular eminence. On each side of the head is a prominent tubercle, and immediately in front of this a well-marked fossa, to both of which the collateral ligament of the metacarpophalangeal joint is attached.

The second is the longest of all the metacarpal bones, and the third, fourth, and fifth successively decrease in length. The several metacarpals possess distinctive characters by which they are readily identified.

The **first metacarpal** (fig. 235) is the shortest and widest of the series. Diverging from the carpus more widely than any of the others the **palmar surface** is directed medially and marked by a ridge placed nearer to the medial border. The lateral portion of the surface slopes gently to the lateral border and gives attachment to the *opponens pollicis;* the medial portion, the smaller of the two, slopes more abruptly to the medial border, is in relation to the deep head of the *flexor pollicis brevis,* and presents the nutrient foramen, directed downward toward the head of the bone and transmitting a branch of the arteria princeps pollicis. The **dorsal surface,** wide and flattened, is in relation to the tendons of the *extensor pollicis longus* and *brevis.* The **base** presents a saddle-shaped articular surface for the greater multangular, prolonged in front into a thin process. There are no lateral facets, but laterally a small tubercle receives the insertion of the *abductor pollicis longus.* Medially is a rough area from which fibers of the

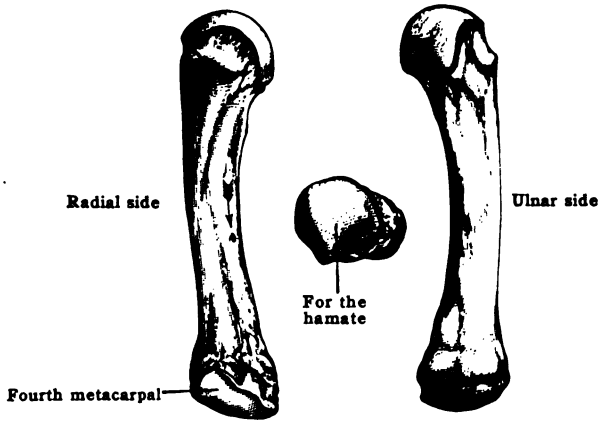
FIG. 238.—THE FOURTH (LEFT) METACARPAL.



inner head of the *flexor pollicis brevis* take origin. The margin of the articular surface gives attachment to the articular capsule of the carpo-metacarpal joint. The inferior extremity or **head** is rounded and articular, for the base of the first phalanx; the greatest diameter is from side to side and the surface is less convex than the corresponding surface of the other metacarpal bones. On the volar surface it presents two articular eminences corresponding to the two sesamoid bones of the thumb. Of the two margins, the medial gives origin to the lateral head of the *first dorsal interosseous,* the lateral receives fibers of insertion of the *opponens pollicis.*

The second metacarpal (fig. 236)—The distinctive features of the four remaining metacarpals are almost exclusively confined to the carpal extremities. The second is easily recognized by its deeply cleft base. The terminal surface presents three articular facets, arranged

FIG. 239.—THE FIFTH (LEFT) METACARPAL.



as follows, from lateral to medial border:—(1) a small oval facet for the greater **multangular;** (2) a hollow for the lesser multangular; and (3) an elongated ridge for the capitate. The dorsal surface is rough for the insertions of the *extensor carpi radialis longus* and a part of the *extensor carpi radialis brevis;* the palmar surface receives the insertion of the *flexor carpi radialis* and gives origin to a few fibers of the *oblique adductor pollicis.* The lateral aspect of the extremity is rough and non-articular; the medial surface bears a bilobed facet for the third metacarpal. The shaft of the second metacarpal gives attachment to three *interosseous* muscles, and the nutrient foramen, directed upward on the ulnar side, transmits a branch of the second volar metacarpal artery.

The **third metacarpal** (fig. 237) is distinguished by the prominent **styloid process projecting**

upward from the dorsolateral angle of the base. Immediately below it, on the dorsal surface, is a rough impression for the *extensor carpi radialis brevis*. The carpal surface is concave behind and convex in front, and articulates with the middle of the three facets on the inferior surface of the capitate. On the lateral side is a bilobed articular facet for the second metacarpal, and on the medial side two small oval facets for the fourth metacarpal. The volar aspect of the base is rough and gives attachment to fibers of the *oblique adductor pollicis* and sometimes a slip of insertion of the *flexor carpi radialis*. The shaft of the third metacarpal serves for the origin of the transverse *adductor pollicis* and two *interosseous* muscles. The nutrient foramen is directed upward on the radial side and transmits a branch of the second volar metacarpal artery.

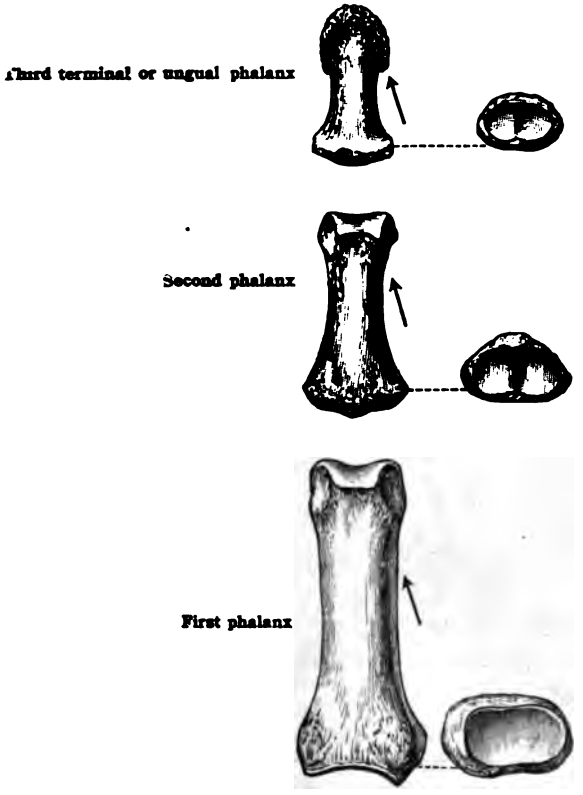
The fourth metacarpal (fig. 238) has a small base. The carpal surface presents two facets; a medial, large and flat, for articulation with the hamate, and a small facet, at the lateral and posterior angle, for the capitate. On the lateral side are two small oval facets for the corresponding surfaces on the third metacarpal and a single concave facet on the medial side for the fifth metacarpal. The shaft of the fourth metacarpal gives attachment to three *interosseous* muscles, and the nutrient foramen, directed upward on the radial side, transmits a branch of the third volar metacarpal artery.

The **fifth metacarpal** (fig. 239) is distinguished by a semilunar facet on the lateral side of the base for the fourth metacarpal, and a rounded tubercle on the medial side for the *extensor carpi ulnaris*, in place of the usual medial facet. The carpal surface is saddle-shaped for the hamate; the palmar surface is rough for ligaments including the pisometacarpal prolongation from the *flexor carpi ulnaris*. The dorsal surface of the shaft presents an *oblique line* separating a lateral concave portion for the fourth dorsal *interosseous* muscle from a smooth medial portion covered by the extensor tendons of the little finger. The palmar surface gives attachment laterally to the third palmar *interosseous* muscle and medially to the *opponens digiti quinti*. The nutrient foramen is directed upward on the radial side and transmits a branch of the fourth volar metacarpal artery.

THE PHALANGES

The **phalanges** (fig. 240) are the bones of the fingers, and number in all fourteen. Each finger contains three phalanges distinguished as first or proximal,

FIG. 240.—THE PHALANGES OF THE THIRD DIGIT OF THE HAND. (Dorsal view.)
(The arrows indicate the direction of the nutrient canals.)



second or middle, and third or distal. In the thumb, the second phalanx is wanting. Arranged in horizontal rows, the phalanges of each row resemble one another and differ from those of the other two rows. In all the phalanges the nutrient canal is directed downward, toward the distal extremity.

First phalanx.—The shaft of a phalanx from the first row is flat on the palmar surface, smooth and rounded on the dorsal surface, *i. e.*, semi-cylindrical in shape. The borders of the palmar surface are rough for the attachment of the sheaths of the flexor tendons. The base or metacarpal extremity presents a single concave articular surface, oval in shape, for the

FIG. 241.—SKELETON OF THE RIGHT HAND OF A BOY AGED 16 YEARS. (From an *X*-ray plate by Dr. Sherwood Moore, Washington University.)

convex head of the metacarpal bone. The distal extremity forms a pulley-like surface, grooved in the center and elevated at each side to form two miniature condyles, for articulation with the base of a second phalanx.

Second phalanx.—The second phalanges are four in number and are shorter than those of the first row, which they closely resemble in form. They are distinguished, however, by the articular surface on the proximal extremity, which presents two shallow depressions, separated

by a ridge and corresponding to the two condyles of the first phalanx. The distal end for the base of the third phalanx is trochlear or pulley-like, but smaller than that of the first phalanx. The palmar surface of the shaft presents on each side an impression for the tendon of the *flexor digitorum sublimis*, and the dorsal aspect of the base is marked by a projection for the insertion of the *extensor digitorum communis*.

Third phalanx.—A third phalanx is readily recognized by its small size. The proximal end is identical in shape with that of a second phalanx, and bears a depression in front for the tendon of the *flexor digitorum profundus*. The free, flattened and expanded distal extremity presents on its palmar surface a rough semilunar elevation for the support of the pulp of the finger. The somewhat horseshoe-shaped free extremity is known as the **ungual tuberosity** [tuberositas unguicularis], and the bone is accordingly referred to as the **ungual phalanx.**

Ossification of the Metacarpus and Phalanges

Each of the metacarpal bones and phalanges is ossified from a primary center for the greater part of the bone, and from one epiphysial center. The primary nucleus appears from the eighth to the tenth week of intrauterine life. In four metacarpal bones the epiphysis is distal, while in the first metacarpal bone, and in all the phalanges, it is proximal. The epiphysial nuclei appear from the third to the fifth year and are united to their respective shafts about the twentieth year. In many cases the first metacarpal has two epiphyses, one for the base in the third year and an additional one for the head in the seventh year, but the latter is never so large as in the other metacarpal bones. The third metacarpal occasionally has an additional nucleus for the prominent styloid process which may remain distinct and form a *styloid bone*, and traces of a proximal epiphysis have been observed in the second metacarpal bone. In many of the Cetacea (whales, dolphins, and porpoises) and in the seal, epiphyses are found at both ends of the metacarpal bones and phalanges (Flower).

The ossification of a terminal phalanx is peculiar. Like the other phalanges, it has a primary nucleus and a secondary nucleus for an epiphysis. But whereas in other phalanges the primary center appears in the middle of the shaft, in the case of the distal phalanges the earthy matter is deposited in the free extremity of the cartilaginous bar, the epiphysis ossifying in membrane.

Sesamoid bones.—The sesamoid bones are small and rounded and occur imbedded in certain tendons where they exert a considerable amount of pressure on subjacent bony structures. In the hand five sesamoid bones are of almost constant occurrence, namely, two over the metacarpophalangeal joint of the thumb in the tendons of the flexor pollicis brevis (fig. 241), one over the interphalangeal joint of the thumb, and one over the metacarpophalangeal joints of the second and fifth fingers. Occasionally sesamoids occur over the metacarpophalangeal joint of the third and fourth digits, and an additional one may occur over that of the fifth.

B. THE BONES OF THE LOWER EXTREMITY

The bones of the lower extremity may be arranged in four groups corresponding to the division of the limb into the *hip*, *thigh*, *leg*, and *foot*. In the *hip* is the coxal or hip-bone, which constitutes the pelvic girdle [cingulum extremitatis inferioris], and contributes to the formation of the pelvis; in the *thigh* is the femur; in the *leg*, the tibia and fibula, and in the *foot* the tarsus, metatarsus, and phalanges. Associated with the lower end of the femur is a large sesamoid bone, the patella or knee-cap.

THE COXAL BONE

The **coxal** (**innominate**) **bone** or hip-bone [os coxæ] (figs. 242, 243) is a large, irregularly shaped bone articulated behind with the sacrum, and in front with its fellow of the opposite side, the two bones forming the anterior and side walls of the pelvis. The coxal bone consists of three parts, named **ilium, ischium,** and **pubis,** which, though separate in early life (figs. 246, 247), are firmly united in the adult. The three parts meet together and form the **acetabulum** (or cotyloid fossa), a large, cup-like socket situated near the middle of the lateral surface of the bone for articulation with the head of the femur.

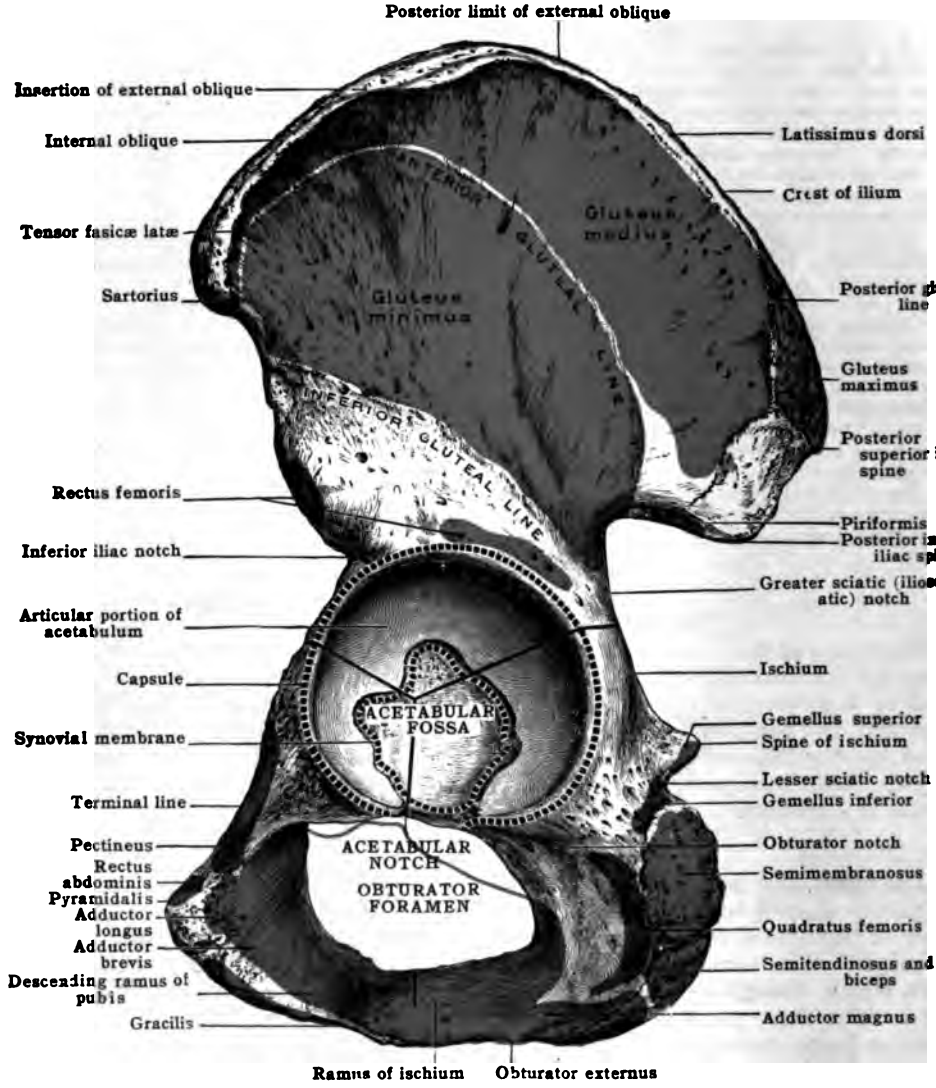
The **ilium** [os ilium] is the upper expanded portion of the bone, and by its inferior extremity forms the upper two-fifths of the acetabulum. It presents three borders and two surfaces.

Borders.—When viewed from above, the thick **crest** [crista iliaca] or superior border of the ilium is curved somewhat like the letter *f*, being concave medially in front and concave laterally behind. Its anterior extremity forms the **anterior superior iliac spine,** which gives attachment to the inguinal (Poupart's) ligament and the *sartorius;* the posterior extremity forms the **posterior superior iliac spine** and affords attachment to the sacrotuberous (great sacrosciatic) ligament, the posterior sacroiliac ligament, and the *multifidus*. The crest is narrow in the middle, thick at its extremities, and may be divided into an inner lip, an outer lip,

and an intermediate line. About 6 cm. (2½ in.) from the anterior superior spine is a prominent tubercle on its external lip.

The external lip of the crest gives attachment in front to the *tensor faciæ latæ;* along its whole length, to the *fascia lata;* along its anterior half to the *external oblique;* and behind this, for about an inch, to the *latissimus dorsi.* The anterior two-thirds of the intermediate line gives origin to the *internal oblique.* The internal lip gives origin, by its anterior two-thirds, to the *transversus;* behind this is a small area for the *quadratus lumborum,* and the remainder is occupied by the *sacrospinalis* (*erector spinæ*). The internal lip, in the anterior two-thirds, also serves for the attachment of the iliac fascia.

FIG. 242.—THE LEFT COXAL OR HIP-BONE. (Lateral view.)



The **anterior border** of the ilium extends from the **anterior superior iliac spine** to the margin of the acetabulum. Below the spine is a prominent notch from which fibers of the *sartorius* arise, and this is succeeded by the **anterior inferior iliac spine,** smaller and less prominent than the superior, to which the straight head of the *rectus* and the iliofemoral ligament are attached. On the medial side of the anterior inferior spine is a broad, shallow groove for the ***iliopsoas*** as it passes from the abdomen into the thigh, limited below by the **iliopectineal** eminence, which indicates the point of union of the ilium and pubis.

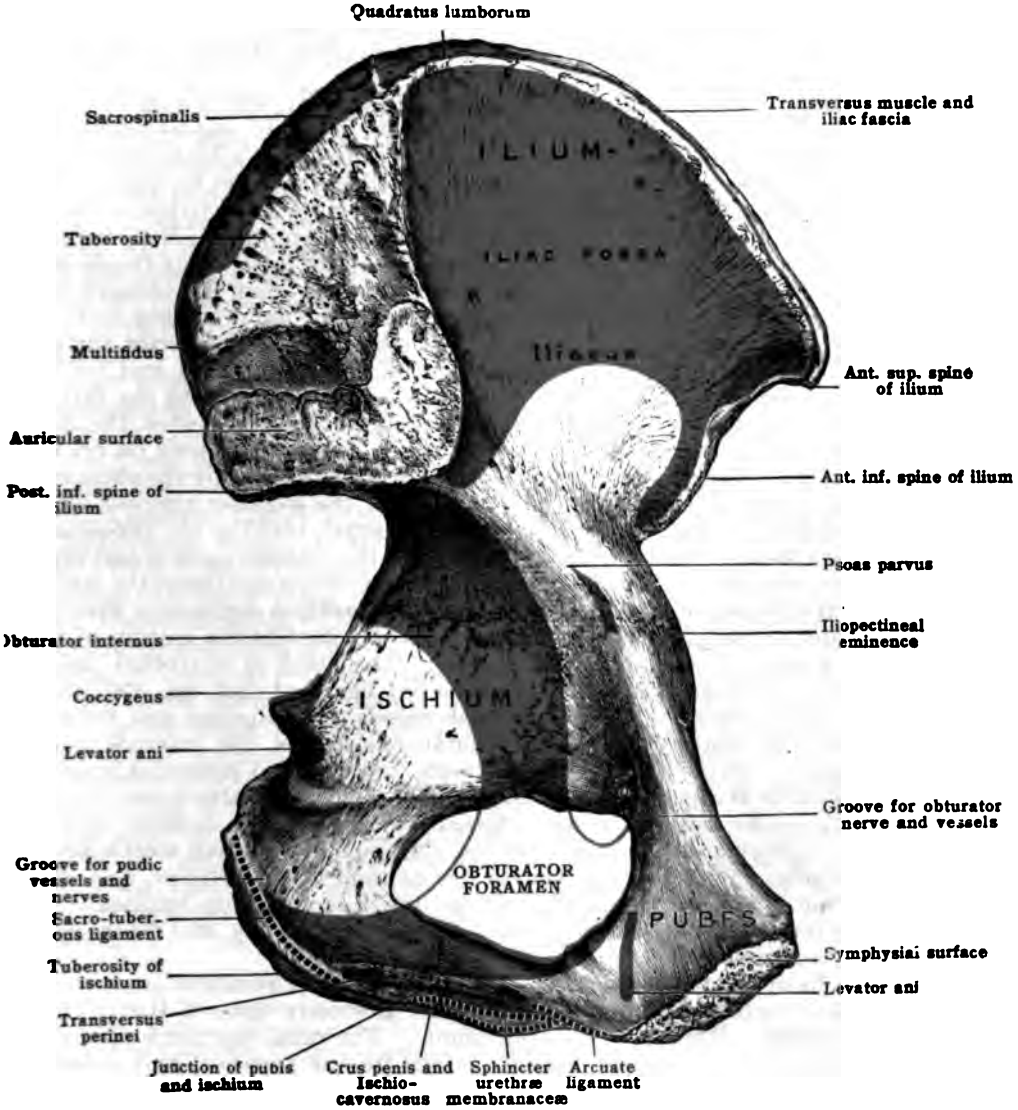
The **posterior border** of the ilium presents the **posterior superior iliac spine** and below this, a shallow notch terminating in the **posterior inferior iliac spin**

which corresponds to the posterior extremity of the auricular surface and gives attachment to a portion of the sacrotuberous (great sacrosciatic) ligament. Below the spine the posterior border of the ilium forms the upper limit of the greater sciatic notch.

Surfaces.—The **external surface** or **dorsum** is concave behind, convex in front, limited above by the thick superior border or **crest,** and traversed by threeg luteal lines.

The **posterior gluteal line** commences at the crest about two inches from the posterior superior iliac spine and curves downward to the upper margin of the **greater sciatic notch.**

FIG. 243.—THE LEFT COXAL OR HIP-BONE. (Medial aspect.)



The space included between this ridge and the crest affords origin at its upper part to the *gluteus maximus*, and at its lower part, to a few fibers of the *piriformis*, while the intermediate portion is smooth and free from muscular attachment. The **anterior gluteal line** begins at the crest, one inch behind its anterior superior iliac spine, and curves across the dorsum to terminate near the lower end of the superior line, at the upper margin of the greater sciatic notch. The surface of bone between this line and the crest gives origin to the *gluteus medius*. The **inferior gluteal line** commences at the notch immediately below the anterior superior iliac spine and terminates posteriorly at the front part of the greater sciatic notch. The space between the anterior and inferior gluteal lines, with the exception of a small area adjacent to the anterior end of the spine for the *tensor fasciæ latæ*, gives origin to the *gluteus minimus*. Between the inferior gluteal line and the margin of the acetabulum the surface affords attach-

ment to the capsule of the hip-joint, and on a rough area (sometimes a depression) toward its anterior part, to the *reflected tendon of the rectus femoris.*

The **internal surface** presents in front a smooth concave portion termed the **iliac fossa,** which lodges the *iliacus* muscle. The fossa is limited below by the linea arcuata, the iliac portion of the terminal (iliopectineal) line. This is a rounded border separating the fossa from a portion of the internal surface below the line, which gives attachment to the *obturator internus* and enters into the formation of the minor (true) pelvis. Behind the iliac fossa the bone is uneven and presents an **auricular surface,** covered with cartilage in the recent state, for articulation with the lateral aspect of the upper portion of the sacrum; above the auricular surface are some depressions for the posterior sacroiliac ligaments and a rough area reaching as high as the crest, from which parts of the *sacrospinalis* (*erector spinæ*) and *multifidus* take origin. The rough surface above the auricular facet is known as the **tuberosity of the ilium.**

The **ischium** [os ischii] consists of a body, a tuberosity, and a ramus. The **body,** which has somewhat the form of a triangular pyramid, enters superiorly into the formation of the acetabulum, to which it contributes a little more than two-fifths, and forms the chief part of the non-articular portion or floor. The **inner surface** forms part of the minor (true) pelvis and gives origin to the *obturator internus.* It is continuous with the ilium a little below the terminal (iliopectineal) line, and with the pubis in front, the line of junction with the latter being frequently indicated in the adult bone by a rough line extending from the iliopectineal eminence to the margin of the obturator foramen. The **outer surface** includes the portion of the acetabulum formed by the ischium. The **posterior surface** is broad and bounded laterally by the margin of the acetabulum and behind by the posterior border. The capsule of the hip-joint is attached to the lateral part and the *piriformis,* the great sciatic and posterior cutaneous nerves, the inferior gluteal (sciatic) artery, and the nerve to the *quadratus femoris* lie on the surface as they leave the pelvis. Inferiorly this surface is limited by the **obturator groove,** which receives the posterior fleshy border of the *obturator externus* when the thigh is flexed. Of the three borders, the **external,** forming the prominent rim of the acetabulum, separates the posterior from the external surface and gives attachment to the glenoid lip. The **inner border** is sharp and forms the lateral boundary of the obturator foramen. The **posterior border** is continuous with the posterior border of the ilium, with which it joins to complete the margin of the **great sciatic notch** [incisura ischiadica major]. The notch is converted into a foramen by the sacrospinous (small sacrosciatic) ligament (see fig. 306), and transmits the *piriformis* muscle, the gluteal vessels, the superior and inferior gluteal nerves, the sciatic and posterior cutaneous nerves, the internal pudic vessels and nerve, and the nerves to the *obturator internus* and *quadratus femoris.* Below the notch is the prominent **ischial spine,** which gives attachment internally to the *coccygeus* and *levator ani,* externally to the *gemellus superior,* and at the tip to the sacrospinous ligament. Below the spine is the **small sciatic notch** [incisura ischiadica minor], covered in the recent state with cartilage, and converted into a foramen by the sacrotuberous (great sacrosciatic) ligament. It transmits the tendon of the *obturator internus,* its nerve of supply, and the internal pudic vessels and nerve.

The **rami** form the flattened part of the ischium which runs first downward, then upward, forward and medially from the tuberosity toward the inferior ramus of the pubis, with which it is continuous. The **rami** together form an L-shaped structure with an upper vertical ramus [ramus superior] and a lower horizontal ramus [ramus inferior]. The outer surface of the rami gives origin to the *adductor magnus* and *obturator externus;* the inner surface, forming part of the anterior wall of the pelvis, receives the crus penis (or clitoridis) and the *ischiocavernosus,* and gives origin to a part of the *obturator internus.* Of the two borders, the upper is thin and sharp, and forms part of the boundary of the obturator foramen; the lower is rough and corresponds to the inferior ramus. It is somewhat everted and gives attachment to the fascia of Colles, and the *transversus perinei.* To a ridge immediately above the impression for the crus penis (or clitoridis) and the *ischiocavernosus,* the urogenital diaphragm is attached. The posterior and inferior aspect of the superior ramus is an expanded area forming the **tuberosity** [tuber ischiadicum].

The tuberosity is that portion of the ischium which supports the body in the sitting posture. It forms a rough, thick eminence continuous with the inferior border of the inferior ramus, and is marked by an oblique line separating two impressions, an upper and lateral for the *semimembranosus*, and a lower and medial for the common tendon of the *biceps* and *semitendinosus*, while the lower part is markedly uneven and gives origin to the *adductor magnus*. The upper border gives origin to the *inferior gemellus;* the inner border, sharp and prominent, receives the sacrotuberous (great sacrosciatic) ligament, while the surface of the tuberosity immediately in front is in relation with the internal pudic vessels and nerve. The outer border gives origin to the *quadratus femoris*.

The **pubis** [os pubis] consists of a **body** and two **rami**—superior and inferior. The **body** is somewhat quadrilateral in shape and presents for examination two surfaces and three borders. The **anterior surface** looks downward, forward and slightly outward, and gives origin to the *adductor longus*, the *adductor brevis*, the *obturator externus*, and the *gracilis*. The **posterior surface** is smooth, looks into the pelvis, and affords origin to the *levator ani*, the *obturator internus*, and the puboprostatic ligaments. The **upper border** or crest of the body is rough and presents laterally a prominent bony point, known as the **tubercle** [tuberculum pubicum] or spine, for the attachment of the inguinal (Poupart's) ligament. The upper border extends from the pubic tubercle medialward to the upper end of the symphysis, with which it forms the *angle* of the pubis. The upper border gives attachment to the *rectus abdominis* and *pyramidalis*. The **medial border** is oval in shape, rough, and articular, forming with the bone of the opposite side the *symphysis pubis* [facies symphyseos]. The **lateral border** is sharp and forms part of the boundary of the obturator foramen.

The **inferior ramus,** like the inferior ramus of the ischium, with which it is continuous, is thin and flattened. To its **anterior surface** are attached the *adductor brevis*, *adductor magnus*, and *obturator externus*. The **posterior surface** is smooth and gives attachment to the *crus penis* or *clitoridis*, the *sphincter urethræ* (**urogenitalis**), the *obturator internus*, and the urogenital diaphragm. The **lateral border forms part of the** circumference of the obturator foramen, and the **medial border forms part of the** pubic arch and gives attachment to the *gracilis*.

The **superior ramus** extends from the body of the pubis to the ilium, forming by its lateral extremity the anterior one-fifth of the articular surface of the acetabulum. It is prismatic in shape and increases in size as it passes laterally. Above it presents a sharp ridge, the **pecten** or pubic portion of the terminal (iliopectineal) line continuous with the iliac portion at the **iliopectineal eminence,** and affording attachment to the conjoined tendon [falx aponeurotica inguinalis], the lacunar (Gimbernat's) ligament, the reflected inguinal ligament, and the pubic portion of the fascia lata; the iliac portion of the terminal line gives attachment to the *psoas minor*, the iliac fascia, and the pelvic fascia. Immediately in front of the pubic portion of the line is the **pectineal surface;** it gives origin at its posterior part to the *pectineus*, and is limited below by the **obturator crest,** which extends from the pubic tubercle to the acetabular notch. The **inferior surface** of the superior ramus forms the upper boundary of the obturator foramen and presents a deep groove [sulcus obturatorius] for the passage of the obturator vessels and nerve. The **posterior surface** is smooth, forms part of the anterior wall of the pelvic cavity, and gives attachment to a few fibers of the *obturator internus*.

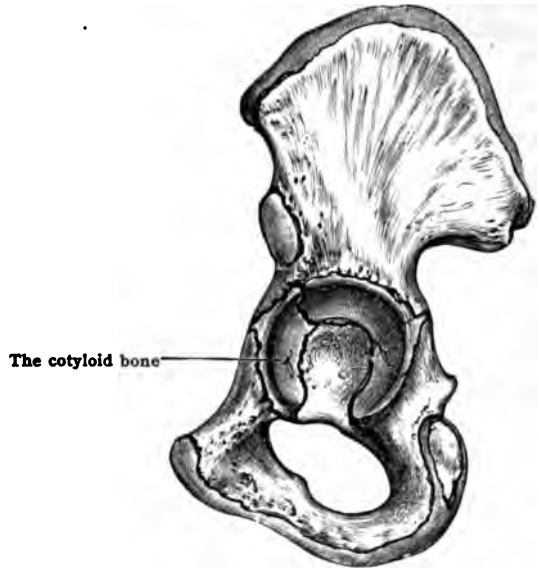
According to the BNA, the body [corpus ossis pubis] is the portion corresponding to the acetabulum. The remainder of the bone is described as consisting of the ramus superior and the ramus inferior, which meet at the symphysis. Thus the divisions according to the BNA are different from those in the description above given.

The **acetabulum** (figs. 242, 244) is a circular depression in which the head of the femur is lodged and consists of an articular and a non-articular portion. The articular portion is circumferential and semilunar in shape [facies lunata], with the deficiency in the lower segment. One-fifth of the acetabulum is formed by the pubis, two-fifths by the ischium, and the remaining two-fifths are formed by the ilium. The non-articular portion [fossa acetabuli] is formed mainly by the ischium, and is continuous below with the margin of the obturator foramen. The articular portion presents a lateral rim to which the glenoid lip is attached, and a medial margin to which the synovial membrane which excludes the ligamentum teres from the synovial cavity is connected. The opposite extremities of the articular lunate surface which limit the **acetabular notch** are united by

the transverse ligament, and through the **acetabular foramen** thus formed a nerve and vessels enter the joint.

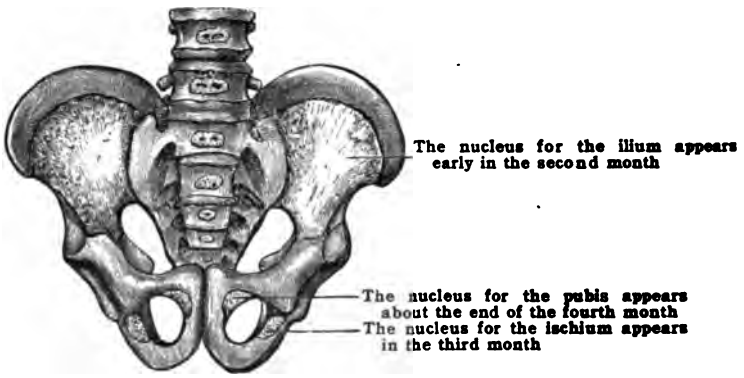
The **obturator** (thyroid) **foramen** (figs. 242, 243) is situated between the ischium and pubis. Its margins are thin, and serve for the attachment of the obturator membrane. At the upper and posterior angle it is deeply grooved for the passage of the obturator vessels and nerve.

FIG. 244.—AN IMMATURE COXAL (INNOMINATE) BONE, SHOWING A COTYLOID BONE.



Blood-supply.—The chief vascular foramina of the coxal bone are found where the bone is thickest. On the inner surface, the ilium receives twigs from the iliolumbar, deep circumflex iliac, and obturator arteries, by foramina near the crest, in the iliac fossa, and below the terminal line near the greater sciatic notch. On the outer surface the chief foramina are found below the inferior gluteal line and the nutrient vessels are derived from the gluteal arteries. The ischium receives nutrient vessels from the obturator, internal and external circumflex arteries, and the largest foramina are situated between the acetabulum and the ischial tuberosity. The pubis is supplied by twigs from the obturator, internal and external circumflex arteries, and from the pubic branches of the common femoral artery.

FIG. 245.—THE PELVIS OF A FETUS AT BIRTH, TO SHOW THE THREE PORTIONS OF THE COXAL BONES.

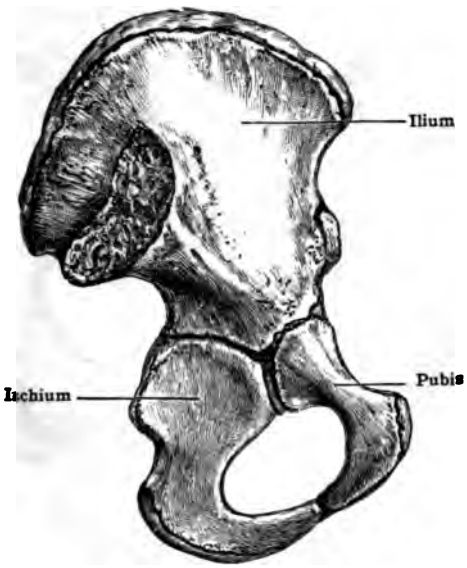


The nucleus for the ilium appears early in the second month
The nucleus for the pubis appears about the end of the fourth month
The nucleus for the ischium appears in the third month

Ossification.—The cartilaginous representative of the hip-bone consists of three distinct portions, an **iliac**, an **ischiatic**, and a **pubic** portion; the iliac and ischiatic portions first unite, and later the pubic portion, so that eventually there is found a single cartilaginous mass. In the second month a center of ossification appears above the acetabulum for the ilium. Later a second nucleus appears below the cavity for the ischium, and this is followed in the fourth month by a deposit in the pubic portion of the cartilage. At birth, the three nuclei are of considerable size, but are surrounded by relatively wide tracts of cartilage (fig. 245); ossification has, however, extended into the margin of the acetabulum. In the eighth year the

rami of the pubis and ischium become united by bone, and in the twelfth year the triradiate cartilage which separates the three segments of the bone in the acetabulum begins to ossify from several centers. Of these, one is more constant than the others and is known as the acetabular nucleus. The triangular piece of bone to which it gives rise is regarded as the representative of the *cotyloid* or acetabular bone (fig. 244), constantly present in a few mammals.

FIG. 246.—COXAL OR HIP-BONE, SHOWING SECONDARY CENTERS.



It is situated at the medial part of the acetabulum and is of such a size as to exclude entirely the pubis from the cavity. With this bone, however, it eventually fuses, and afterward becomes joined with the ilium and ischium, so that by the eighteenth or twentieth year the several parts of the acetabulum have become united. In the fifteenth year other centers appear in the cartilage of the crest of the ilium, the anterior inferior iliac spine, the tuberosity of the ischium,

FIG. 247.—COXAL OR HIP-BONE (INNER SURFACE) AT THE EIGHTEENTH YEAR.

and the pubic pecten. The epiphyses fuse with the main bone about the twentieth year. The fibrous tissue connected with the tubercle of the pubis is believed to represent the epipubic bones of marsupials.

Variations.—The hip-bone is subject to relatively little variation. The cotyloid bone was noted above. Conversion of the obturator groove into a bony walled foramen, and defective union of the rami of the pubis and ischium are the chief variations observed.

THE PELVIC SKELETON

The skeletal **pelvis** (figs. 248, 249) is composed of four bones: the two **coxæ** or hip-bones, the sacrum, and the coccyx. The hip-bones form the lateral and anterior boundaries, meeting each other in front to form the pubic symphysis

FIG. 248.—THE MALE PELVIS. (Anterior view.)

[symphysis ossium pubis]; posteriorly they are separated by the sacrum. The interior of the pelvis is divided into the **major** and **minor** pelvic cavities.

The **major** (or false) **pelvis** is that part of the cavity which lies above the terminal (iliopectineal) lines and between the iliac fossæ. This part belongs really to the abdomen, and is in relation with the hypogastric and iliac regions.

FIG. 249.—THE FEMALE PELVIS. (Anterior view.)

The **minor** (or true) **pelvis** is situated below the terminal (iliopectineal) lines. The upper circumference, known as the **superior aperture** (inlet or brim) of the pelvis, is bounded anteriorly by the crest and pecten of the pubis on each side, posteriorly by the anterior margin of the base of the sacrum, and laterally by the terminal lines. The inlet in normal pelves is heart-shaped, being obtusely pointed in front; posteriorly it is encroached upon by the promontory of the sacrum. It

principal **diameters**; of these, the anteroposterior, called the **conjugate** [conjugata], is measured from the **sacrovertebral angle** to the symphysis. **sverse** diameter represents the greatest width of the pelvic cavity. The iameter is measured from the sacroiliac synchondrosis of one side to the eal eminence of the other.

avity of the minor (true) pelvis is bounded in front by the pubes, behind crum and coccyx, and laterally by a smooth wall of bone formed in part um and in part by the ischium. The cavity is shallow in front, where it by the pubes, and is deepest posteriorly.

ıterior aperture, or outlet, of the minor pelvis is very irregular, and en- upon by three bony processes: the posterior process is the coccyx, and lateral processes are the ischial tuberosities. They separate three The anterior notch is the **pubic arch** (or angle), and is bounded on each ıe conjoined rami of the pubes and ischium. Each of the two remaining ınded by the ischium anteriorly, the sacrum and coccyx posteriorly, and above, corresponds to the greater and lesser sciatic notches. These are l into foramina by the sacrotuberous and sacrospinous ligaments.

sition of the pelvis.—In the erect position of the skeleton the plane of the pelvic s an angle with the horizontal plane, which varies in individuals from 50° to 60°. of the sacrum in an average pelvis lies nearly ten cm. (four inches) above the upper the symphysis pubis.

is of the pelvis.—This is an imaginary curved line drawn through the minor pelvis gles to the planes of the **inlet, cavity,** and **outlet** through their central points. posterior wall, formed by sacrum and coccyx, is 12 cm. (five inches) long and con- the anterior wall at the symphysis pubis 3.5 to 5 cm. long, it follows that the axis ırved.

erage measurements of the diameters of the minor pelvis in the three planes are w:—

	Conjugate or Anteroposterior.	Oblique.	Transverse.
.....	10.6 cm. (4¼ inches)	12.5 cm. (5 inches)	13.0 cm. (5¼ inches)
.....	11.8 cm. (4¾ inches)	13.0 cm. (5¼ inches)	11.8 cm. (4¾ inches)
.....	9.0 cm. (3¾ inches)	11.2 cm. (4½ inches)	10.6 cm. (4¼ inches)

s, however, a difference between the sexes, the diameters of the male pelvis in general slightly less, and those of the female slightly greater than the figures above given.

nces according to sex.—There is a marked difference in the size and form of the emale pelvis, the pecularities of the latter being necessary to qualify it for its func- ırturition. The various points of divergence may be tabulated as follows:—

Male.	Female.
vier and rougher.	Bones more slender.
ırrower; more curved.	Sacrum broader; less curved.
rtical.	Ilia more vertical.
deeper.	Iliac fossæ shallower.
tic notch narrower.	Great sciatic notch wider.
vis relatively wider.	Major pelvis relatively narrower.
vis deeper and narrower.	Minor pelvis shallower and wider.
f minor pelvis less.	Capacity of minor pelvis greater.
perture more heart-shaped.	Superior aperture more oval.
deeper.	Symphysis shallower.
es of ischia inflexed.	Tuberosities of ischia everted.
le narrow and pointed.	Pubic arch wider and more rounded.
f ischiopubic rami more everted.	Margins of ischiopubic rami less everted.
foramen oval.	Obturator foramen triangular.

parison with the pelves of lower animals, which, speaking generally, are elongated w, the human pelvis is characterized by its breadth, shallowness, and great capacity. s are also to be recognized in the form of the pelvis in the various races of mankind, the rtant being the relation of the anteroposterior to the transverse diameter, measured t. This is expressed by the *pelvic index* $= \frac{100 \times \text{conjugate diameter}}{\text{transverse diameter}}$.

average European male the index is about 80; in the lower races of mankind, 90 to 95. h an index below 90 are *platypellic*, from 90 to 95 are *mesatipellic*, and above 95 *ic.* (Sir William Turner.)

e **development and growth** of the pelvis, see p. 32.

THE FEMUR

emur or thigh-bone (figs. 250, 251) is the largest and longest bone in the , and transmits the entire weight of the trunk from the hip to the tibia.

FIG. 250.—THE LEFT FEMUR. (Anterior view.)

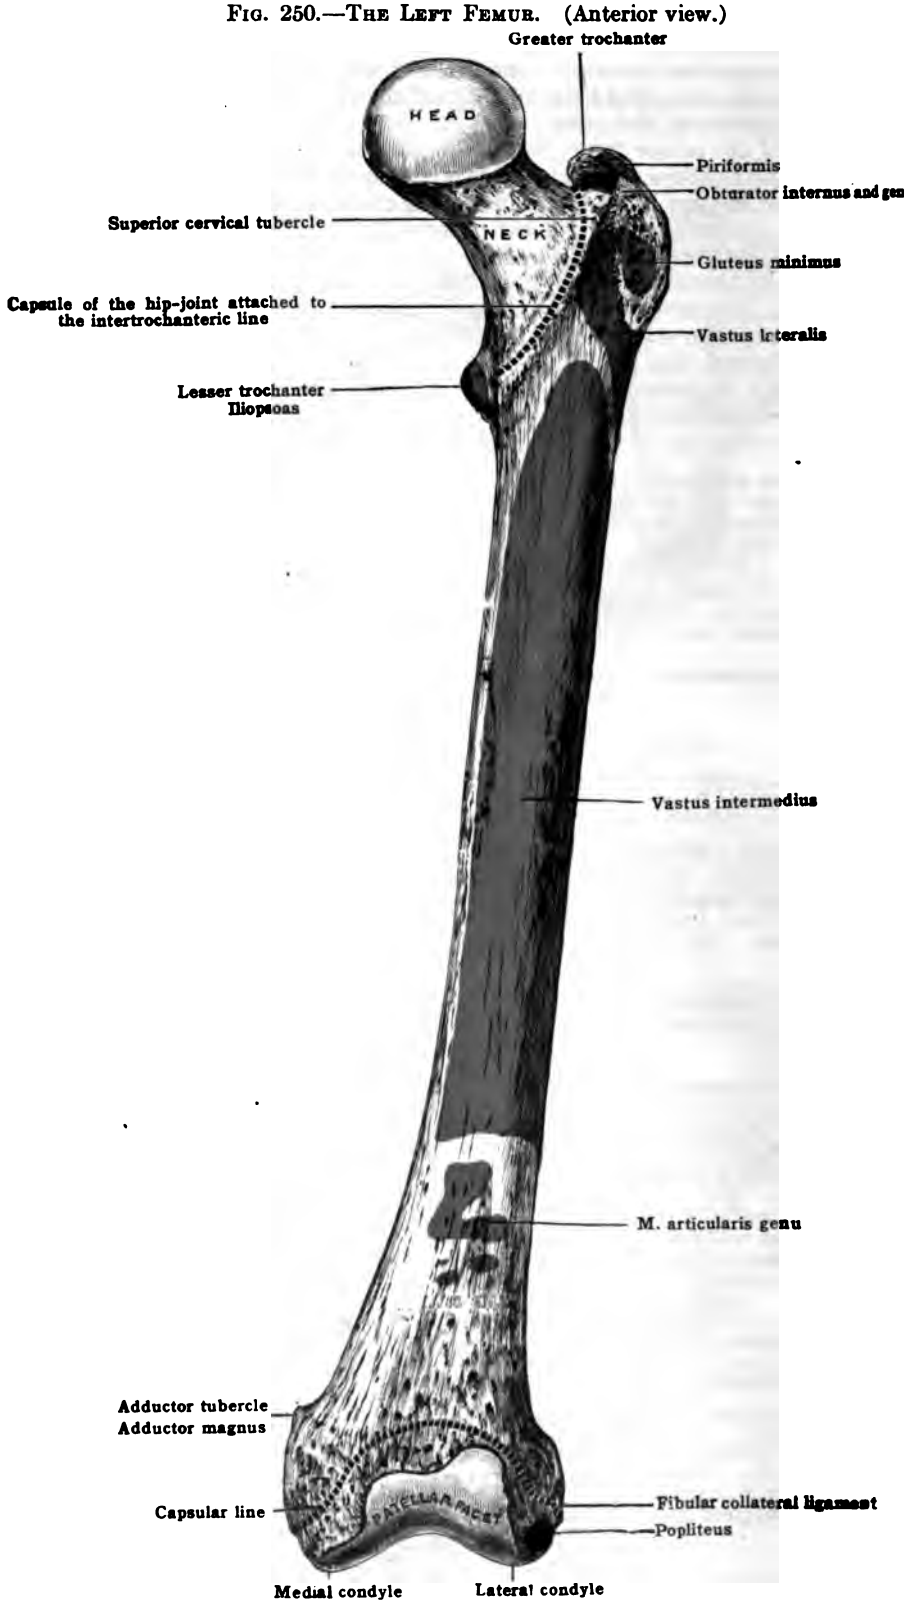

FIG. 251.—THE LEFT FEMUR. (Posterior view.)

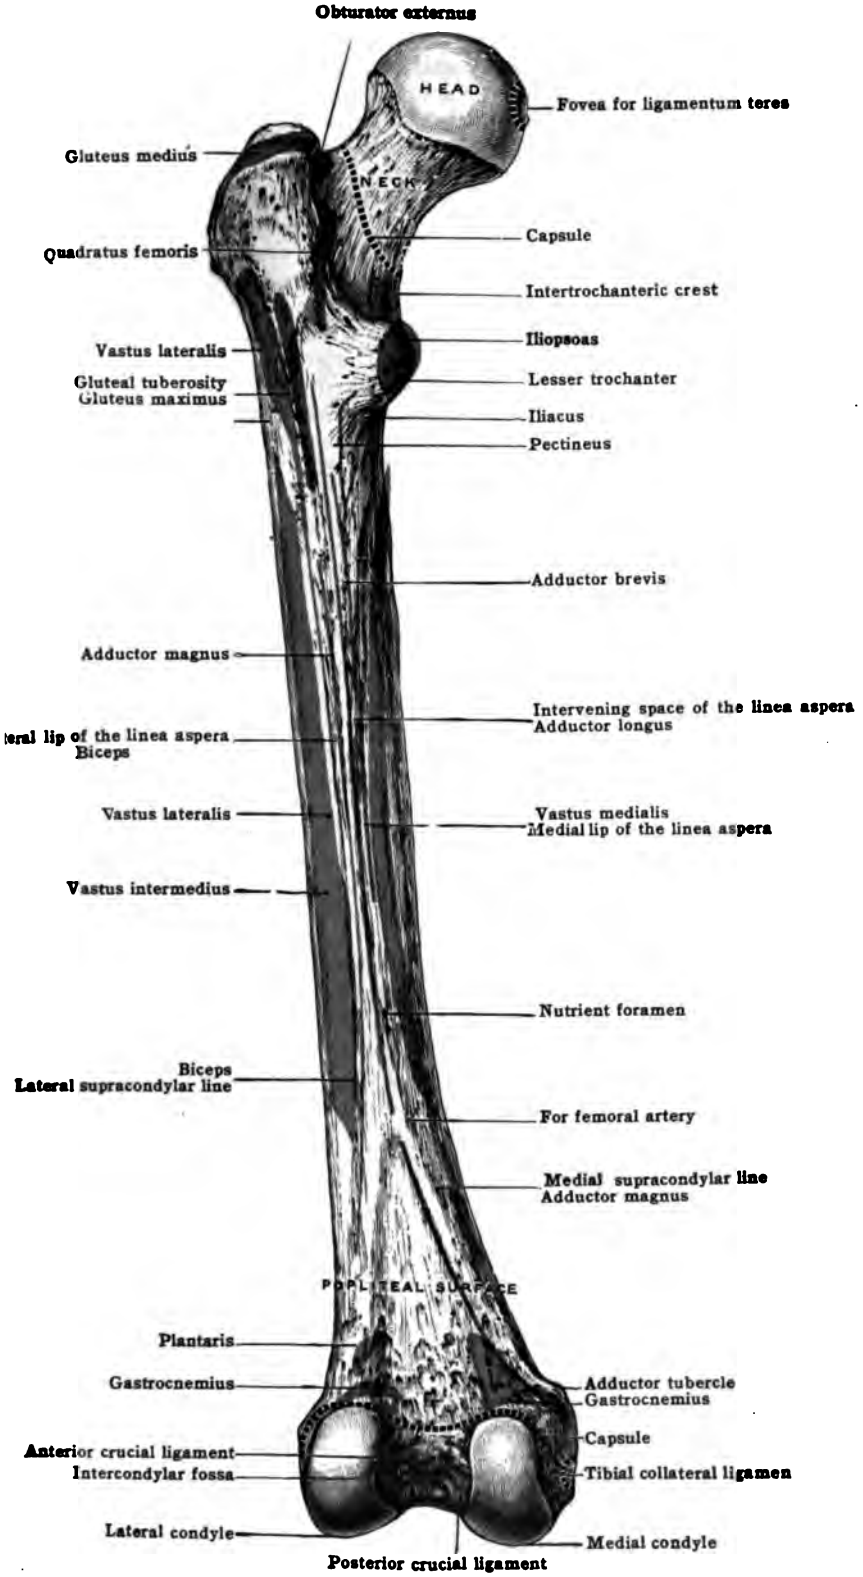


In the erect posture it inclines from above downward, slightly backward and medially, approaching at the lower extremity its fellow of the opposite side, but separated from it above by the width of the minor pelvis. It presents a superior extremity, including the head, neck and two trochanters, a shaft, and an inferior extremity, expanded laterally into two condyles.

The **upper extremity** is surmounted by a smooth, globular portion called the **head** [caput femoris] forming more than half a sphere, directed upward and medially for articulation with the acetabulum. Its surface is covered with cartilage in the recent state, with the exception of a small rough depression, the **fovea,** for the ligamentum teres, a little below and behind the center of the head. The head is connected with the shaft by the **neck** [collum femoris], a stout rectangular column of bone which forms with the shaft, in the adult, an angle of about 125°. The anterior surface of the neck is in the same plane with the front aspect of the shaft, but is marked off from it by a ridge to which the capsule of the hip-joint is attached. The ridge, which commences at the great trochanter in a small prominence, or **tubercle,** extends obliquely downward, and winding to the back of the femur, passes by the lesser trochanter and becomes continuous with the medial lip of the linea aspera, on the posterior aspect of the shaft. This ridge forms the **intertrochanteric line** or **spiral line** of the femur.

The intertrochanteric line receives the bands of the iliofemoral thickening of the capsule of the hip-joint. The posterior surface of the neck is smooth and concave and its medial two-thirds is enclosed in the capsule of the hip-joint. The superior border of the neck, perforated by large nutrient foramina, is short and thick, and runs downward to the great trochanter. The inferior border, longer and narrower than the superior, curves downward to terminate at the lesser trochanter. At the junction of the neck and head there is a sharp line of demarcation excepting in front, where the iliofemoral ligament exerts great pressure upon the bone.

The **trochanters** are the prominences which afford attachment to the rotator muscles of the thigh; they are two in number—great and lesser.

The **great trochanter** [trochanter major] is a thick, quadrilateral process surmounting the junction of the neck with the shaft, and presents two surfaces and four borders. The lateral surface is broad, rough, and continuous with the lateral surface of the shaft. It is marked by a diagonal ridge running from the posterosuperior to the anteroinferior angle, which receives the insertion of the *gluteus medius.* The ridge divides the surface into two triangular areas: an upper, covered by the *gluteus medius,* and occasionally separated from it by a bursa, and a lower, covered by a bursa to permit the free gliding of the tendon of the *gluteus maximus.* Of the medial surface the lower and anterior portion is joined with the rest of the bone; the upper and posterior portion is free, concave, and presents a deep depression, the **trochanteric** or **digital fossa,** which receives the tendon of the *obturator externus.* The fore part of the surface is marked by an impression for the insertion of the *obturator internus* and two *gemelli.*

Of the four borders, the superior, thick and free, presents near the center an oval mark for the insertion of the *piriformis;* the anterior border, broad and irregular, receives the *gluteus minimus;* the posterior border, thick and rounded, is continuous with the **intertrochanteric crest,** the prominent ridge uniting the two trochanters behind. Above the middle of this line is an elevation, termed the **tubercle of the quadratus,** for the attachment of the upper part of the *quadratus femoris.* The inferior border corresponds with the line of junction of the base of the trochanter with the shaft; it is marked by a prominent ridge for the origin of the upper part of the *vastus lateralis.*

The **lesser trochanter** [trochanter minor] is a conical eminence projecting medially from the posterior and medial aspect of the bone, where the neck is continuous with the shaft. Its summit is rough and gives attachment to the tendon of the *iliopsoas.* The fibers of the *iliacus* extend beyond the trochanter and are inserted into the surface of the shaft immediately below.

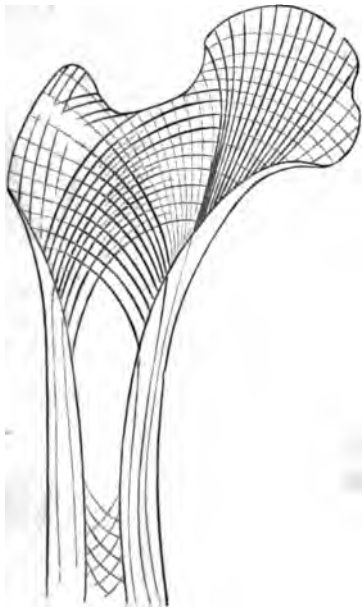
The **body** [corpus femoris] or **shaft** of the femur is almost cylindrical, but is slightly flattened in front and strengthened behind by a projecting longitudinal ridge, the **linea aspera,** for the origin and insertion of muscles. The linea aspera extends along the middle third of the shaft and presents a medial lip and a lateral lip separated by a narrow interval. When followed into the upper third of the shaft, the three parts diverge. The lateral lip becomes continuous with the **gluteal tuberosity** and ends at the base of the great trochanter. The ridge affords insertion to the *gluteus maximus,* and when very prominent is termed the **third trochanter.** The medial lip curves medialward below the lesser trochanter,

where it becomes continuous with the intertrochanteric line; the intervening portion bifurcates and is continued upward as two lines, one of which ends at the small trochanter, and receives some fibers of the *iliacus*, whilst the other is the **linea pectinea** and marks the insertion of the pectineus muscle.

Toward the lower third of the shaft the medial and lateral lips of the linea aspera again diverge, and are prolonged to the condyles by the **medial** and **lateral supracondylar lines,** enclosing between them a triangular surface of bone, the popliteal surface **[planum popliteum]** of the femur, which forms the upper part of the floor of the popliteal space. The lateral line is the more prominent and terminates below in the lateral epicondyle. The medial one is interrupted above, where the femoral vessels are in relation with the bone, better marked below, where it terminates in the **adductor tubercle,** a small sharp projection at the summit of the medial epicondyle, which affords insertion to the tendon of the *adductor magnus*.

Near the center of the linea aspera is the foramen for the medullary artery, directed upward toward the head of the bone. From the medial lip of the linea aspera and the lower part of the intertrochanteric line arises the *vastus medialis* (internus), and from the lateral lip and the side

FIG. 252.—A DIAGRAM TO SHOW THE PRESSURE AND TENSION CURVES OF THE FEMUR. (After Wagstaffe.)



of the gluteal ridge arises the *vastus lateralis* (externus). The *adductor magnus* is inserted into the medial lip of the linea aspera, from the medial side of the gluteal tuberosity above, and the medial supracondylar line below. Between the *adductor magnus* and *vastus medialis* (internus) four muscles are attached: the *pectineus* and *iliacus* above, then the *adductor brevis*, and lowest of all, the *adductor longus*. Above, in the interval between the *adductor magnus* and the *vastus lateralis* (externus), the *gluteus maximus* is inserted; in the interval lower down is the short head of the *biceps*, taking origin from the lower two-thirds of the lateral lip of the linea aspera and the upper two-thirds of the lateral supracondylar line. On the popliteal surface of the bone, just above the condyles, are two rough areas from which the two heads of the *gastrocnemius* take origin. Above the area for the lateral head of the gastrocnemius is a slight roughness for the *plantaris*.

For purposes of description it is convenient to regard the shaft of the femur as presenting anterior, medial, and lateral surfaces, although all three surfaces are smooth and the anterior is not separated from the lateral by ridges of any kind. In the middle third of the shaft the medial and lateral surfaces approach each other behind, being separated by the linea aspera.

The shaft is overlapped on its medial side by the *vastus medialis* (internus), and on its lateral side by the *vastus lateralis* (externus). The upper three-fourths of the anterior and lateral surfaces afford origin to the *vastus intermedius* (crureus), and the lower fourth of the anterior surface, to the *articularis genu* (subcrureus). The medial surface is free from muscular attachment.

The **lower extremity** presents two cartilage-covered eminences or **condyles,** separated behind by the **intercondyloid fossa.** The lateral condyle is wider than its fellow and more prominent anteriorly; the medial condyle is narrower,

FIG. 253.—TRANSVERSE SECTION OF SHAFT OF FEMUR TO SHOW THE MEDULLARY CAVITY.

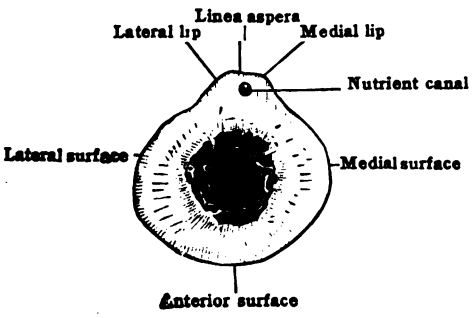


FIG. 254.—SECTION OF UPPER END OF FEMUR TO SHOW THE CALCAR FEMORALE.

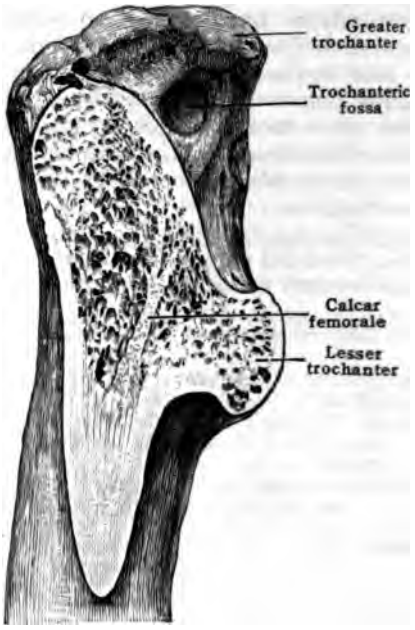
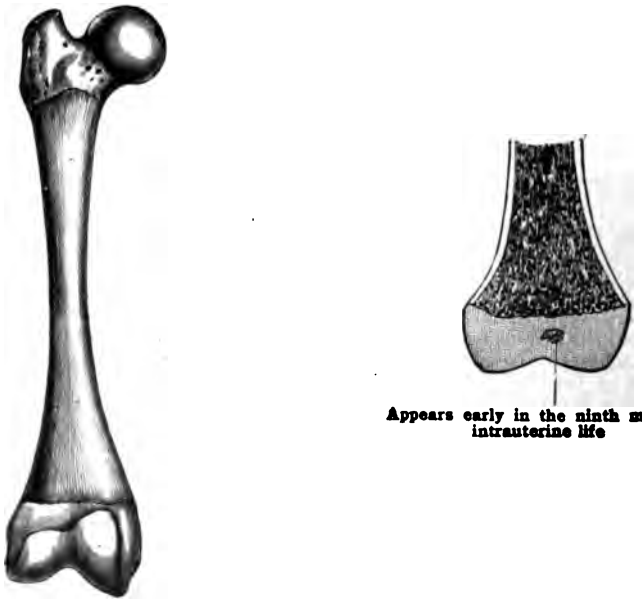


more prominent, and longer, to compensate for the obliquity of the shaft. When the femur is in the natural position, the inferior surfaces of the condyles are on the same plane, and almost parallel, for articulation with the upper surfaces on the

FIG. 255.—THE FEMUR AT BIRTH.



head of the tibia. The two condyles are continuous in front, **forming a smooth trochlear surface** [facies patellaris] for articulation with the patella.

The trochlear surface presents a median vertical groove and two convexities, **the lateral of** which is wider, more prominent, and prolonged farther upward The **patellar surface is**

faintly marked off from the tibial articular surfaces by two irregular grooves, best seen while the lower end is still coated with cartilage. The lateral groove commences on the medial margin of the lateral condyle near the front of the intercondylar fossa, and extends obliquely forward to the lateral margin of the bone. The general direction of the medial groove is from front to back, turning medially in front and extending backward as a faint ridge which marks off from the rest of the medial condyle a narrow semilunar facet for articulation with the medial perpendicular facet of the patella in extreme flexion. The grooves receive the semilunar menisci (see fig. 353) in the extended position of the joint. The tibial surfaces are almost parallel except in front, where the medial turns laterally to become continuous with the patellar surface.

The opposed surfaces of the two condyles form the boundaries of the **intercondylar fossa** and give attachment to the crucial ligaments which are lodged within it. The posterior crucial ligament is attached to the fore part of the lateral surface of the medial condyle and the anterior crucial ligament to the back part of the medial surface of the lateral condyle. The two remaining surfaces of the

condyles are broad and convex, and each presents an **epicondyle** (tuberosity) for the attachment of lateral ligaments. The medial epicondyle, the larger of the two, is surmounted by the adductor tubercle, behind which is an impression for the medial head of the *gastrocnemius* on the upper aspect of the condyle; below and behind the lateral epicondyle is a deep groove which receives the tendon of the *popliteus* muscle when the knee is flexed, and its anterior end terminates in a pit from which the tendon takes origin. Above the lateral epicondyle is a rough impression for the lateral head of the *gastrocnemius*.

The interior of the shaft of the femur is hollowed out by a large medullary canal, and the extremities are composed of cancellated tissue invested by a thin compact layer (figs. 252–254) The arrangement of the cancelli in the upper end of the bone forms a good illustration of the adaptation to mechanical conditions to which bones are subject. In the upper end of the bone the cancellous tissue is arranged in divergent curves. One system springs from the lower part

of the neck and upper end of the shaft medially and spreads into the great trochanter ('pressure lamellæ'). A second system springs from the lateral part of the shaft and arches upward into the neck and head ('tension lamellæ'), crossing the former almost at right angles. A second set of pressure lamellæ springs from the lower thick wall of the neck, and extends into the upper part of the head to end perpendicularly in the articular surface mainly along the lines of greatest pressure. A nearly vertical plate of compact tissue, the **calcar femorale** (fig. 254) projects into the neck of the bone from the inferior cervical region toward the great trochanter. This is placed in the line through which the weight of the body falls, and adds to the stability of the neck of the bone; it is said to be liable to absorption in old age. In the lower end of the bone the vertical and horizontal fibers are so disposed as to form a rectangular meshwork.

Blood-supply. The head and neck of the femur receive branches from the inferior gluteal, obturator, and circumflex arteries, and the trochanters from the circumflex arteries. The nutrient vessel of the shaft is derived from either the second or third perforating artery, or there may be two nutrient vessels arising usually from the first and third perforating. The vessels of the inferior extremity arise from the articular branches of the popliteal and the anastomotic branch of the femoral (genu suprema).

The angle which the neck of the femur forms with the shaft at birth measures, on an average, 160°. In the adult it varies from 110° to 140°; hence the angle decreases greatly during the period of growth. When once growth is completed, the angle, as a rule, remains fixed. (Humphry.)

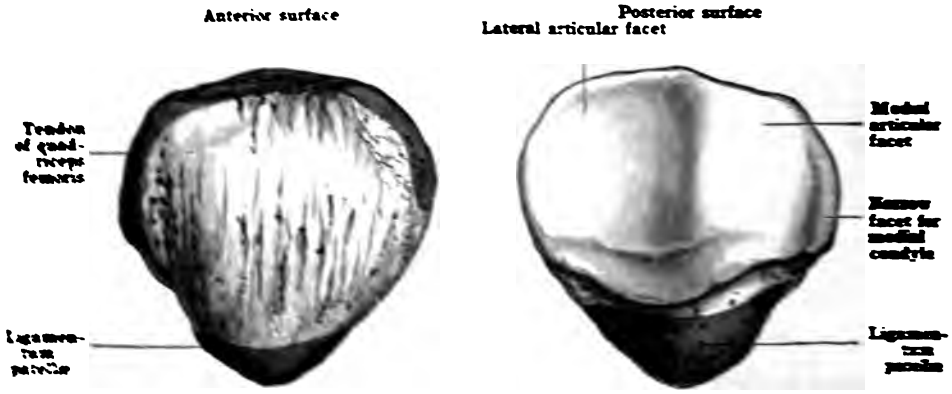
Ossification. The femur is ossified from one primary center for the shaft and from four epiphysial centers. The shaft begins to ossify in the seventh week of intra-uterine life. Early in the ninth month a nucleus appears for the lower extremity. During the first year the nucleus for the head of the bone is visible, and in the fourth year that for the trochanter major. The center for the lesser trochanter appears about the eleventh or twelfth year. The lesser trochanter joins the shaft at the seventeenth, the great trochanter at the eighteenth, the head about the nineteenth, and the lower extremity at the twentieth year (figs. 256, 1147).

Variations. *Platymerism* is the name given to a tendency to anteroposterior flattening of the femoral shaft. The variation of the gluteal tuberosity to form a third trochanter has been referred to; the tuberosity may be absent and its place taken by a hypotrochanteric fossa. The adductor tubercle may form a large spine.

THE PATELLA

The **patella** (figs. 257, 261) or knee-pan, situated in front of the knee-joint, is a sesamoid bone, triangular in shape, developed in the tendon of the *quadriceps femoris*. Its **anterior surface**, marked by numerous longitudinal striæ, is slightly

FIG. 257. THE LEFT PATELLA.



convex, and perforated by small openings which transmit nutrient vessels to the interior of the bone. It is covered in the recent state by a few fibers prolonged from the common tendon of insertion. Superficial to the tendon of the quadriceps femoris is the bursa patellæ subcutanea, and it is separated from the skin by one or more bursæ. The **posterior surface** is largely articular, covered with cartilage in the recent state, and divided by a slightly marked vertical ridge, corresponding to the groove on the anterior surface of the femur, into a lateral and a medial facet. The lateral facet, which is the larger, presents two or three vertical lines, and the medial facet a faint vertical ridge, sometimes marked at a corresponding distance from the medial margin of the medial facet. Below the articular surface is a rough area for the attachment of the ligamentum patellæ, and the intervening portion is separated by a mass

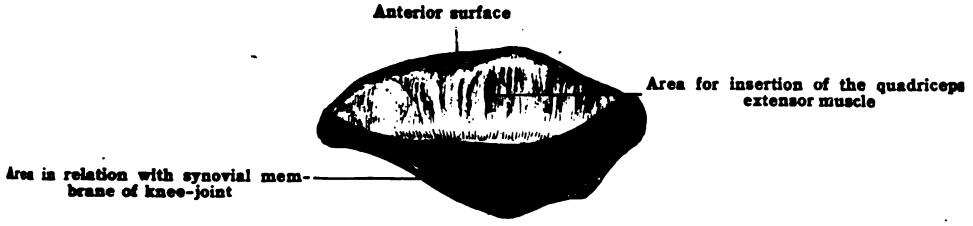
The **base** is directed upward, and receives the attachment of the quadriceps femoris; its attachment extends near the posterior margin to the common

tendon of the *quadriceps*. The **borders**, thinner than the base, converge to the apex below, and receive parts of the two *vasti* muscles. The **apex** forms a blunt point directed downward, and gives attachment to the ligamentum patellæ, by which the patella is attached to the tibia.

Structurally the patella consists of dense cancellous tissue covered by a thin compact layer, and it receives nutrient vessels from the articular branch of the genu suprema (anastomotic), the anterior tibial recurrent, and the inferior articular branches of the popliteal.

Ossification.—The cartilaginous deposit in the tendon of the *quadriceps* muscle takes place in the fourth month of intrauterine life. Ossification begins from a single center during the third year, and is completed about the age of puberty.

FIG. 258.—THE SUPERIOR BORDER OR BASE OF THE LEFT PATELLA.



Anterior surface

Area in relation with synovial membrane of knee-joint

THE TIBIA

The **tibia** (figs. 259, 260) or shin-bone is situated at the front and medial side of the leg and nearly parallel with the fibula. Excepting the femur, it is the largest bone in the skeleton, and alone transmits the weight of the trunk to the foot. It articulates above with the femur, below with the tarsus, and laterally with the fibula. It is divisible into two extremities and a shaft.

The **upper extremity** (or head) consists of two lateral eminences, or **condyles** which contribute to the roundness of the knee and are subcutaneous in front and at either side. Their superior articular surfaces receive the condyles of the femur, the articular parts being separated by a non-articular interval, to which ligaments are attached.

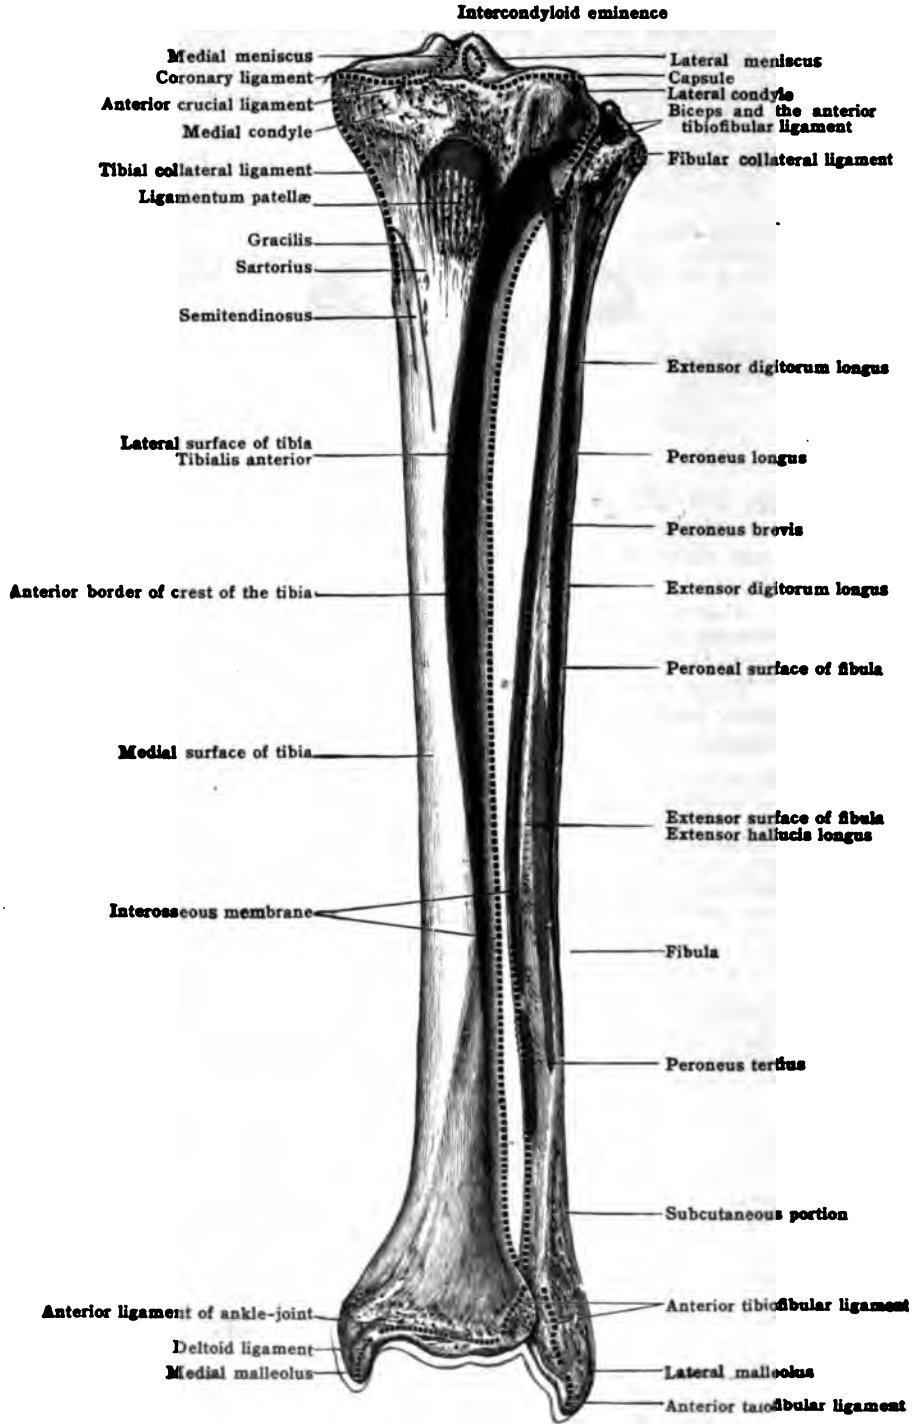
The *medial articular surface* is oval in shape and concave for the medial condyle of the femur. The *lateral articular surface* is smaller, somewhat circular in shape, and presents an almost plane surface for the lateral condyle. The peripheral portion of each articular surface is overlaid by a fibrocartilaginous meniscus of semilunar shape, connected with the margins of the condyles by bands of fibrous tissue termed coronary ligaments (fig. 353). Each semilunar meniscus is attached firmly to the rough interval separating the articular surfaces. This interval is broad and depressed in front, the **anterior intercondyloid fossa**, where it affords attachment to the anterior extremities of the medial and lateral menisci and the anterior crucial ligament; elevated in the middle to form the **intercondyloid eminence** or spine of the tibia, a prominent eminence, presenting at its summit two compressed **intercondyloid tubercles**, on to which the condylar articular surfaces are prolonged; the posterior aspect of the base of the eminence affords attachment to the posterior extremities of the lateral and medial semilunar menisci. A deep notch, the **posterior intercondyloid fossa** or popliteal notch, separates the condyles on the posterior aspect of the head and gives attachment to the posterior crucial ligament, and part of the posterior ligament of the knee-joint.

Anteriorly, the two condyles are confluent, and form a somewhat flattened surface of triangular outline, the apex of which forms the **tuberosity** of the tibia. The tuberosity is divisible into two parts. The upper part, rounded and smooth receives the insertion of the ligamentum patellæ. The lower part is rough, and into its lateral edges prolongations of the ligamentum patellæ are inserted. A prominent bursa intervenes between the ligament and the anterior aspect of the upper extremity of the bone.

The medial condyle is less prominent though more extensive than the lateral, and near the posterior part of its circumference is a deep horizontal groove for the attachment of the central portion of the *semimembranosus* tendon. The margins of this groove, and the surface of bone below, give attachment to the tibial (internal) lateral ligament of the knee. On the under aspect of the lateral condyle is a rounded articular facet for the head of the fibula, flat and nearly circular in outline, directed downward, backward, and laterally. The circumference of the facet is rough and gives attachment to the ligaments of the superior tibiofibular joint, while above and in front of the facet, at the junction of the anterior and lateral surfaces of the condyle, is a ridge for the iliotibial band. Slips from the tendons of the *biceps*, the *extensor digitorum longus* and *peroneus longus* muscles are attached to the head below the iliotibial band.

The **shaft** or **body** [corpus] of the tibia, thick and prismatic above, becor thinner as it descends for about two-thirds of its length, and then gradually pands toward its lower extremity. It presents three borders and three surfa

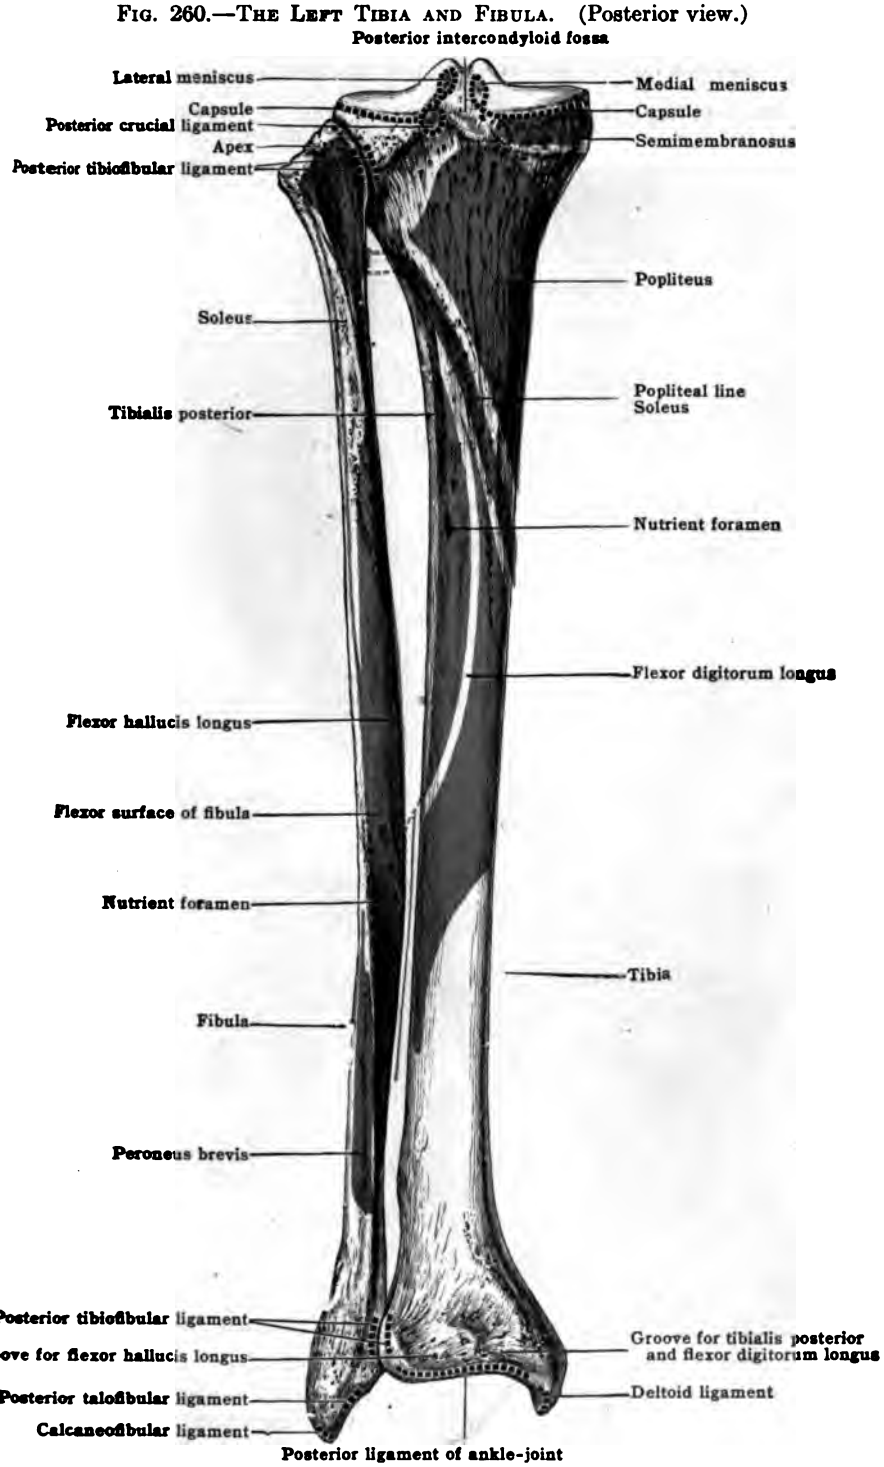
FIG. 259.—THE LEFT TIBIA AND FIBULA. (Anterior view.)



The **anterior border** is very prominent, subcutaneous, and known as the ant **crest** of the tibia. It commences above on the lateral edge of the tuberosity terminates below at the anterior margin of the medial malleolus. It runs a s what sinuous course, and gives attachment to the deep fascia of the leg.

medial border extends from the back of the medial condyle to the posterior margin of the medial malleolus, and affords attachment above, for about three inches, to the tibial (internal) lateral ligament of the knee-joint and in the middle third, to

FIG. 260.—THE LEFT TIBIA AND FIBULA. (Posterior view.)



e soleus. The **interosseous crest** or lateral border, thin and prominent, gives tachment to the interosseous membrane. It commences in front of the fibular cet, on the upper extremity, and toward its termination bifurcates to enclose a

triangular area for the attachment of the interosseous ligament uniting the lower ends of the tibia and fibula.

The **medial surface** is bounded by the medial margin and the anterior crest: it is broad above, where it receives the insertions of the *satorius, gracilis,* and *semi-tendinosus;* convex and subcutaneous in the remainder of its extent. The **lateral surface** lies between the crest of the tibia and the interosseous crest. The upper two-thirds presents a hollow for the origin of the *tibialis anterior;* the rest of th

FIG. 261.—KNEE-JOINT OF A BOY OF SIXTEEN YEARS. From an X-ray plate by Dr. Sherwood Moore, Washington University.

surface is convex and covered by the extensor tendons and the anterior tibial vessels. The **posterior surface** is limited by the interosseous crest and the medial border. The upper part is crossed obliquely by a rough **popliteal line,** extending from the fibular facet on the lateral condyle to the medial border, a little above the middle of the bone.

The popliteal line gives origin to the *soleus* and attachment to the popliteal fascia, while the triangular surface above is occupied by the *popliteus* muscle. Descending along the posterior surface from near the middle of the popliteal line is a vertical ridge, well marked at

its commencement, but gradually becoming indistinct below. The portion of the surface between the ridge and the medial border gives origin to the *flexor digitorum longus;* the lateral and narrower part, between the ridge and the interosseous border, to fibers of the *tibialis posterior*. The lower third of the posterior surface is covered by flexor tendons and the posterior tibial vessels. Immediately below the popliteal line and near the interosseous border is the large medullary foramen directed obliquely downward.

The **lower extremity,** much smaller than the upper, is quadrilateral in shape and presents a strong process called the **medial malleolus,** projecting downward from its medial side. The anterior surface of the lower extremity is smooth and rounded above, where it is covered by the extensor tendons, rough and depressed below for the attachment of the anterior ligament of the ankle-joint. It sometimes bears a facet for articulation with the neck of the talus (astragalus). The posterior surface is rough and is marked by two grooves. The medial and deeper of the two encroaches on the malleolus, and receives the tendons of the *tibialis posterior* and *flexor digitorum longus;* the lateral, very shallow and sometimes indistinct, is for the tendon of the *flexor hallucis longus*. The lateral surface is triangular and hollowed for the reception of the lower end of the fibula and rough for the interosseous ligament which unites the two bones, except near the lower border, where there is usually a narrow surface, elongated from before backward, covered with cartilage in the recent state for articulation with the fibula. The lines in front of and behind the triangular surface afford attachment to the anterior and posterior ligaments of the inferior tibiofibular articulation. The medial surface, prolonged downward on the medial malleolus, is rough, convex, and subcutaneous. The lateral surface of this process is smooth and articulates with the facet on the medial side of the talus (astragalus). Its lower border is notched, and from the notch, as well as from the tip and anterior border, the deltoid ligament of the ankle-joint descends. The inferior or terminal surface, by which the tibia articulates with the talus, is of quadrilateral form, concave from before backward, wider in front than behind, and laterally than medially where it is continuous with the lateral surface of the malleolus.

Variations.—The occasional facet on the anterior surface of the lower extremity of the tibia is a pressure facet, produced by extreme flexion of the ankle joint. It is constantly present in aboriginal peoples who assume the squatting position and is therefore sometimes designated as the 'squatting facet.' Two other variations are: the bilateral compression of the shaft called *platycnemism;* and the retroversion of the head of the tibia. Both have been observed in ancient races and also in some of the living aboriginal races.

The tibia is relatively longer in the lower races than in white and yellow people as shown by the femorotibial index: $\frac{\text{length of tibia} \times 100}{\text{length of femur}}$.

Blood-supply.—The tibia is a very vascular bone. The nutrient artery of the shaft is furnished by the posterior tibial, and is the largest of its kind in the body. The head of the bone receives numerous branches from the inferior articular arteries of the popliteal and the recurrent branches of the anterior and posterior tibial. The lower extremity receives twigs from the posterior and anterior tibial, the peroneal, and the medial malleolar arteries.

Ossification.—The tibia is ossified from one principal center for the shaft, which appears in the seventh week (forty-second day, Mall) of intrauterine life, and two epiphyses, the centers for which appear in the cartilaginous head of the bone toward the end of the ninth month, and in the lower extremity during the second year. The latter unites with the shaft at eighteen, (figs. 261, 1146) but the union of the head with the shaft does not take place until the twenty-first year, and it may even be delayed until twenty five. The tubercle of the tibia is ossified from a nucleus which appears from the seventh to the fifteenth year in a strip of cartilage prolonged down from the cartilage of the head of the bone; the center fuses with the proximal epiphysis about the fifteenth year.

THE FIBULA

The **fibula** (figs. 259, 260) is situated on the lateral side of the leg and, in proportion to its length is the most slender of all the long bones. It is placed nearly parallel to the tibia with which it is connected above and below. In man it is a rudimentary bone and bears none of the weight of the trunk, but is of importance on account of its muscular attachments and its participation in the formation of the ankle-joint. Like other long bones, it is divisible into a shaft and two extremities.

The **head** [capitulum fibulæ] or upper extremity, is a rounded expansion of the bone which produces the prominence at the lateral side of the knee posterior and inferior to the lateral condyle of the tibia. Its upper surface presents laterally a rough eminence for the attachment of the *biceps* tendon and the fibular

(long external) collateral ligament of the knee-joint, and medially a round or oval facet [facies articularis capituli], directed upward, forward, and medially, for articulation with the lateral condyle (tuberosity) of the tibia. The margin of the facet gives attachment to the articular capsule of the superior tibiofibular articulation. Posteriorly, the head rises into a pointed **apex** (styloid process), which affords attachment to the short lateral ligament of the knee-joint, and on the lateral side, to part of the *biceps* tendon.

The posterior aspect of the head gives attachment to the *soleus*, the lateral aspect, extending also in front of the eminence for the *biceps*, to the *peroneus longus;* from the anterior aspect fibers of the *extensor digitorum longus* arise, whilst the medial side lies adjacent to the tibia.

The **shaft** [corpus fibulæ], in its upper three-fourths, is quadrangular, possessing four borders and four surfaces, whereas its lower fourth is flattened from side to side, so as to be somewhat triangular. The borders and surfaces vary exceedingly so that their description is difficult.

The **anterior crest** (or anterolateral border) commences in front of the head and terminates below by dividing to enclose a subcutaneous surface, triangular in shape, immediately above the lateral malleolus. It gives attachment to a septum separating the extensor muscles in front from the peronei muscles on the lateral aspect. The **interosseous crest** (or anteromedial border), so named from giving attachment to the interosseous membrane, also commences in front of the head, close to the anterior crest, and terminates below by dividing to enclose a rough triangular area immediately above the facet for the talus (astragalus); this area gives attachment to the inferior interosseous ligament, and may present at its lower end a narrow facet for articulation with the tibia. The **medial crest** (or posteromedial border), sometimes described as the **oblique line** of the fibula, commences at the medial side of the head and terminates below by joining the interosseous crest, in the lower fourth of the shaft. It gives attachment to an aponeurosis separating the *tibialis posterior* from the *soleus* and *flexor hallucis longus*. The **lateral crest** (or posterolateral border) runs from the back of the head to the medial border of the peroneal groove on the back of the lower extremity; it gives attachment to the fascia separating the peronei from the flexor muscles.

The **anterior** or **extensor surface** is the interval between the interosseous and anterior crests. In the upper third it is extremely narrow, but broadens out below, where it is slightly grooved longitudinally. It affords origin to three muscles: laterally, in the upper two-thirds, to the *extensor digitorum longus*, and, in the lower third, to the *peroneus tertius;* medially, in the middle third, also to the *extensor hallucis longus*. The **medial surface**, situated between the interosseous and medial crests, is narrow above and below, and broadest in the middle. It is grooved and sometimes crossed obliquely by a prominent ridge, the **secondary oblique line** of the fibula; the surface gives origin to the *tibialis posterior*, and the ridge to a tendinous septum in the substance of the muscle. The **posterior surface** is the interval between the medial and lateral crests, and is somewhat twisted so as to look backward above and medially below. It serves, in its upper third, for the origin of the *soleus*, and in its lower two-thirds for the *flexor hallucis longus*. Near the middle of the surface is the medullary foramen, directed downward toward the ankle. The **lateral surface**, situated between the anterior and lateral crests, is also somewhat twisted, looking laterally above and backward below, where it is continuous with the groove on the back of the lateral malleolus. The surface is often deeply grooved and is occupied by the *peroneus longus* in the upper two-thirds and by the *peroneus brevis* in the lower two-thirds.

The **lateral malleolus** or lower extremity is pyramidal in form, somewhat flattened from side to side, and joined by its base to the shaft. It is longer, more prominent, and descends lower than the medial malleolus. Its lateral surface is convex, subcutaneous, and continuous with the triangular subcutaneous surface on the shaft, immediately above. The medial surface is divided into an anterior and upper area [facies articularis malleoli], triangular in outline and convex from above downward for articulation with the lateral side of the talus (**astragalus**), and a lower and posterior excavated area, the **digital fossa**, in which are attached the transverse inferior tibiofibular ligament and the posterior talofibular ligament of the ankle. The anterior border is rough and gives attachment to the anterior talofibular ligament of the ankle, and the anterior inferior tibiofibular ligament. The posterior border is grooved for the peronei tendons, and near its upper part gives attachment to the posterior inferior tibiofibular ligament. The apex or summit of the process affords attachment to the calcaneofibular ligament of the ankle.

Blood-supply.—The shaft of the fibula receives its nutrient artery from the peroneal branch of the posterior tibial. The head is nourished by branches from the inferior lateral articular branch of the popliteal artery, and the lateral malleolus is supplied mainly by the peroneal, and its perforating and malleolar branches.

Ossification.—The shaft of the fibula commences to ossify in the eighth week (fifty-fifth day, Mall) of intrauterine life. A nucleus appears for the lower extremity in the second year, and one in the upper extremity during the fourth or fifth year. The lower extremity fuses with the shaft about twenty (fig. 1146), but the upper extremity remains separate until the twenty-second year or even later.

It is interesting, in connection with the times of appearance of the two epiphyses of the fibula, to note that the ossification of the lower epiphysis is contrary to the general rule—viz., that the epiphysis toward which the nutrient artery is directed is the last to undergo ossification. This is perhaps explained by the rudimentary nature of the upper extremity. In birds the head of the bone is large and enters into the formation of the knee-joint; and in human embryos, during the second month, the fibula is quite close up to the femur.

The human fibula is characterized by the length of its malleolus, for in no other vertebrate does this process descend so far below the level of the tibial malleolus. On the other hand, in the majority of mammals the tibial descends to a lower level than the fibular malleolus. In the human embryo of the third month, the lateral is equal in length to the medial malleolus; but the former grows more rapidly and by the second year it assumes its adult proportion.

The chief **variations** of the fibula are fluctuations in the form and relative size of the surfaces of the shaft, correlated with the attachment of muscles and the occasional absence of the bone.

THE TARSUS

The **tarsal bones** [ossa tarsi] (figs. 262, 263) are grouped in two rows:—a proximal row, consisting of the **talus** and **calcaneus**, and a distal row, consisting of four bones which, enumerated from the tibial side, are the **first, second,** and **third cuneiform** bones and the **cuboid.** Interposed between the two rows on the tibial side of the foot is a single bone, the **navicular**; on the fibular side the proximal and distal rows come into contact.

Compared with the carpus, the tarsal bones present fewer common characters, and greater diversity of size and form, modifications correlated with the function of supporting the weight of the trunk. On each, however, six surfaces can generally be recognized, articular when in contact with neighboring bones, elsewhere subcutaneous or rough for the attachment of ligaments. As regards ossification, they correspond in the main with the bones of the carpus.

The Talus

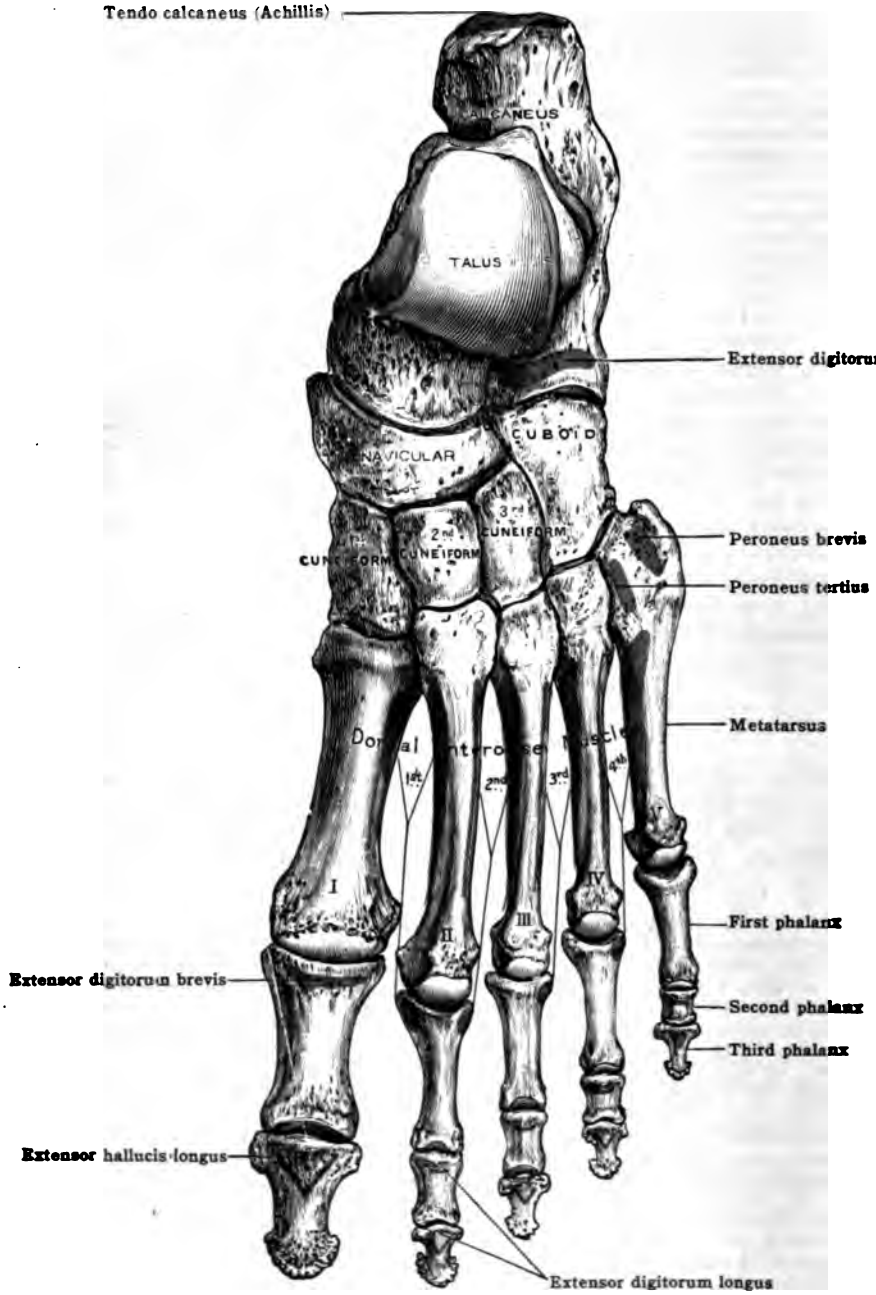
The **talus** (or astragalus) (figs. 264, 265) is, next to the calcaneus, the largest of the bones of the tarsus. Above it supports the tibia, below it rests on the calcaneus, at the sides it articulates with the two malleoli, and in front it is received into the navicular. For descriptive purposes, it may be divided into a **head, neck,** and **body.**

The **body** is somewhat quadrilateral in shape. The **upper surface** presents a broad, smooth surface for the tibia, slightly concave from side to side, convex from before backward, and wider in front than behind. The diminution in width posteriorly is associated with an obliquity of the lateral margin, which is directed medially as well as backward and downward. The **inferior surface** is occupied by a transversely disposed oblong facet [facies articularis calcanea posterior], deeply concave from side to side, which articulates with a corresponding surface on the calcaneus. Of the malleolar surfaces, the lateral is almost entirely occupied by a large triangular facet, broad above, where it is continuous with the superior surface, concave from above downward, for articulation with the lateral malleolus; on the **medial malleolar surface** is a pyriform facet continuous with the superior surface, broad in front and narrow behind, which articulates with the medial malleolus. Below this facet the medial surface is rough for the attachment of the deep fibers of the deltoid (internal lateral) ligament of the ankle. The superior surface and the two malleolar surfaces together constitute the **trochlea.** The **posterior surface** is of small extent and marked by a groove which lodges the tendon of the *flexor hallucis longus.* Bounding the groove on either side are two tubercles, of which the lateral [processus posterior tali] is usually the more prominent, for attachment of the posterior talofibular ligament of the ankle-joint; the medial tubercle gives attachment to the medial talocalcaneal ligament. Continuous with the anterior aspect of the body is the **neck,** a constricted part of the bone supporting the head. Above it is rough, and perforated by numerous vascular foramina. Below, it presents a deep groove [*sulcus tali*], directed from behind forward and lateralward. When the talus is articulated with the calcaneus, this furrow is converted into a canal [*sinus tarsi*] in which is lodged the interosseous talocalcaneal ligament. The **head** is the rounded anterior end of the bone, and its large articular surface is divisible into three parts: in front, a smooth, oval convex area, directed downward and forward for the navicular bone; below, an elongated facet, convex from front to back, for articulation with the sustentaculum tali of the calcaneus; and between these is a small facet which rests on the calcaneo-

navicular ligament, separated from it by the synovial membrane of the talocalcaneonavicular joint.

Articulations.—The talus articulates with four bones and two ligaments. Above and medially with the tibia, below with the calcaneus, in front with the navicular, laterally with the fibula. The head articulates with the calcaneonavicular ligament and the lateral border of the superior surface, at its posterior part, with the transverse ligament of the inferior tibiofibular joint.

FIG. 262.—BONES OF THE LEFT FOOT (Superior Surface.)

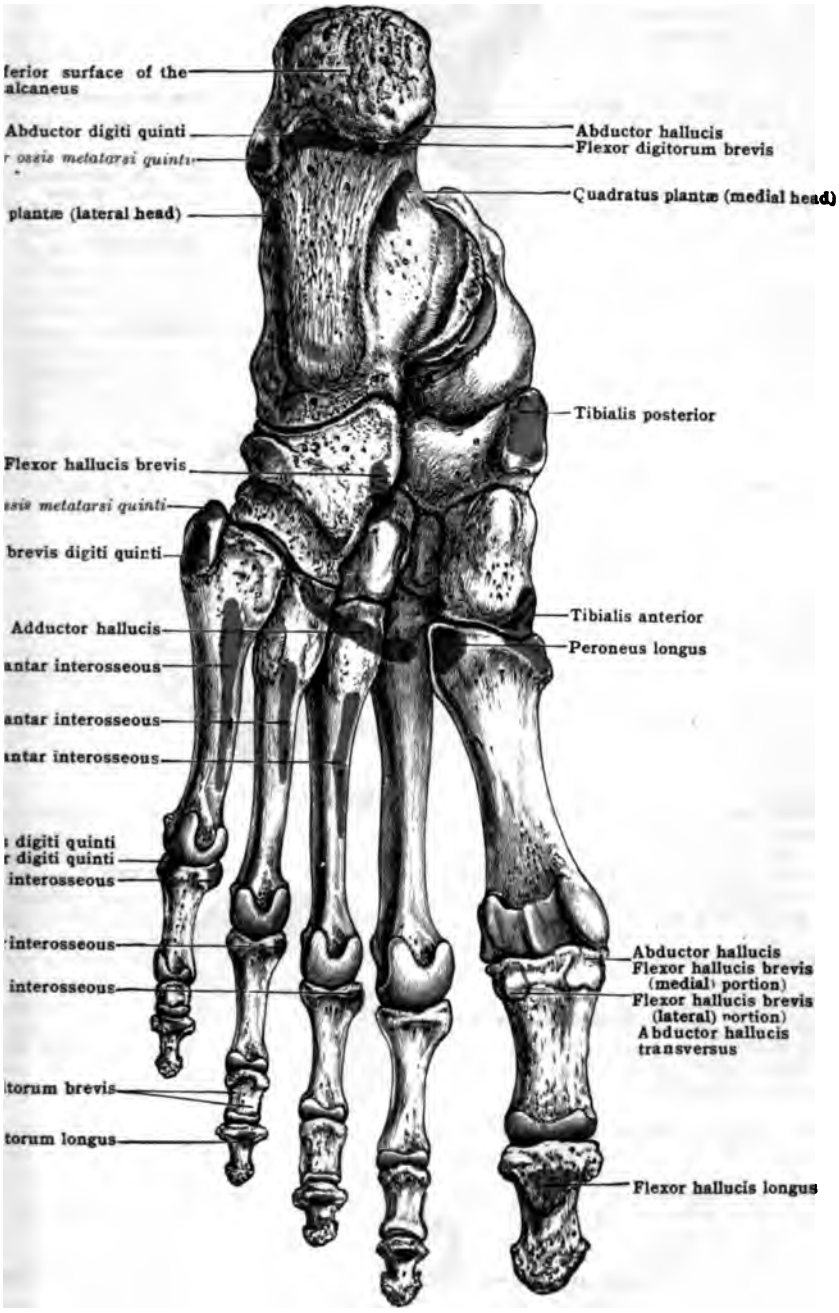


The talus is a very vascular bone and is nourished by the dorsalis pedis artery and its tarsal branch. It gives attachment to no muscles.

Ossification.—The talus is ossified from one nucleus, occasionally from two. The principal center for this bone appears in the middle of the cartilaginous talus at the seventh month of intrauterine life. The additional center is deposited in the posterior portion of the bone, and forms the lateral posterior tubercle which may remain separate from the rest of the bone and form the os trigonum (fig. 265). At birth, the talus presents some important peculiarities in

›n of the articular facet on the tibial side of its body, and in the obliquity of its neck. lt talus, a line be drawn through the middle of the superior trochlear surface parallel ial border, and a second line be drawn along the lateral side of the neck of the bone ect the first, the angle formed by these two lines will express the obliquity of the bone. This in the adult varies greatly, but the average may be taken as 10°. angle averages 35°, while in a young orang it measures 45°. In the normal he articular surface on the tibial side is limited to the body of the bone. In the

FIG. 263.—BONES OF THE LEFT FOOT. (Plantar surface.)



it extends for some distance on to the neck, and sometimes reaches almost as far he navicular facet on the head of the bone. This disposition of the medial malleolar aracteristic feature of the talus in the chimpanzee and the orang. It is related to l position of the foot which is found in the human fetus almost up to the period of of interest to the surgeon in connection with some varieties of club-foot. (Shattock)

FIG. 264.—THE LEFT TALUS. (Plantar view.)

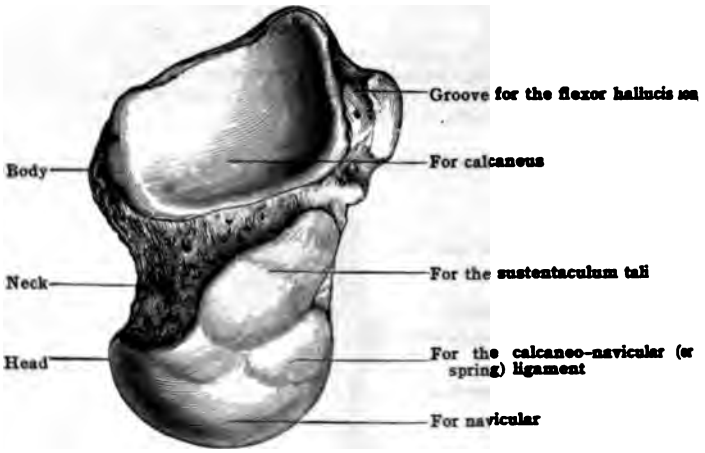


FIG. 265.—A TALUS WITH THE OS TRIGONUM.

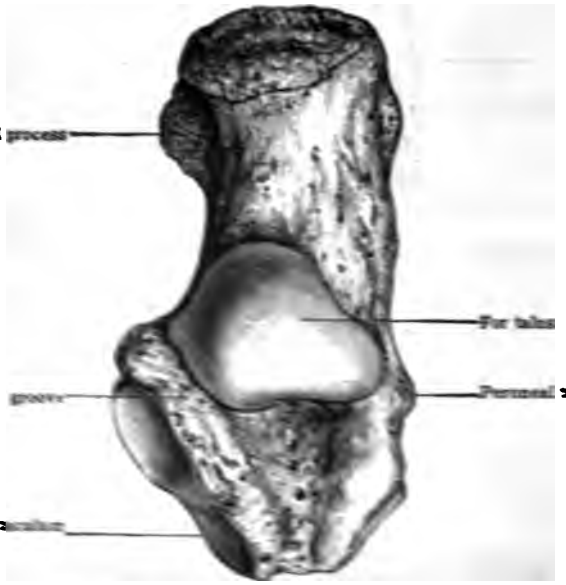
FIG. 266.—THE LEFT CALCANEUS. (Superior view.)



The Calcaneus

The **calcaneus** (or os calcis) (figs. 266, 267) is the largest and strongest bone of the foot. It is of an elongated form, flattened from side to side, and expanded at its posterior extremity, which projects downward and backward to form the heel. It presents six surfaces, superior, inferior, lateral, medial, anterior and posterior.

The **superior surface** presents in the middle a large, oval, convex, articular facet for the under aspect of the body of the talus. In front of the facet the bone is marked by a deep depression, the floor of which is rough for the attachment of ligaments, especially the talocalcaneal, and the origin of the *extensor digitorum brevis* muscle; when the calcaneus and talus are articulated, this portion of the bone forms the floor of a cavity called the **sinus tarsi**. Medially, the upper surface of the bone presents a well-marked process, the **sustentaculum tali**, furnished with an elongated concave facet, occasionally divided into two, for articulation with the under aspect of the head of the talus. The posterior part of the upper surface is non-articular, convex from side to side, and in relation with a mass of fat placed in front of the tendo Achillis.

The **inferior surface** is narrow, rough, uneven, and ends posteriorly in two **processes**: the **medial** is the larger and broader, the **lateral** is narrower but prominent. The medial process affords origin to the *abductor hallucis*, the *flexor digitorum brevis*, and the *abductor digiti quinti;* the last muscle also arises from the lateral process and from the ridge of bone between. The rough surface in front of the tubercles gives attachment to the long plantar ligament (calcaneocuboid) and the lateral head of the *quadratus plantæ*. Near its anterior end this surface forms a rounded eminence, the **anterior tubercle**, from which (as well as from the shallow groove in front) the plantar (short) calcaneocuboid ligament arises.

The **lateral surface** is broad, flat, and slightly convex. It represents near the middle a small eminence for the calcaneofibular ligament of the ankle-joint. Below and in front of this is a well-marked tubercle—the **trochlear process** (or peroneal tubercle), separating two grooves, the upper for the *peroneus brevis* and the lower for the *peroneus longus*.

Fig. 267.—The Calcaneus at the Fifteenth Year, showing the Epiphysis.

Appears at the tenth, and unites at the sixteenth year

The **medial surface** is deeply concave, the hollow being increased by the prominent medial process behind and the overhanging **sustentaculum** tali in front. The latter forms a prominence of bone projecting horizontally, concave and articular above, grooved below for the tendon of the *flexor hallucis longus*, and giving attachment to a slip of the tendon of the *tibialis posterior*, the inferior calcaneonavicular ligament, and some fibers of the deltoid ligament of the ankle-joint. The hollow below the process receives the plantar vessels and nerves and its lower part gives attachment to the medial head of the *quadratus plantæ*.

The **anterior surface** is somewhat quadrilateral in outline with rounded angles, and presents a saddle-shaped articular surface for the cuboid.

The **posterior surface** is oval in shape, rough, and convex. It is divided into three parts:—an upper, smooth and separated by a bursa from the tendo Achillis; a middle part giving insertion to the *tendo Achillis* and the *plantaris*, and a lower part in relation to the skin and fat of the heel. The expanded posterior extremity of the bone is known as the **tuber calcanei**.

Articulations.—The calcaneus articulates with two bones, the talus above and the cuboid in front.

Blood-supply.—The calcaneus is nourished by numerous branches from the posterior tibial and the medial and lateral malleolar arteries. They enter the bone chiefly on the inferior and medial surfaces.

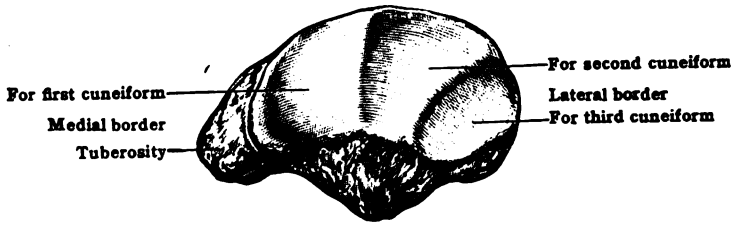
Ossification.—The primary nucleus appears in the sixth month of intrauterine life. The epiphysis, for its posterior extremity, begins to be ossified in the sixth to the tenth year and is united to the body of the bone between the thirteenth and twentieth years (girls earlier than boys). The epiphysis may extend over the whole of the posterior surface, as shown in fig. 267, or over the lower two-thirds only, leaving a part above in relation to the bursa beneath the tendo Achillis, which is formed from the pimary nucleus. The medial and lateral processes are formed by the epiphysis.

The Navicular

The **navicular** [os naviculare pedis] (figs. 268, 269) is oval in shape, flattened from before backward, and situated between the talus behind and the three cuneiform bones in front. It is characterized by a large oval, concave, articular

facet on the **posterior surface,** which receives the head of the talus; a broad, rough, rounded eminence on the **medial surface,** named the **tuberosity** of the navicular, the lower part of which projects downward and gives insertion to the tendon of the *tibialis posterior;* and an oblong-shaped **anterior surface,** convex and divided by two vertical ridges into three facets which articulate with the three cuneiform bones. The **superior** (dorsal) **surface** is rough, convex, and slopes downward to the tuberosity; the **inferior** (plantar) **surface** is irregular and rough for the attachment of the inferior calcaneonavicular ligament, and the **lateral surface** is rough and sometimes presents a small articular surface for the cuboid.

FIG. 268.—THE LEFT NAVICULAR. (Anterior view.)

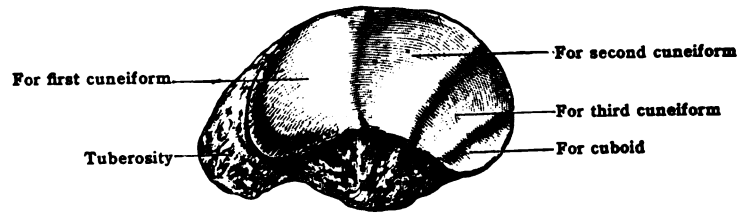


The tuberosity can be easily distinguished by palpation and constitutes an important surgical landmark of the foot.

Articulations.—With the talus behind, with the three cuneiform bones in front, and occasionally with the cuboid on its lateral aspect.

Ossification.—The nucleus for the navicular appears in the course of the fourth year. The tuberosity of the navicular, into which the *tibialis posterior* acquires its main insertion, occasionally develops separately, and sometimes remains distinct from the rest of the bone.

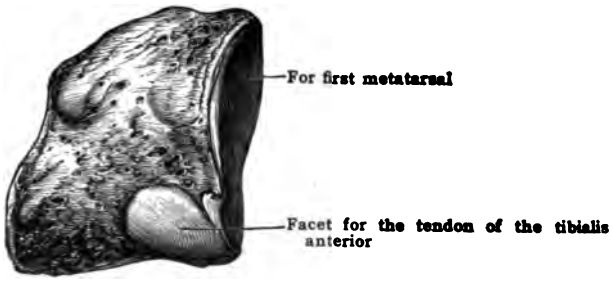
FIG. 269.—THE LEFT NAVICULAR SHOWING A FACET FOR THE CUBOID.



THE CUNEIFORM BONES

Of the three cuneiform bones (figs. 262, 263), the first is the largest, the second is the smallest, and the third intermediate in size. They are wedge-shaped bones placed between the navicular and the first, second and third metatarsal bones. Posteriorly, the ends of the bones lie in the same transverse line, but in front, the first and third project farther forward than the second, and form the sides of a deep recess into which the base of the second metatarsal bone is received.

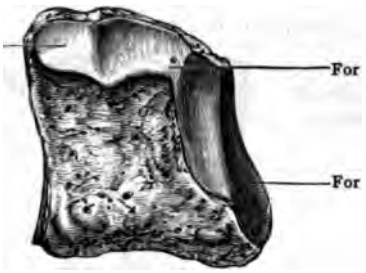
FIG. 270.—THE LEFT FIRST CUNEIFORM. (Medial surface.)



The **first cuneiform** [os cuneiforme primum] (figs. 270, 271) is distinguished by its large size and by the fact that when articulated, the base of the wedge is directed downward and the apex upward. The **posterior surface** is concave and pyriform for articulation with the medial facet on the anterior surface of the navicular. The **anterior surface** forms a reniform articular

he base of the first metatarsal. The **medial surface** is rough, and presents an oblique
: the tendon of the *tibialis anterior;* this groove is limited inferiorly by an oval facet
ı a portion of the tendon is inserted. The **lateral surface** is concave and presents along
or and posterior borders a reversed L-shaped facet for articulation with the second
, and, at its anterior extremity, with the second metatarsal. Anteriorly it is rough

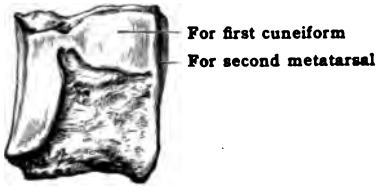
FIG. 271.—THE LEFT FIRST CUNEIFORM. (Lateral aspect.)



nts. The **inferior surface** is rough for the insertion of the *peroneus longus, tibialis* nd (usually) the *tibialis posterior.* The **superior surface** is the narrow part of the l is directed upward.

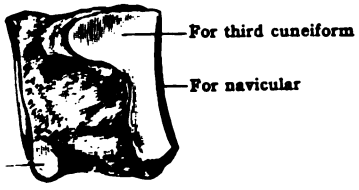
lations.—With the navicular behind, second cuneiform and second metatarsal on side, and first metatarsal in front.

FIG. 272.—THE LEFT SECOND CUNEIFORM. (Medial surface.)



ation.—From a single nucleus which appears in the course of the third year. **econd cuneiform** [os cuneiforme secundum] (figs. 272, 273) is placed with the broad upward and the narrow end downward, and is readily recognized by its nearly se. The **posterior surface,** triangular and concave, articulates with the middle facet terior surface of the navicular. The **anterior surface,** also triangular, but narrower

FIG. 273.—THE LEFT SECOND CUNEIFORM. (Lateral surface.)



posterior surface, articulates with the base of the second metatarsal. The **medial** is a reversed L-shaped facet running along its superior and posterior margins for n with the corresponding facet on the first cuneiform, and is rough elsewhere for the t of ligaments. On the **lateral surface** near its posterior border is a vertical facet, bilobed, for the third cuneiform, and occasionally a second facet at the anterior

FIG. 274.—THE LEFT THIRD CUNEIFORM. (Medial surface.)

For navicular
For second metatarsal. The circular facet near the inferior angle is for the second cuneiform

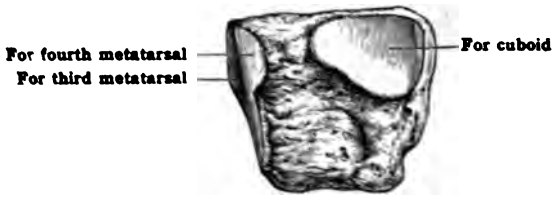
gle. The **superior surface** forms the square-cut base of the wedge and is rough for ment of ligaments. The **inferior surface** is sharp and rough for ligaments and a slip ion of the *tibialis posterior.*

ations.—With the navicular behind, second metatarsal in front, third cuneiform on l side, and first cuneiform on the medial side.

Ossification.—From a single nucleus which appears in the fourth year.

The **third cuneiform bone** (figs. 274, 275) also placed with the broad end directed upward and the narrow end downward, is distinguished by the oblong shape of its base. Like the second cuneiform, the **posterior surface** presents a triangular facet for the navicular; and the **anterior surface** a triangular facet, longer and narrower, for the third metatarsal. The **medial surface** has a large facet extending along the posterior border for the second cuneiform, and along the anterior border a narrow irregular facet for the lateral side of the base of the second

FIG. 275.—THE LEFT THIRD CUNEIFORM. (Lateral surface.)



metatarsal. Occasionally, a small facet is present near the anterior inferior angle for the second cuneiform. The **lateral surface** has a large distinctive facet near its posterior superior angle for the cuboid, and at the anterior superior angle there is usually a small facet for the medial side of the base of the fourth metatarsal. The **superior surface**, oblong in shape, is rough for ligaments, and the **inferior**, forming a rounded margin, receives a slip of the *tibialis posterior* and gives origin to a few fibers of the *flexor hallucis brevis*.

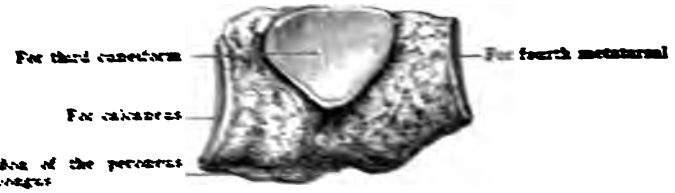
Articulations. With the navicular behind, third metatarsal in front, cuboid and fourth metatarsal on the lateral side, second cuneiform and second metatarsal on the medial side.

Ossification. A single nucleus appears in the course of the first year.

THE CUBOID

The **cuboid** (figs. 276–278), irregularly cubical in shape, is placed on the lateral aspect of the foot, forming a continuous line with the calcaneus and the fourth and fifth metatarsals.

FIG. 276.—THE LEFT CUBOID. (Medial view.)



Its **posterior surface** is [illegible] and presents a saddle-shaped [illegible] for the calcaneus. Its lateral angle is somewhat prolonged backward beneath the [illegible] process of the cuboid, by which the upward or outward movement of the bone is opposed. This process occasionally terminates in a [illegible] at the side of the [illegible] for the calcaneo-navicular ligament. The **anterior surface** is [illegible] by a vertical ridge into two [illegible] facets, the lateral for the base of the fifth and the medial for the base of the fourth metatarsal. The **superior surface** is [illegible] and directed upward. The **inferior surface** presents a [illegible] for the plantar calcaneo-cuboid ligament.

FIG. 277.—THE LEFT CUBOID. (Medial view.)

[illegible]

frequently seen (fig. 277). Generally the two facets are confluent and then form an elliptical surface (fig. 278). The remainder of this surface is rough for the attachment of strong interosseous ligaments.

The **lateral surface,** the smallest and narrowest of all surfaces, presents a deep notch which leads into the peroneal gooves.

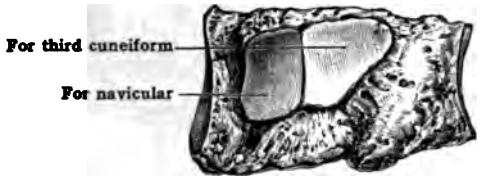
Articulations.—With the calcaneus behind, fourth and fifth metatarsals in front, third cuneiform and frequently the navicular on the medial side; occasionally also the talus.

Ossification.—The cuboid is ossified from a single nucleus which appears about the time of birth.

Accessory tarsal elements.—As in the carpus, a number of additional elements may occur in the tarsus. The most frequent of these is the **os trigonum,** which has already been noticed. Next in frequency is an additional first cuneiform, resulting from the ossification of the plantar half of that bone independently of the dorsal half, so that the bone is represented by a plantar and a dorsal first cuneiform. Other additional elements may occasionally occur at the upper posterior angle of the sustentaculum tali; at the anterior superior angle of the calcaneus, between that bone and the navicular; in the angle between the first cuneiform and the first and second metatarsals; and in the lateral angle between the fifth metatarsal and the cuboid (**os Vesalianum.**)

The lateral portion of the navicular is sometimes united to the cuboid and quite separate from the rest of the navicular, the cuboid in such cases articulating with the talus. This condition suggests the recognition of this portion of the navicular as a distinct accessory tarsal element, the *cuboides secundarium,* though it has not yet been observed as an independent bone in the human foot.

FIG. 278.—THE LEFT CUBOID. (Medial view.)



THE METATARSUS

The **metatarsus** [ossa metatarsalia] consists of a series of five somewhat cylindrical bones (figs. 262, 263). Articulated with the tarsus behind, they extend forward, nearly parallel with each other, to their anterior extremities, which articulate with the phalanges, and are numbered according to their position from great toe to small toe. Like the corresponding bones in the hand, each presents a three-sided shaft, a proximal extremity termed the base, and a distal extremity or head. The shaft tapers gradually from the base to the head, and is slightly curved longitudinally so as to be convex on the dorsal and concave on the plantar aspect.

A typical metatarsal bone.—The **shaft** [corpus] is compressed laterally and presents three borders and three surfaces. The two **borders,** distinguished as **medial** and **lateral,** are sharp and commence behind, one on each side of the dorsal aspect of the tarsal extremity, and, gradually approaching in the middle of the shaft, separate at the anterior end to terminate in the corresponding tubercles. The **inferior border** is thick and rounded and extends from the under aspect of the tarsal extremity to near the anterior end of the bone, where it bifurcates, the two divisions terminating in the articular eminences on the plantar aspect of the head. Of the three surfaces, the **dorsal** is narrow in the middle and wider at either end. It is directed upward and is in relation with the extensor tendons. The **medial** and **lateral surfaces,** more extensive than the dorsal, corresponding with the interosseous spaces, are separated above, but meet together at the inferior border; they afford origin to the *interosseous* muscles. The **base** is wedge-shaped, articulating by its terminal surface with the tarsus, and on each side with the adjacent metatarsal bones. The dorsal and plantar surfaces are rough for the attachment of ligaments. The **head** presents a semicircular articular surface for the base of the first phalanx, and on each side a depression, surmounted by a tubercle, for the attachment of the lateral ligaments of the metatarsophalangeal joint. The inferior surface of the head is grooved for the passage of the flexor tendons and is bounded by two eminences continuous with the terminal articular surface.

The several metatarsals possess distinctive characters by which they can be readily recognized

The **first metatarsal** (fig. 279) is the most modified of all the metatarsal bones, and deviates widely from the general description given above. It is the shortest, the thickest, the strongest, and most massive of the series. The **base** presents a large reniform, slightly concave facet for the first cuneiform and projects downward into the sole to form the **tuberosity**, a rough eminence into which the *peroneus longus* and a slip of the *tibialis anterior* are inserted. A little above the tuberosity, on its lateral side, there is occasionally a shallow, but easily recognized

FIG. 279.—THE FIRST (LEFT) METATARSAL.

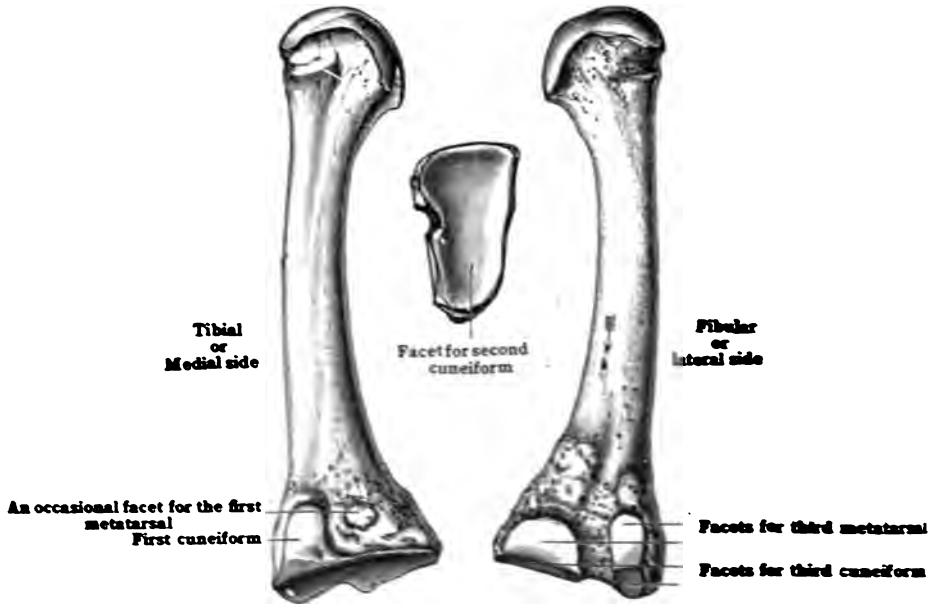
facet, for articulation with the base of the second metatarsal. The **head** is marked on the plantar surface by two deep grooves, separated by a ridge, in which the two sesamoid bones of the *flexor hallucis brevis* glide. The **shaft** is markedly prismatic. The **dorsal surface** is smooth, broad, and convex, directed obliquely upward; the **plantar surface** is concave longitudinally and covered by the *flexor hallucis longus* and *brevis*, whilst the **lateral surface** is triangular in outline, almost vertical, and in relation with the first *dorsal interosseous* and *adductor hallucis*

FIG. 280.—THE SECOND (LEFT) METATARSAL.



Tibial or Medial side

obliquus. A few fibers of the medial head of the first *dorsal interosseous* occasionally arise from the hinder part of the surface adjoining the base, or from the border separating the lateral from the dorsal surface. Somewhere near the middle of the shaft, and on its fibular side, is the nutrient foramen, directed toward the head of the bone.

The second metatarsal (fig. 280) is the longest of the series. **Its base is prolonged backward** to occupy the space between the first and third cuneiform, **and accordingly it is marked**

by facets for articulation with each of these bones. The tarsal surface is triangular in outline, with the base above and apex below, and articulates with the second cuneiform bone. On the tibial side of the base, near the upper angle, is a small facet for the first cuneiform, and occasionally another for the first metatarsal a little lower down. The fibular side of the base presents an upper and a lower facet, separated by a non-articular depression, and each facet is divided by a vertical ridge into two, thus making four in all. The two posterior facets articulate with the third cuneiform and the two anterior with the third metatarsal. The base gives

FIG. 281.—THE THIRD (LEFT) METATARSAL.

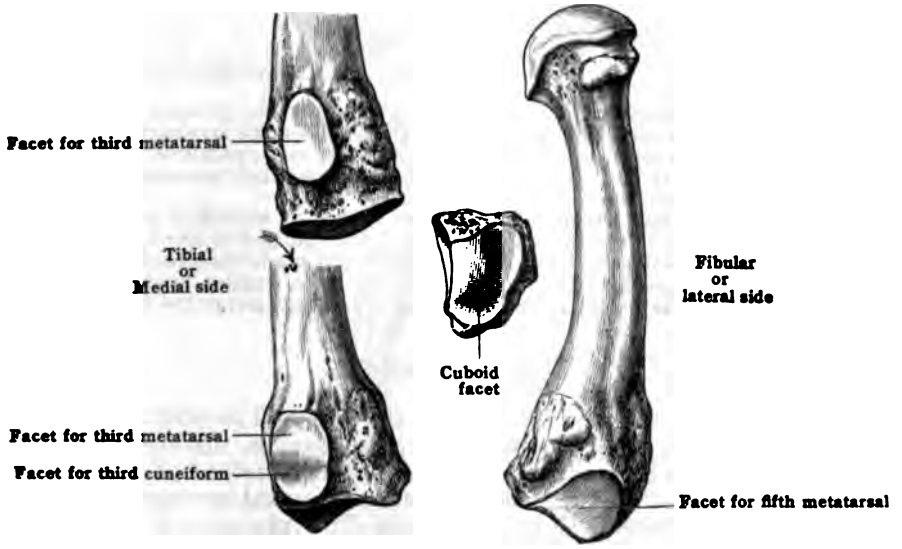
insertion to a slip of the *tibialis posterior* and the *adductor hallucis obliquus*, while from the shaft the first and second *dorsal interosseous* muscles take origin. The nutrient foramen is situated on the fibular side of the shaft near the middle and is directed toward the base of the bone.

The **third metatarsal** (fig. 281), a little shorter than the second, articulates by the triangular surface of its base with the third cuneiform. On the medial side are two small facets,

FIG. 282.—THE FOURTH (LEFT) METATARSAL.



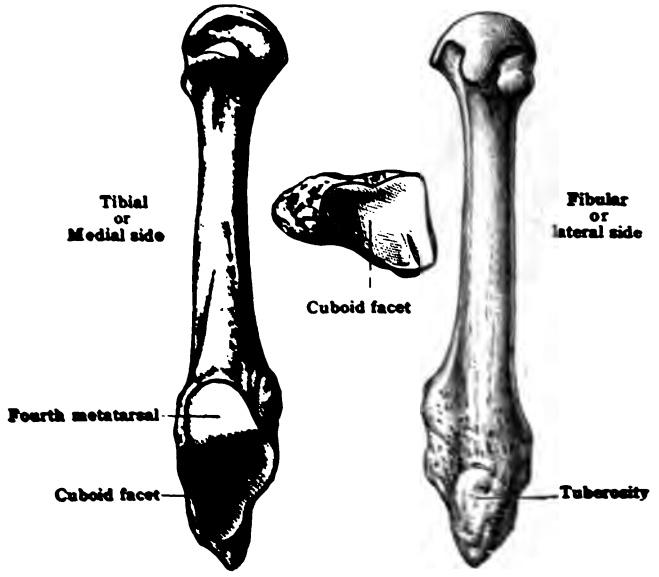
one below the other, for the second metatarsal, and on the lateral side, a single large facet for the fourth metatarsal. The base gives attachment to a slip of the *tibialis posterior* and the *adductor hallucis obliquus*, and from the shaft three *interosseous* muscles take origin. The nutrient foramen is situated on the tibial side of the shaft and is directed toward the base.

The **fourth metatarsal** (fig. 282), smaller in size than the preceding, is distinguished by the quadrilateral facet on the base, for the cuboid. The medial side presents a large facet

divided by a ridge into an anterior portion for articulation with the third metatarsal and a posterior portion for the third cuneiform. Occasionally the cuneiform part of the facet is wanting. On the lateral side of the base is a single facet for articulation with the fifth metatarsal.

The **fifth metatarsal** (fig. 283), is shorter than the fourth, but longer than the first. It is recognized by the large nipple-shaped process, known as the **tuberosity,** which projects on the lateral side of the base. It constitutes the hindmost part of the bone and gives insertion to the *peroneus brevis* on the dorsal aspect, and *flexor brevis digiti quinti* and the occasional *abductor ossis metatarsi quinti* on the plantar aspect. The fifth metatarsal articulates behind by an obliquely directed triangular facet with the cuboid, and on the medial side with the fourth metatarsal. The plantar aspect of the base is marked by a shallow groove which lodges the tendon of the *abductor digiti quinti,* and the dorsal surface, continuous with the superior surface of the shaft, receives the insertion of the *peroneus tertius.* The **head** is small and turned somewhat laterally in consequence of the curvature of the shaft in the same direction. The **shaft** differs from that of any of the other metatarsals in being compressed from above downward, instead of from side to side, so as to present superior, inferior, and medial surfaces. It gives origin to the lateral head of the fourth *dorsal interosseous* and the third *plantar interosseous* muscles. The nutrient foramen is situated on its tibial side and is directed toward the base.

FIG. 283.—THE FIFTH (LEFT) METATARSAL.



Ossification.—Each metatarsal ossifies from two centers. The primary nucleus for the shaft appears in the eighth week of embryonic life in the middle of the cartilaginous metatarsus. At birth, each extremity is represented by cartilage, and that at the proximal end is ossified by extension from the primary nucleus, except in the case of the first metatarsal. For this, a nucleus appears in the third year.

The distal ends of the four lateral metatarsals are ossified by secondary nuclei which make their appearance about the third year. Very frequently an epiphysis is found at the distal end of the first metatarsal as well as at its base. The shafts and epiphyses consolidate in a period extending from the fourteenth to twenty-first year, earlier in females, later in males. The sesamoids belonging to the flexor hallucis brevis begin to ossify about the fifth year.

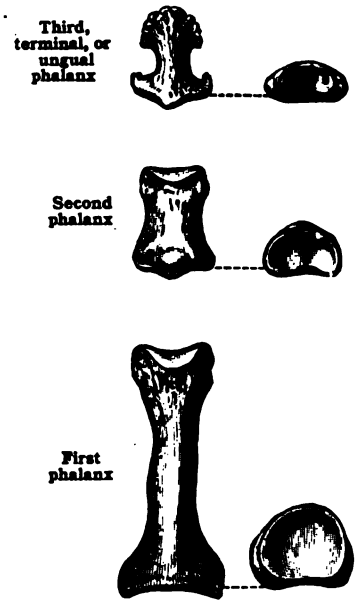
THE PHALANGES

The **phalanges** fig. 284 are the bones of the toes, and number in all fourteen. Except the great toe, each consists of three phalanges, distinguished as first (proximal), second and third (distal); in the great toe the second phalanx is absent. There is thus a similarity as regards number and general arrangement with the phalanges of the fingers. With the exception of the phalanges of the great toe, which are larger than those of the thumb, the bones of the toes are smaller and more rudimentary than the corresponding bones of the fingers. In all the phalanges, the nutrient foramen is directed toward the distal extremity.

The phalanges of the first row are constricted in the middle and expanded at either extremity. The shafts are narrow and laterally compressed, rounded on the dorsal and concave on the plantar aspects. The base of each presents a single oval concave facet for the convex

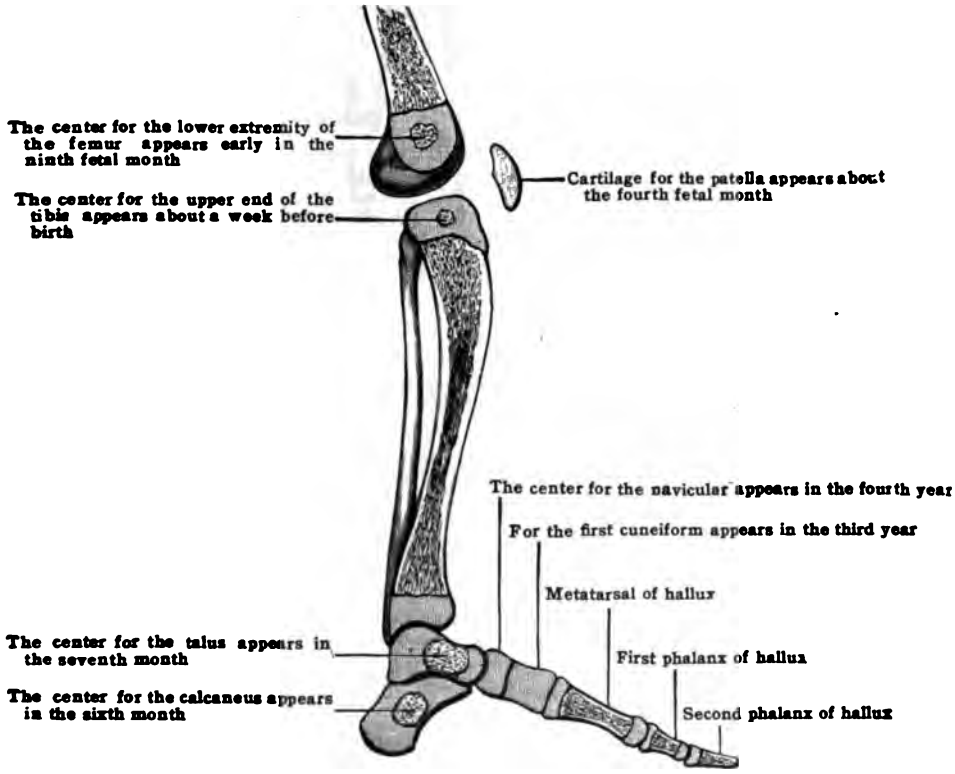
dead of the corresponding metatarsal, whilst the head forms a pulley-like surface [trochlea phalangis], grooved in the center and elevated on each side for the second phalanx.

FIG. 284.—THE PHALANGES OF THE MIDDLE TOE.



The phalanges of the second row are stunted, insignificant bones. Their shafts, beside being much shorter, are flatter than those of the first row. The bases have two depressions separated by a vertical ridge, and the heads present trochlear surfaces for the ungual phalanges

FIG. 285.—A LONGITUDINAL SECTION OF THE BONES OF THE LOWER LIMB AT BIRTH.



The center for the lower extremity of the femur appears early in the ninth fetal month
Cartilage for the patella appears about the fourth fetal month
The center for the upper end of the tibia appears about a week before birth
The center for the navicular appears in the fourth year
For the first cuneiform appears in the third year
Metatarsal of hallux
The center for the talus appears in the seventh month
First phalanx of hallux
The center for the calcaneus appears in the sixth month
Second phalanx of hallux

The third, or ungual phalanges are easily recognized. The bases articulate with the second phalanges; the shafts are expanded, forming the ungual tuberosities which support the nails, and their plantar surfaces are rough where they come into relation with the pulp of the digits.

The muscles attached to the various phalanges may be tabulated thus:—

The **first phalanx of the hallux** gives insertion to the flexor hallucis brevis; abductor hallucis; adductor hallucis transversus and obliquus; extensor digitorum brevis.

The **first phalanx of second toe**: The first and second dorsal interosseous.

The **first phalanx of third toe**: Third dorsal interosseous; first plantar interosseous.

The **first phalanx of fourth toe**: Second plantar interosseous; fourth dorsal interosseous.

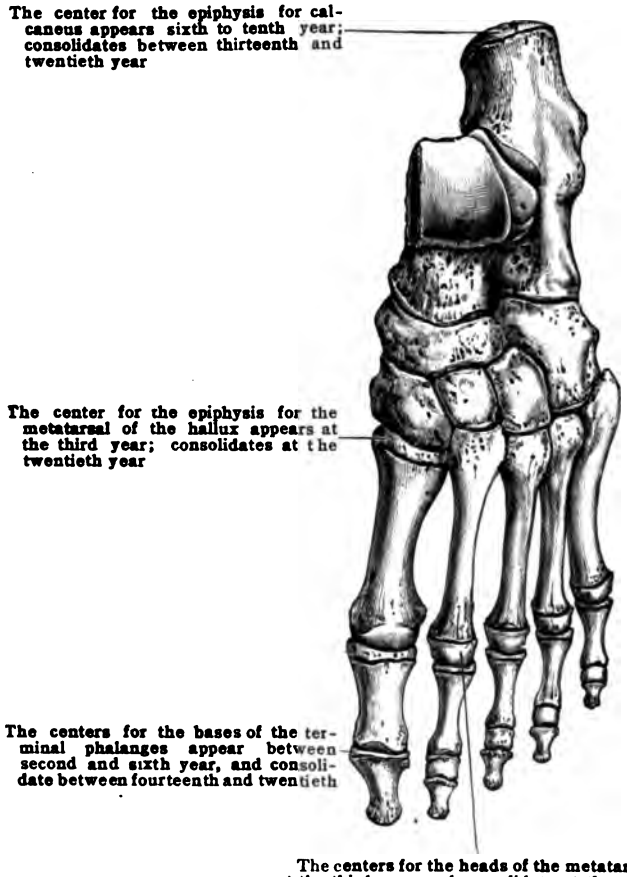
The **first phalanx of fifth toe**: Third plantar interosseous; flexor digiti quinti brevis; and abductor digiti quinti.

The **terminal phalanx of hallux**: Flexor hallucis longus; extensor hallucis longus.

The **second phalanges of the remaining toes**: Dorsal expansion of the extensor tendons, including extensor digitorum longus, extensor digitorum brevis (except in the case of the fifth toe), and expansions from the interossei and lumbricales.

The **third phalanges**: Flexor digitorum longus; dorsal expansion of the extensor tendon with the associated muscles.

FIG. 286.—THE SECONDARY OSSIFIC CENTERS OF THE FOOT.



The center for the epiphysis for calcaneus appears sixth to tenth year; consolidates between thirteenth and twentieth year
The center for the epiphysis for the metatarsal of the hallux appears at the third year; consolidates at the twentieth year
The centers for the bases of the terminal phalanges appear between second and sixth year, and consolidate between fourteenth and twentieth
The centers for the heads of the metatarsals appear at the third year, and consolidate at the twentieth year

Ossification.—Like the corresponding bones of the fingers, the phalanges of the toes ossify from a primary and a secondary nucleus. The centers for the shaft appear during the period extending between the eighth week and tenth month of prenatal life; those for the distal phalanges appear earliest; the middle appear last. The secondary center forms a scale-like epiphysis for the proximal end between the second and sixth years, and union takes place in the fourteenth to seventeenth year—i.e., earlier than the corresponding epiphyses in the fingers. The union occurs earlier in females than in males. The primary centers for the third phalanges appear at the distal extremities of the bones.

SESAMOID BONES

As previously mentioned, the patella is in reality a large sesamoid bone. In the foot a pair of sesamoid bones is constant over the metatarsophalangeal joint of the great toe in the tendons of the flexor hallucis brevis. One sometimes occurs over the interphalangeal joint of the same toe and over the metatarsophalangeal joints of the second and fifth and rarely of the third and fourth toes.

A sesamoid also occurs in the tendon of the peroneus longus, where it glides over the groove in the cuboid; another may be found, especially in later life, in the tendon of the tibialis anterior over the first cuneiform bone, and another in the tendon of the tibialis posterior over the medial

ce of the head of the talus. Further a sesamoid, the *fabella*, sometimes occurs in the al head of the gastrocnemius, and another may be found in the tendon of the iliopsoas the pubis.

BONES OF THE FOOT AS A WHOLE

Arches of the foot.—Although the foot is constructed on the same general plan he hand, there is a marked difference in its architecture to qualify it for the erent functions which it is called upon to perform. When in the erect posture, foot forms a firm basis of support for the rest of the body, and the bones are anged in an elliptical arch, supported on two pillars, a posterior or *calcaneal* ar and an anterior or *metatarsal* pillar. It is convenient, however, to regard anterior part of the arch as consisting of two segments, corresponding to the dial and lateral borders of the foot respectively. The medial segment is made of the three metatarsal bones, the three cuneiform, the navicular, and talus; lateral segment is made up of the fourth and fifth metatarsal bones, the oid, and the calcaneus, and both segments are supported behind on a common *aneal* pillar.

The division corresponds to a difference in function of the two *longitudinal arches*. Both intimately concerned in ordinary locomotion. In addition, the medial, characterized by its t curvature and remarkable elasticity, sustains the more violent concussions in jumping and lar actions, whereas the lateral, less curved, more rigid, and less elastic arch forms, with the rs in front and behind, a firm basis of support in the upright posture.

Both arches are completed and maintained by strong ligaments and tendons. The weakest is the joint between the talus and navicular bone, but this appears to be strengthened by trong calcaneonavicular ligament, for the support of the head of the talus. This ligament is rn supported by its union with the deltoid ligament of the ankle, and by the tendon of the *lis posterior* which passes beneath it to its insertion.

Besides being arched longitudinally, the foot presents a *transverse arch* formed he metatarsal bones in front and the distal row of the tarsus behind. It is luced by the marked elevation of the central portion of the medial longitudinal above the ground, whereas the lateral longitudinal arch is much less raised, at its anterior end becomes almost horizontal. Both the longitudinal and sverse arches serve the double purpose of increasing the strength and elasticity e foot and of providing a hollow in which the muscles, nerves, and vessels of ole may lie protected from pressure.

Homology of the Bones of the Extremities

at there is a general correspondence in the plan of construction of the two extremities is ent to a superficial observer, and this becomes more marked when a detailed examination individual bones, their forms and relations, their embryonic and adult peculiarities, is natically carried out. In each limb there are four segments, the shoulder girdle corre- ing to the pelvic girdle, the arm to the thigh, the forearm to the leg, and the hand to the These parts have been variously modified, in adaptation to the different functions of the mbs. particularly in regard to the deviations or changes from what is considered as their ive position, and as a knowledge of these changes is essential to a clear understanding of mologous bones, it will be advantageous to refer briefly to the relations of the limbs in the t stages of development.

e limbs first appear as flattened, bud-like outgrowths from the sides of the trunk. Each ts a *dorsal* or *extensor* surface, and a *ventral* or *flexor* surface, as well as two borders, *erior*, or *cephalic*, directed toward the head end of the embryo, and a *posterior* or *caudal*, ed toward the tail end. In reference to the axis of the limb itself, the borders have alled *preaxial* and *postaxial*, respectively. When, somewhat later, the various divisions limb make their appearance, it is seen that the greater tuberosity, the lateral epicondyle, dius, and the thumb lie on the preaxial border of the forelimb, and the small trochanter, dial condyle, the tibia, and the great toe on the preaxial border of the hind limb. Further postaxial border of the forelimb are seen the lesser tuberosity, the medial epicondyle, the nd little finger, whilst on the corresponding border of the hind limb are the great trochan- e lateral condyle, the fibula, and the little toe. The parts enumerated on the correspond- orders of the two limbs have been regarded as serially homologous (fig. 287). The pmental flexures and rotation by which the limbs are shifted from their primitive onic to their adult positions have been mentioned (p. 20).

rthermore, as shown in fig. 287, it is evident that the shoulder-girdle and the pelvic- are comparable structures. The scapula probably corresponds to the ilium, and the id process to the ischium. The clavicle (corresponding to the reptilian precoracoid) e the homolog of the clavicle, but this is doubtful.

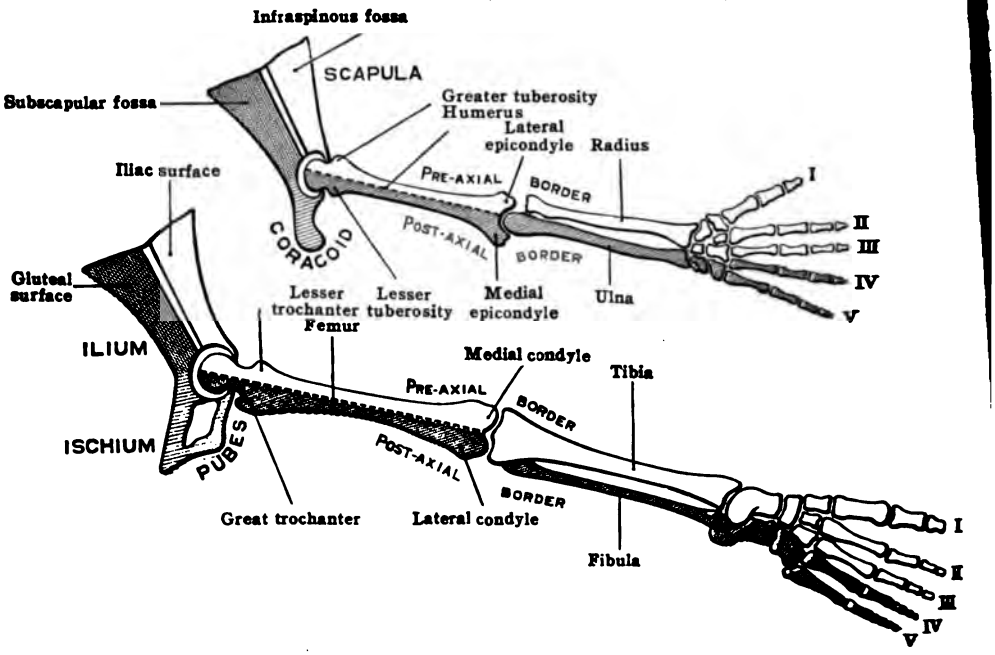
nes of the hand and foot.—The carpus and tarsus, the metacarpus and metatarsus, and rious digits, commencing at the thumb, in the hand, and at the great toe, in the foot, are ed as serially homologous.

order to trace the correspondence between the various elements of the carpus and tarsus nvenient to refer in the first place to a simple type of hand and foot as found in the

water-tortoise and the lizard (fig. 288). In each segment nine elements may be recognised, arranged in a proximal row of three, named respectively *radiale* or *tibiale*, *intermedium*, and *ulnare*, or *fibulare*, a distal row of five *carpalia*, or *tarsalia*, numbered from one to five, commencing at the preaxial border, and between the two rows an *os centrale*.

In man the carpus may be compared with the simple type in the following manner: The radiale forms the navicular, intermedium the lunate, and the ulnare, the triquetral; carpale

FIG. 287.—DIAGRAMMATIC REPRESENTATION OF THE BONES OF THE TWO LIMBS, TO SHOW HOMOLOGOUS PARTS. (Modified from Flower.)



I forms the greater multangular, carpale II the lesser multangular, carpale III the capitate, while carpalia IV and V coalesce to form the hamate. The os centrale is present in the human carpus at an early stage, but in the second month it joins the navicular. It is occasionally separate—a normal arrangement in most of the primates.

In the tarsus, the tibiale and intermedium coalesce to form the talus, and the fibulare becomes the calcaneus. It is interesting to note that although in the human subject there are

FIG. 288.—DORSAL SURFACE OF THE RIGHT MANUS OF A WATER-TORTOISE, *Chelydra serpentina*. (After Gegenbaur.)

three bones in the first row of the carpus and two in the first row of the tarsus, in carnivores the navicular and lunate are united to form a naviculo-lunate bone—the homologue of the talus. In the human tarsus the intermedium occasionally remains distinct as the *os trigonum*.

Tarsale I forms the first cuneiform, tarsale II the second cuneiform, tarsale III the third cuneiform, and tarsale IV and V are joined to form the cuboid. The os centrale forms the navicular.

In addition to the carpal and tarsal elements enumerated above, brief mention must now be made of the sesamoid bones of the two segments, which are regarded by many anatomists

iges of suppressed digits. In the hand are the **ulnar** and **radial sesamoids**, the ulnar epresented by the pisiform and the radial probably by the tuberosity of the navicular mole and other allied species with fossorial habits, the radial sesamoid is greatly de- l to form a sickle-shaped bone which has received the name of *os falciforme*.
corresponding structures in the foot are the **tibial** and **fibular sesamoids**, the tibial nost nearly represented by the tuberosity of the navicular and the fibular by the tuber calcaneus.

SECTION IV

THE ARTICULATIONS

REVISED FOR THE SIXTH EDITION

BY ROBERT J. TERRY, M.D.

PROFESSOR OF ANATOMY IN WASHINGTON UNIVERSITY

---

section devoted to the Articulations or Joints deals with the union of the rious parts of the human skeleton. The following structures enter to the formation of joints.

s constitute the basis of most joints. The long bones articulate by their flat by their edges, and the short at various parts on their surfaces. The ends of long bones are expanded, and are composed of cancellous tissue, led by a dense and strong shell of compact tissue.

cartilage which covers the articular ends of the bones is called **articular,** the **hyaline variety.** It is firmly implanted on the bone by one surface, other is smooth, polished, and free, thus reducing friction to a minimum, slight elasticity tends to break jars. It ends abruptly at the edge of the ion, and is thickest over the areas of greatest pressure.

r form of cartilage, the **white fibrous**, is also found in joints:—
interarticular cartilage in diarthrodial joints—viz., in the knee, mandibular, sterno-radiocarpal, and occasionally in the acromioclavicular joint. It is interposed he ends of the bones, partially or completely dividing the synovial cavity into two. o adjust dissimilar bony surfaces, adding to the security of, while it increases the notion at, the joint; it also acts as a buffer to break shocks.
circumferential or marginal fibrocartilages, which serve to deepen the sockets for ion of the heads of bones—e. g., the glenoid ligaments of the shoulder and hip.
r form of marginal plate is seen in the accessory volar ligaments of the fingers and deepen the articulations of the phalanges and add to their security.
connecting fibrocartilage. The more pliant and elastic is the more cellular form, id in the intervertebral disks; while the less yielding and more fibrous form is seen in iac and pubic articulations, where there is little or no movement.

igaments which bind the bones together are strong bands of white fibrous those joints having an articular cavity, they form a more or less perfect capsula articularis], round the articulation. They are pliant but inex- arying in shape, strength, and thickness according to the kind of articu- o which they enter. They are closely connected with the periosteum ones they unite. In some cases—as the ligamenta flava which unite t in contact—they are formed of yellow elastic tissue. Besides the ous structure serving to maintain the bones in apposition, security is in tances brought about by the conformation of articular surfaces, as for at the humeroulnar articulation. Strength is given also by muscles, ndons frequently are in the closest relations with the ligaments. Finally, eric pressure must be taken into consideration as an important factor in ing to the stability of the articulations.

ynovial membrane [stratum synoviale] lines the interior of the fibrous ligaments, thus excluding them, as well as the cushions or pads of fatty uated within and the tendons which perforate the fibrous capsule, from **lar cavity.** It is a thin delicate membrane, frequently forming folds [plicæ] es which project into the cavity of the joint; or, as in the knee, it across the cavity, forming a so-called synovial ligament. In these folds found pads of fatty tissue, which fill up interstices, and form soft between the contiguous bones. The amount of fat that is mormally

present within a joint varies greatly. It is an old observation that although there is always fat in the hip- and knee-joints, there is usually none within the shoulder-joint. Sometimes these fringes become villous and pedunculated, and cause pain on movement of the joints. They contain fibrous tissue and fat, with isolated cartilage cells. The synovial membrane is well supplied with blood, especially near the margins of the articular cartilages and in the fringes. It secretes a thick, glairy fluid (94 per cent. water, albumin, salts, oil) like the white of egg, called **synovia**, which lubricates the joint. Another variety of synovial membrane is seen in the bursæ, which are interposed between various moving surfaces. In some instances bursæ in the neighborhood of a joint may communicate with the synovial cavity of that joint.

Vascular and nervous supply.—Articular cartilage contains neither vessels nor nerves, vessels are present in the perichondrium and the cartilage is nourished by imbibition. Both vessels and nerves are distributed to the ligaments of a joint after the manner of supply to tendons. The nerves are vasomotor and sensory, terminal twigs of the latter being provided with lamellar corpuscles in the case of diarthrodial joints. Frequently a rich anastomatic network of blood-vessels is present over the surface of the articular capsule. The synovial membrane is very vascular in adaptation to the secretion of synovial fluid. Lymphatic vessels are also present. Nerves penetrate to the synovial layer from the ligamentous capsule.

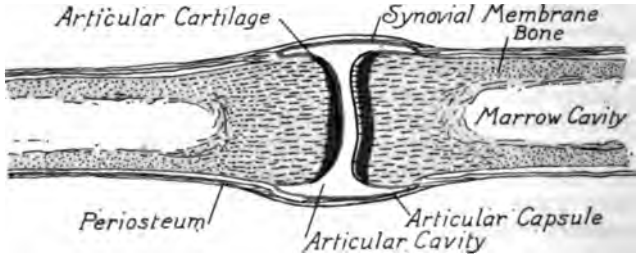
CLASSIFICATION OF ARTICULATIONS

Joints may be classified:—(*a*) From an anatomical point of view, with regard to the substances and the arrangement of the substances by which the constituent parts are united. (*b*) From a physiological standpoint, with regard to the greater or smaller mobility at the seat of union. (*c*) From a physical standpoint, either the shapes of the portions in contact being mainly considered or the axes round which movement can occur. Or again (*d*) a combination of the preceding methods may be adopted, and this is the plan most generally followed. None of the classifications hitherto used is quite satisfactory; that suggested by Macalister with slight modification is utilized here.

There are three chief groups of joints:—

1. *Synarthroses.* In joints of this class the bones are united by fibrous tissue.
2. *Synchondroses.* Joints in which the uniting substance intervening between the bones is cartilage.
3. *Diarthroses.* The constituent parts of joints of this class are (*a*) two or more bones each covered by articular hyaline cartilage; (*b*) a fibrous capsule

FIG. 289.—DIAGRAM OF A DIARTHROSIS.



uniting the bones, and (*c*) a synovial membrane which lines the fibrous capsule and covers any part of bone enclosed in the capsule and not covered with articular cartilage. An interarticular plate of cartilage may or may not be present.

I. **Synarthroses.**—
- (*a*) *Sutures* or immovable joints, in which the fibrous tissue between the bones is small in amount and movement is not permitted.
  - (1) *Harmonic.* The edges of the bones are comparatively smooth and are in even apposition, e.g., vertical plate of palate and maxilla.
  - (2) *Squamous.* The margin of one bone overlaps the other, e. g., temporal and parietal.
  - (3) *Serrate.* The opposed edges interlock by processes tapering to a point.
  - (4) *Dentate.* The opposed edges are dovetailed, e. g., occipital and parietal.
  - (5) *Limbous.* The opposed edges alternately overlap, e. g., parietal and frontal.
  - (6) *Schindylesis.* A ridge or flattened process is received into a corresponding socket, e. g., rostrum of sphenoid and vomer.

(7) *Gomphosis.* A peg-like process is lodged in a corresponding socket, e. g., the fangs of the teeth.

(*b*) *Syndesmoses.* Movable joints in which the fibrous tissue between bones or cartilages is sufficiently lax to allow movement between the connected parts, e.g., thyrohyoid membrane. Interosseous membranes of forearm and leg.

II. **Synchondroses.**—In all synchrondroses a certain amount of movement is possible, and they are often called amphiarthroses.

(1) *True synchondroses.* The cartilage connecting the bones is derived from the bar in which the bones were ossified, e. g., occipitosphenoidal joint.

(2) *False synchondroses.* The plate of cartilage intervening between and connecting the bones is fibrocartilage and is not part of the cartilage in which the bones were ossified, but is developed separately, e. g., intervertebral joint and pubic symphysis. The articular end of each bone may be covered with hyaline cartilage and there may be a more or less well-marked cavity in the intervening plate of fibrocartilage.

III. **Diarthroses.**—In diarthrodial joints the surfaces in contact may be equal and similar or unequal and dissimilar. In the former case the joints are homomorphic; in the latter, heteromorphic.

(*a*) *Homomorphic.*

(1) *Plane or arthrodial.* Flat surfaces, admitting gliding movement, e. g., intercarpal and acromioclavicular joints.

(2) *Ephippial.* Saddle-shaped surfaces, admitting free movement in all directions (except rotation), e. g., carpometacarpal joint of thumb.

(*b*) *Heteromorphic.*

(1) *Enarthrodial.* Ball-and-socket, allowing the most free movement, e. g., hip- and shoulder-joints.

(2) *Condylarthroses.* The convex surface is ellipsoidal, and fits into a corresponding concavity, e.g., wrist and metacarpophalangeal joints.

(3) *Ginglymi.* One surface consists of two conjoined condyles or of a segment of a cone or cylinder, and the opposite surface has a reciprocal contour. In these joints movement is permitted round only one axis, which may be transverse; e. g., elbow, ankle; or it may be vertical, in which case the joint is trochoid; e. g., dens epistrophei with atlas, radius with ulna.

Such a classification should be considered as being purely academic and the student must always remember that it is not enough to discuss a joint by assigning it to a particular class in any scheme; for he must be familiar with the actual conditions present in every joint. No classification, however perfect, must be taken as final, and each joint should be studied as a separate thing altogether apart from any general systematic arrangement.

The movements which may take place at a joint are either gliding, angular, rotatory, or circumductory.

The **gliding** motion is the simplest, and is characteristic of the plane or arthrodial joints; it consists of a simple sliding of the apposed surfaces of the bones upon one another, without angular or rotatory motion. It is the only kind of motion permitted in the carpal and tarsal joints, and in those between the articular processes of the vertebræ.

The **angular** motion is more elaborate, and increases or diminishes the angle between different parts. There are four varieties, viz., *flexion* and *extension*, which bend or straighten the various joints, and take place in a forward and backward direction (in a perfect hinge-joint this is the only motion permitted); and *adduction* and *abduction*, which, except in the case of the fingers and toes, signifies an approach to, or deviation from, the median plane of the body. In the case of the hand, the line to or from which adduction and abduction are made is drawn through the middle finger, while in the foot it is through the second toe.

Rotation is the revolution of a bone about its own axis without much change of position. It is only seen in enarthrodial and trochoidal joints. The knee also permits of slight rotation in certain positions, which is a distinctive feature of this articulation.

Circumduction is the movement compounded of all angular movements in succession, by which the moving bone describes a cone, the proximal end of the bone forming the apex, while the distal end describes the base of the cone. It is seen in the hip and shoulder, as well as in in the carpometacarpal joint of the thumb, which thus approximates to the ball-and-socket joint.

In some situations where a variety of motion is required, strength, security, and celerity are obtained by the combination of two or more joints, each allowing a different class of action, as in the case of the wrist, the ankle, and the head with the spine. Many of the long muscles, which pass over two or more joints, act on all, so tending to co-ordinate their movements and enabling them to be produced with the least expenditure of power. Muscles also act as elastic ligaments to the joints; and when acting as such, are diffusers and combiners, not producers of movement.

Muscles are so disposed at their attachments near the joints as never to strain the ligaments by tending to pull the bones apart; but, on the contrary, they add to the security of the joint by bracing the bones firmly together during their action.

The articulations may be divided for convenience of description into those: (1) of the SKULL; (2) of the TRUNK; (3) of the UPPER LIMB; and (4) of the LOWER LIMB.

THE ARTICULATIONS OF THE SKULL

The movable articulations of the skull comprise (1) the mandibular; and (2) those between the skull and the vertebral column, namely (*a*) between the occiput and atlas; (*b*) between the atlas and epistropheus (axis); and (*c*) the ligaments which connect the occiput and epistropheus. The form of the sutures will be found described in the section on OSTEOLOGY.

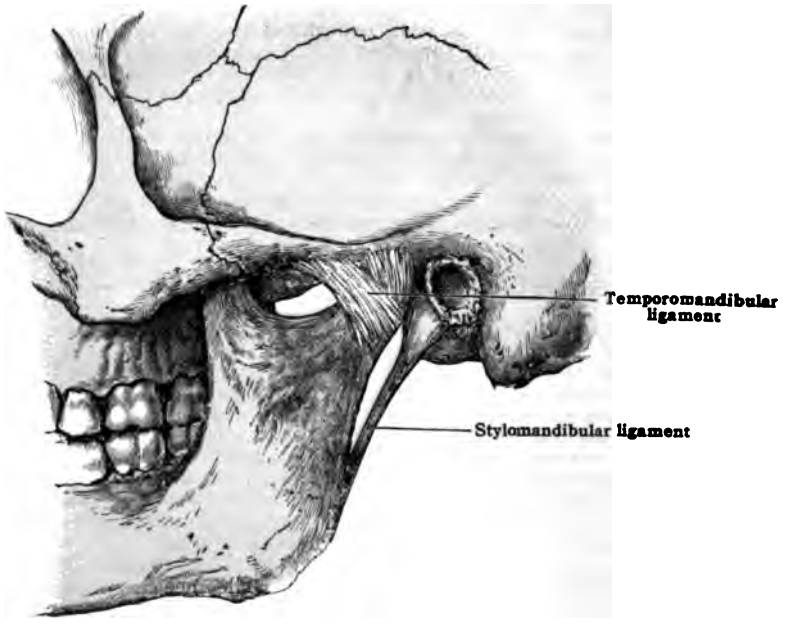
The union of the atlas and epistropheus is described in this section because, (1) there is often a direct communication between the synovial cavity of the transverse epistrophic and the occipitoatlantal joints; (2) the rotatory movements of the head take place around the dens (odontoid process); and (3) important ligaments from the dens pass over the atlas to the occiput.

(1) THE MANDIBULAR ARTICULATION

Class.—*Diarthrosis.* **Subdivision.**—*Condylarthrosis.*

The parts entering into the formation of this joint (figs. 290, 291) are:—the anterior portion of the mandibular fossa and articular tubercle [tuberculum articulare] constituting the articular surface of the temporal bone above, and the condyle of the lower jaw below. Both are covered with fibrocartilage, which approximates pure fibrous tissue on the back of the capitulum. The ligaments which unite the bones are:

FIG. 290.—LATERAL VIEW OF THE MANDIBULAR JOINT.



1. Articular capsule.
2. Articular disk.
3. Sphenomandibular.
4. Stylomandibular.

The **articular capsule** is often described as consisting of four portions, anterior, posterior, lateral and medial, which are, however, continuous with one another around the articulation.

1. The **anterior portion** consists of a few stray fibers connected with the anterior margin of the articular disk, and attached below to the anterior edge of the condyle, and above to the front of the articular tubercle. Some fibers of insertion of the external pterygoid muscle pass between them to be inserted into the margin of the articular disk.

2. The **posterior portion** is attached above, just in front of the petrotympanic (Glaserian) fissure, and is inserted into the back of the jaw just below its neck.

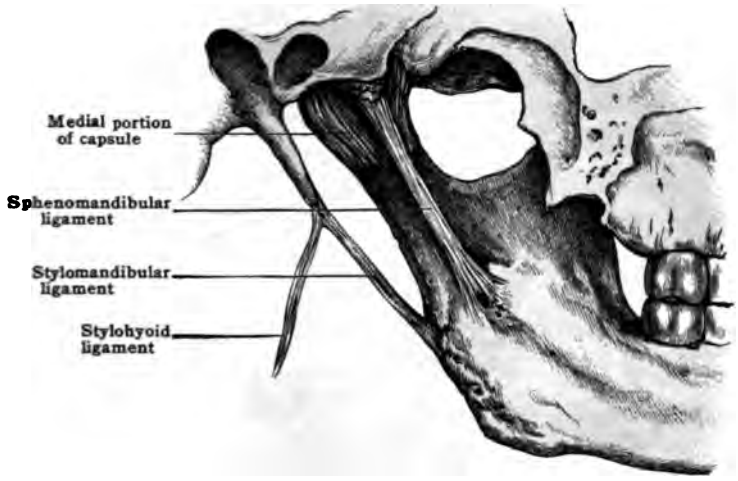
3. The **lateral portion** or **temporomandibular** (external lateral) **ligament** (fig. 290) is the strongest part of the capsule. It is broader above, where it is attached to the lower edge of the zygoma, as well as to the tubercle at the point where the two roots of the zygoma meet. It is inclined downward and backward, to be inserted into the condyle and neck of the mandible laterally. Its fibers diminish in obliquity and strength from before backward, those coming from the tubercle being short and nearly vertical.

4. The **medial portion** (or short internal lateral ligament) (fig. 291) consists of well-defined fibers, having a broad attachment, above to the lateral side of the spine of the sphenoid and medial edge of the mandibular fossa; and below, a narrow insertion to the medial side of the neck of the condyle. Fatty and cellular tissue separate it from the sphenomandibular ligament which is medial to it.

The **articular disk** (fig. 292) is an oval plate of fibrocartilage interposed between and adapted to the two articular surfaces. It is thinner at the center than at the circumference, and is thicker behind, where it covers the thin bone at the bottom of the mandibular fossa which separates it from the dura mater, than in front, where it covers the articular tubercle.

Its *inferior surface* is concave and fits on to the condyle of the lower jaw; while its *superior surface* is concavoconvex from before backward, and is in contact with the articular surface of the temporal bone. It divides the joint into two separate synovial cavities, but is occasion-

FIG. 291.—MEDIAL VIEW OF THE MANDIBULAR JOINT.



ally perforated in the center, and thus allows them to communicate. It is connected with the articular capsule at its circumference, and has some fibers of the external pterygoid muscle inserted into its anterior margin.

There are usually two **synovial membranes** (fig. 292), the superior being the larger and looser, passing down from the margin of the articular surface above, to the upper surface of the articular disk below; the lower and smaller one passes from the articular disk above to the condyle of the jaw below, extending somewhat further down behind than in front. When the disk is perforated, the two sacs communicate.

The **sphenomandibular ligament** (long internal lateral) (fig. 291) is a thin, loose band, situated some little distance from the joint. It is attached above to the spine of the sphenoid and contiguous part of the temporal bone, and below to the lingula of the lower jaw.

It covers the upper end of the mylohyoid groove, and is here pierced by the mylohyoid nerve. Its origin is a little medial to, and immediately behind, the origin of the medial portion of the capsule. It is separated from the joint and ramus of the jaw by the external pterygoid muscle, the internal maxillary artery and vein, the inferior alveolar (dental) nerve and artery, the auriculotemporal nerve, and the middle meningeal artery. It is really the fibrous remnant of a part of the mandibular (Meckelian) bar.

The **stylomandibular ligament** (stylomaxillary) (figs 290, 291) is a process of the deep cervical fascia extending from near the tip of the styloid process

to the angle and posterior border of the ramus of the jaw, between the masseter and internal pterygoid muscles. It separates the parotid from the submaxillary gland, and gives origin to some fibers of the styloglossus muscle.

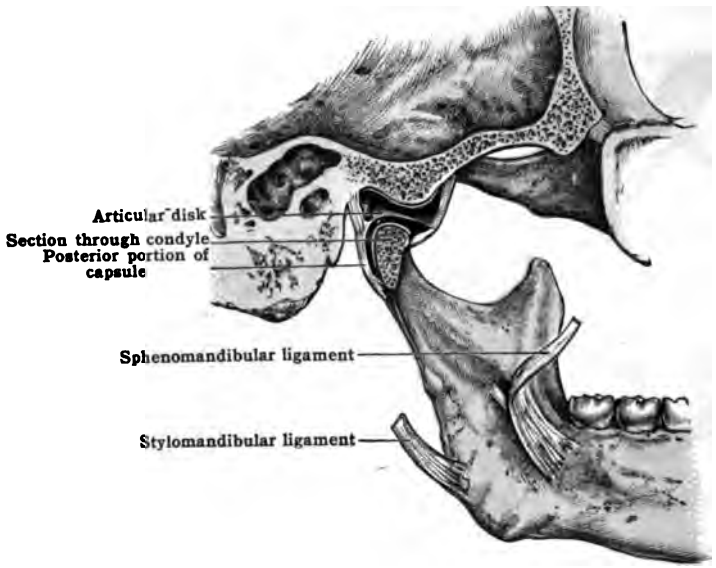
The **arterial supply** of the mandibular joint is derived from the temporal, middle meningeal and ascending pharyngeal arteries, and from the latter by its branches to the Eustachian tube.

The **nerves** are derived from the masseteric and auriculotemporal.

Movements.—(1) The chief movement of this joint is of a **ginglymoid or hinge character**, accompanied by a slight gliding action, as in opening or shutting the mouth. In the opening movement the condyle turns like a hinge on the articular disk, while at the same time the articular disk, together with the condyle, glides forward so as to rise upon the **tuberculum articulare**, reaching as far as the anterior edge of the tubercle; but the condyle never reaches quite so far as the summit of the tubercle. Should the condyle, however, by excessive movement (as in a convulsive yawn), glide over the summit, it slips into the zygomatic fossa, the mandible is dislocated, and the posterior portion of the capsule is torn. In the shutting movement the condyle revolves back again, and the articular disk glides back, carrying the condyle with it. This combination of the hinge and gliding motions gives a tearing as well as a cutting action to the incisor teeth, without any extra muscular exertion.

There is (2) a **horizontal gliding action** in an anteroposterior direction, by which the lower teeth are thrust forward and drawn back again: this takes place almost entirely in the upper compartment, because of the closer connection of the articular disk with the condyle than with

FIG. 292.—SAGITTAL SECTION THROUGH THE CONDYLE OF JAW TO SHOW THE TWO SYNOVIAL SACS AND THE ARTICULAR DISK.



the squamosal bone, and also because of the insertion of the external pterygoid into both bone and cartilage. In these two sets of movements the joints of both sides are simultaneously and similarly engaged.

(3) The form of movement called the **oblique rotatory** is that by which the grinding and chewing actions are performed. It consists in a rotation of the condyle about the vertical axis of its neck in the lower compartment, while the cartilage glides obliquely forward and inward on one side, and backward and inward on the other, upon the articular surface of the squamosal bones, each side acting alternately. If the symphysis be simply moved from the center to one side and back again, and not from side to side as in grinding, the condyle of that side moved round the vertical axis of its neck, and the opposite condyle and cartilage glide forward and inward upon the mandibular fossa. But in the ordinary grinding movement, one condyle advances and the other recedes, and then the first recedes while the other advances, slight rotation taking place in each joint meanwhile. For further details on the movements of the mandibular joint see p. 533.

Relations.—The chief relations are: Behind, and overlapping the lateral side, the parotid gland. Laterally, the superficial temporal artery. Medially, the internal maxillary artery and auriculotemporal nerve. In front, the nerve to the masseter muscle.

Muscles acting on the joint (cf. also p. 373).—*Elevators of the mandible.*—**Temporals, masseters**, internal pterygoids.

Depressors.—Mylohyoid, digastric, geniohyoid, muscles connecting the hyoid bone to lower points. External pterygoid. The weight of the jaw.

Protractors.—External pterygoids, superficial layer of masseter, anterior fibers of temporal.

Retractors.—Posterior fibers of temporal, slightly by the internal pterygoid and deep layer of the masseters.

(2) THE LIGAMENTS AND JOINTS BETWEEN THE SKULL AND VERTEBRAL COLUMN, AND BETWEEN THE ATLAS AND EPISTROPHEUS

(*a*) The Articulation of the Atlas With the Occiput

Class.—*Diarthrosis.* **Subdivision.**—*Double Condylarthrosis.*

This articulation [articulatio atlantooccipitalis] consists of a pair of joints symmetrically situated on either side of the middle line. The parts entering into their formation are the cup-shaped superior articular processes of the atlas and the condyles of the occipital bone. They are united by the following ligaments:—

1. Anterior atlanto-occipital.
2. Posterior atlanto-occipital.
3. Two articular capsules.
4. Two anterior oblique.

Fig. 293.—Anterior View of the Upper End of the Vertebral Column.

Anterior longitudinal ligament

The **anterior atlanto-occipital ligament** [membrana atlantooccipitalis anterior] (fig. 293) is about 2 cm. wide, and is composed of densely woven fibers most of which radiate slightly lateralward as they ascend from the front surface and upper margin of the anterior arch of the atlas to the anterior border of the foramen magnum; it is continuous at the sides with the articular capsules, the fibers of which overlap its edges, and take an opposite direction medially and upward.

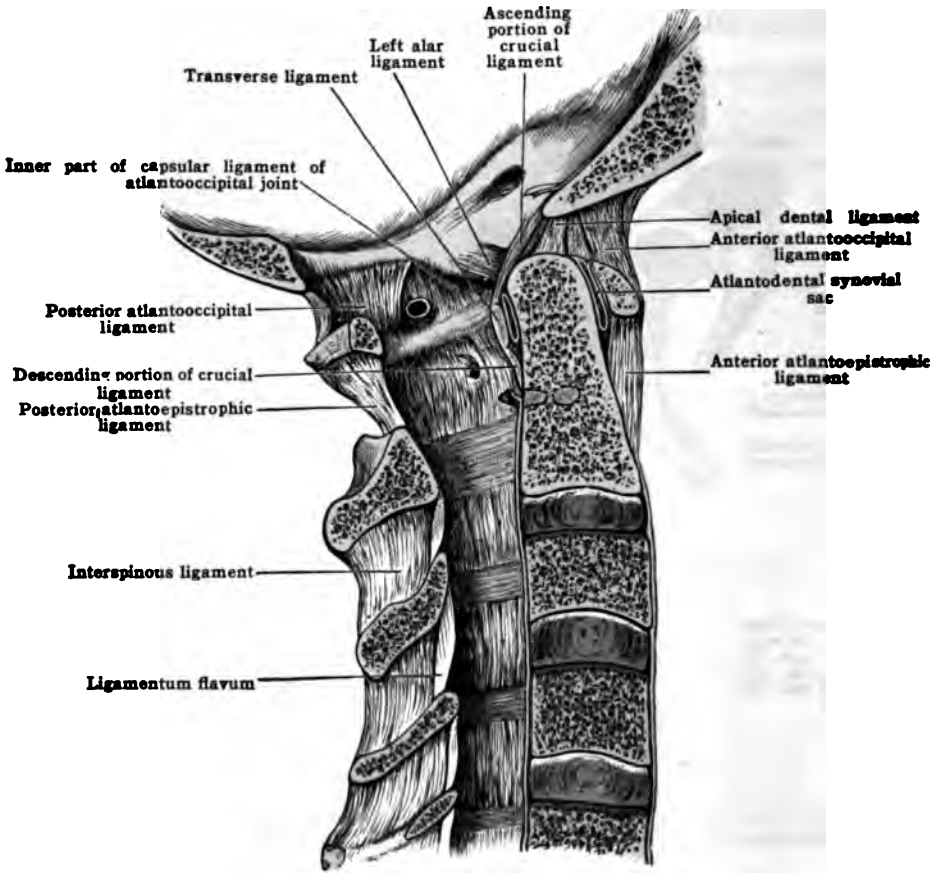
The central fibers ascend vertically from the anterior tubercle of the atlas to the pharyngeal tubercle on the occipital bone; they are thicker than the lateral fibers,and are continuous below with the superficial part of the anterior atlantoepistrophic ligament, and through it with the anterior longitudinal ligament of the vertebral column. It is in relation, in front, with the recti capitis anteriores; and behind, with the apical dental or suspensory ligament.

The **posterior atlanto-occipital ligament** (fig. 294) is broader, more membranous, and not so strong as the anterior. It extends from the posterior surface and upper border of the posterior arch of the atlas to the posterior margin of the foramen magnum from condyle to condyle; being incomplete on either side for the

passage of the vertebral artery into, and suboccipital nerve out of, the canal. It is somewhat thickened in the middle line by fibers, which pass from the posterior tubercle of the atlas to the lower end of the occipital crest.

It is not tightly stretched between the bones, nor does it limit their movements; it corresponds with the position of the ligamenta flava, but has no elastic tissue in its composition. It is in relation in front with the dura mater, which is firmly attached to it; and behind with the recti capitis posteriores minores and enters into the floor of the suboccipital triangle. Its lateral margins, which do not reach the occipital bone but terminate on the posterior end of the superior articular processes of the atlas, form the so-called *oblique ligaments of the atlas*. The lateral margins of these ligaments are free and they form the posterior boundaries of the apertures through which the vertebral arteries enter and the suboccipital nerves leave the vertebral canal.

FIG. 294.—MEDIAN SAGITTAL SECTION OF VERTEBRAL COLUMN SHOWING LIGAMENTS.



The **atlanto-occipital articular capsules** (figs. 293 and 294) are very distinct and strongly marked, except on the medial side, where they are thin and formed only of short membranous fibers. They are lax, and do not add much to the security of the joint.

In front, the capsule descends upon the atlas, to be attached, some distance below the articular margin, to the front surface of the lateral mass and to the base of the transverse process; these fibers take an oblique course upward and medialward, overlapping the anterior atlanto-occipital. At the sides and behind, the capsule is attached above to the margins of the occipital condyles; below, it skirts the medial edge of the foramen for the vertebral artery, and behind is attached to the prominent tubercle overhanging the groove for that vessel; these latter fibers are strengthened by a band running obliquely upward and medialward to the posterior margin of the foramen magnum.

The **anterior oblique** or **lateral occipito-atlantal ligament** is an accessory band which strengthens the capsule laterally (fig. 293). It is an oblique, thick band of fibers, sometimes quite separate and distinct from the rest, passing upward and medialward from the upper surface of the transverse process beyond the costo-transverse foramen to the jugular process of the occipital bone.

The **synovial membrane** of these joints occasionally communicates with the synovial sac between the dens (odontoid process) and the transverse ligament.

The **arterial** supply is derived from twigs of the vertebral, and occasionally from twigs from the meningeal branches of the ascending pharyngeal.

The **nerve-supply** comes from the anterior division of the suboccipital nerve.

Movements (Cf. p. 535).—By the symmetrical and bilateral arrangement of these joints, security and strength are gained at the expense of a very small amount of actual articular surface; the basis of support and the area of action being equal to the width between the most distant borders of the joint.

The principal movement permitted at these joints is of a ginglymoid character, producing flexion and extension upon a transverse axis drawn across the condyles at their slightly constricted parts. In flexion, the forehead and chin drop, and what is called the nodding movement is made; in extension, the chin is elevated and the forehead recedes.

There is also a slight amount of gliding movement, which may be directly lateral, the lateral edge of one condyle sinking a little within the lateral edge of the socket of the atlas, and that of the opposite condyle projecting to a corresponding degree. The head is thus tilted to one side, and it is even possible that the weight of the skull may be borne almost entirely on one joint, the articular surfaces of the other being thrown partly out of contact.

Or the movement may be obliquely lateral, when the lower side of the head will be a trifle in advance of the elevated side. In this motion, which takes place on the anteroposterior axis, one condyle advances slightly and approaches the middle line, while the other recedes. This is of the nature of rotation, though there is no true rotation round a vertical axis possible between the occiput and atlas.

These lateral movements are checked by the alar ligaments and the lateral part of the capsules; extension is checked by the anterior atlanto-occipital and anterior oblique ligaments, and flexion by the posterior part of the capsule and the tectorial membrane.

Muscles acting upon the occipitoatlantal joint (Cf. p. 535).—Flexion whereby the chin is approximated toward the sternum is produced by the weight of the anterior part of the head and by all muscles which are attached to the hyoid bone or to the bones of the skull in front of a transverse axis between the two condyles. These muscles take their fixed point below either from the vertebral column, the sternum, or the bones of the shoulder girdle. Before those connected with the mandible can act that bone must be fixed by the muscles of mastication which, therefore, also take part in the movements.

Extension is due to the action of muscles or portions of muscles inserted into the skull behind the transverse axis above mentioned, and connected below either with the vertebral column, shoulder girdle, or sternum. The sternomastoid muscles are chiefly extensors, although their most anterior portions may serve as flexors of the joint.

Lateral movement is produced by the anterior and posterior groups of muscles on the same side acting simultaneously and aided by the rectus capitis lateralis of that side.

(*b*) The Articulations between the Atlas and Epistropheus (Axis).

1. The Lateral Atlantoepistrophic Joints. { **Class.**—*Diarthrosis.* / **Subdivision.**—*Arthrodia.*
2. The Central Atlantoepistrophic Joint or The Atlantodental. { **Class.**—*Diarthrosis.* / **Subdivision.**—*Trochoides*

The bones that enter into the formation of the lateral joints are the inferior articular processes of the atlas and the superior of the epistropheus (axis); the central joint is formed by the dens (odontoid process) articulating in front with the atlas, and behind with the transverse ligament.

The ligaments which unite the epistropheus and atlas are:—

1. The anterior atlantoepistrophic.
2. The posterior atlantoepistrophic.
3. Two articular capsules (for lateral joints).
4. The transverse ligament.
5. The atlantodental articular capsule.

The **anterior atlantoepistrophic ligament** (figs. 293 and 294) is a narrow but strong membrane filling up the interval between the lateral joints. It is attached above to the front surface and lower border of the anterior arch of the atlas, and below to the transverse ridge on the front of the body of the epistropheus. Its fibers are vertical, and are thickened in the median line by a dense band which is a continuation upward of the anterior longitudinal ligament of the vertebral column.

This band is fixed above to the anterior tubercle of the atlas, where it becomes continuous with the central part of the anterior atlanto-occipital ligament (fig. 293); it is sometimes separated by an interval from the deeper ligament, and is often described as the superficial atlantoepistrophic ligament. It is in relation with the longus colli muscle.

The **posterior atlantoepistrophic ligament** (fig. 294) is a deeper, but thinner and looser membrane than the anterior. It extends from the posterior root of the

transverse process of one side to that of the other, projecting laterally beyond the posterior part of the capsules which are connected with it. It is attached above to the posterior surface and lower edge of the posterior arch of the atlas, and below to the superior edge of the laminæ of the epistropheus on their dorsal aspect.

It is denser and stronger in the median line, and has a layer of elastic tissue on its anterior surface like the ligamenta flava, to which it corresponds in position. It is connected in front with the dura mater; behind, it is in relation with the inferior oblique muscles, and is perforated at each side by the second cervical nerve.

1. The Lateral Atlantoepistrophic Joints are provided with short, ligamentous fibers, forming **articular capsules** (fig. 293), which completely surround the lateral articular facets. Lateral to the canal they are attached some little distance from the articular margins, extending along the roots of the transverse processes of the epistropheus nearly to the tips, but between the roots they skirt the medial edge of the costotransverse foramina. They are strengthened in front and behind by the atlantoepistrophic ligaments. There is a **synovial membrane** for each joint.

Medially each capsule is thinner, and attached close to the articular margins, being strengthened behind by a strong band of slightly oblique fibers passing upward along the lateral edge of the tectorial membrane from the body of the epistropheus to the lateral mass of the atlas behind the transverse ligament; some of these fibers pass on, thickening and blending with the atlantooccipital capsule, to be inserted into the margin of the foramen magnum. This band is sometimes called the **accessory band** (fig. 297).

Fig. 295.—Horizontal Section Through the Lateral Masses of the Atlas and the Top of the Dens (Odontoid Process).

2. The Central Atlantoepistrophic Joint, although usually described as one, is composed of two articulations, which are quite separate from each other: an anterior between the dens and the arch of the atlas, and a posterior between the dens and the transverse ligament.

The **transverse ligament** (figs. 294, 295, 297) is one of the most important structures in the body, for on its integrity and that of the **alar ligaments** our lives largely depend. It is a thick and very strong band, as dense and closely woven as fibrocartilage, about 6 mm. deep at the sides, and somewhat more in the midline. Attached at each end to a tubercle on the inner side of the lateral mass of the atlas, it crosses the ring of this bone in a curved manner, so as to have the concavity forward; thus dividing the ring into a smaller anterior portion for the dens and a larger posterior part for the spinal cord and its membranes, and the spinal accessory nerves.

It is flattened from before backward, [illegible] and covered by synovial membrane to allow it to glide [illegible]. Where it is attached to the atlas it is smooth and [illegible] communication between the transverse and [illegible]

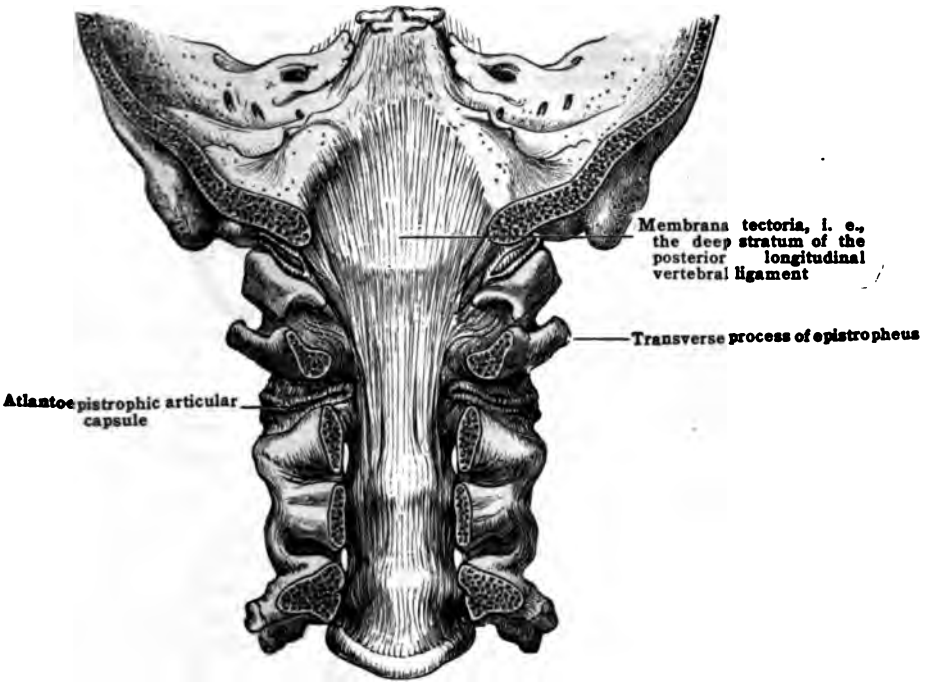
To its posterior surface is added in the middle a strong fasciculus of vertical fibers passing upward from the [illegible] to the basilar border of the foramen magnum, in its [illegible]. Some of these fibers are derived from the transverse ligament. These vertical fibers give the transverse ligament a cruciform appearance, and the whole the **crucial ligament** (figs. 294 and 297) applied to the whole.

The **atlantodental articular capsule** (fig. 295) is a tough, loose membrane, completely surrounding the apposed articular surfaces of the atlas and dens.

At the dens it blends above with the front of the alar and central occipitodental ligaments, and arises also along the sides of the articular facet as far as the neck of the dens; the fibers are thick, and blend with the capsules of the lateral joint. At the atlas they are attached to the nonarticular part of the anterior arch in front of the tubercles for the transverse ligament, blending, above and below the borders of the bone, with the anterior atlanto-occipital and atlantoepistrophic ligaments, as well as with the medial portion of the articular capsules. It holds the dens to the anterior arch of the atlas after all the other ligaments have been divided.

The **synovial membranes** (figs. 294, 295) are two in number:—one for the joint between the dens and atlas; and another (transversodental) for that between the transverse liagment and the dens. This last often communicates with the atlanto-occipital articulations; it is closed in by membranous tissue between the borders of the transverse ligament and the margin of the facet on the dens, and is separated from the front sac by the atlantodental articular capsule.

FIG. 296.—THE TECTORIAL MEMBRANE. DEEP STRATUM OF THE POSTERIOR LONGITUDINAL VERTEBRAL LIGAMENT. SUPERFICIAL LAYER REMOVED. POSTERIOR VIEW.



Membrana tectoria, i. e., the deep stratum of the posterior longitudinal vertebral ligament
Transverse process of epistropheus
Atlantoepistrophic articular capsule

The **arterial supply** is from the vertebral artery, and the **nerve-supply** from the loop between the first and second cervical nerves.

Movements (Cf. p. 536).—The chief and characteristic movement at these joints is the rotation, in a nearly horizontal plane, of the collar formed by the atlas and transverse ligament, round the dens as a pivot, which is extensive enough to allow of an all-round view without twisting the trunk. Partly on account of its ligamentous attachments, and partly on account of the shape of the articular surfaces, the cranium must be carried with the atlas in these movements. The rotation is checked by the ligaments passing from the dens to the occiput (alar ligaments), and also by the atlantoepistrophic. Owing to the fact that the facets of both atlas and epistropheus, which enter into the formation of the lateral atlantoepitrophic articulations, are convex from before backward, and have the articular cartilage thicker in the center than at the circumference, the motion is not quite horizontal but slightly curvilinear. In the erect position, with the face looking directly forward, the most convex portions of the articular surfaces are alone in contact, there being a considerable interval between the edges; during rotation, therefore, the prominent portions of the condyles of the atlas descend upon those of the epistropheus, diminishing the space between the bones, slackening the ligaments, and thus increasing the amount of rotation, without sacrificing the security of the joint in the central position.

Besides rotation, forward and backward movements and some lateral flexion are permitted between the atlas and epistropheus, even to a greater extent than in most of the other vertebral joints.

The muscles acting upon the atlantoepistrophic joints (Cf. p. 536).—The muscles capable of producing rotation at the atlantoepistrophic joints are those which take origin from near the mesial plane, either in front or behind and which are attached above either to the atlas or

the skull, lateral to the atlantoepistrophic joints. When the muscles which lie at the back of the joint on one side act they will turn the head to the same side and will be aided by the muscles in front on the opposite side. If the muscles in front and behind on the same side act simultaneously, they will pull down the head to that side and will be aided by muscles which pass more or less vertically from the transverse process of the atlas to points below.

(*c*) The Ligaments uniting the Occiput and Epistropheus

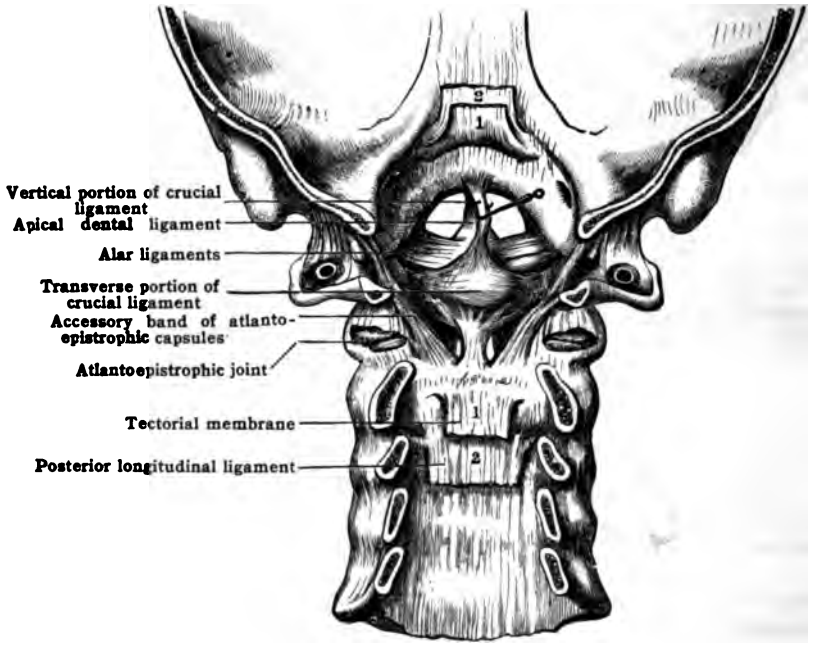
The following ligaments unite bones not in contact, and are to be seen from the interior of the canal after removing the posterior arches of the epistropheus and atlas and posterior ring of the foramen magnum:—

1. The tectorial membrane.
2. The crucial ligament.
3. Two alar (or check) ligaments.
4. The apical dental ligament.

The **tectorial membrane** (occipitocervical ligament) (figs. 295, 297) consists of a very strong band of fibers, connected below to the upper part of the body

Fig. 297.—Coronal Section of the Vertebral Column and the Occipital Bone to show Ligaments.

The tectorial membrane (1), though shown as a distinct stratum, is really the deeper part of the posterior longitudinal ligament (2). The upper ends have been reflected upward, the lower downward. Viewed from behind.)



of the third vertebra and lower part of the body of the epistropheus as far as the root of the dens. It is narrow below, but widens out as it ascends, to be fastened to the basilar groove of the occiput. Laterally, it is connected with the accessory fibers of the atlantoepistrophic capsule. It is really only the upward prolongation of the deep stratum of the posterior longitudinal ligament, the superficial fibers of which run on to the occipital bone without touching the the epistropheus, thus giving rise to two strata. It is in relation in front with the crucial ligament.

The **crucial ligament** has been already described (see p. 264).

The **alar** (or check) **ligaments** (figs. 294, 297) are two strong rounded cords, which extend from the sides of the apex of the dens, transversely lateralward to the medial edge of the anterior portion of the occipital condyles.

They are to be seen immediately above the upper border of the transverse ligament, which they cross obliquely owing to its forward curve at its attachments to the atlas. Some of their fibers occasionally run across the middle line from one alar ligament to the other. At the dens they are connected with the atlantodental capsule, and at the condyles they strengthen the atlanto-occipital articular capsule.

The **apical dental** (or suspensory) ligament (figs. 294, 297) consists of a slender band of fibers ascending from the summit of the dens to the lower surface of the occipital bone, close to the foramen magnum. It is best seen from the front after removing the anterior atlanto-occipital ligament, or from behind by drawing aside the crucial ligament.

The apical ligament is tightened by extension and relaxed by flexion or nodding; the alar ligaments not only limit the rotatory movements of the head and atlas upon the epistropheus, but by binding the occiput to the pivot, round which rotation occurs, they steady the head and prevent its undue lateral inclination upon the vertebral column. (See TRANSVERSE LIGAMENT, p. 264.)

By experiments, it has been proved that the head, when placed so that the orbits look a little upward, is poised upon the occipital condyles in a line drawn a little in front of their middle; the amount of elevation varies slightly in different cases, but the balance is always to be obtained in the human body—it is one of the characteristics of the human figure. It serves to maintain the head erect without undue muscular effort, or a strong ligamentum nuchæ and prominent dorsal spines such as are seen in the lower animals. Disturb this balance, and let the muscles cease to act, the head will either drop forward or backward according as the center of gravity is in front or behind the balance line. The ligaments which pass over the dens to the occiput are not quite tight when the head is erect, and only become so when the head is flexed; if this were not so, no flexion would be allowed; thus, muscular action, and not ligamentous tension, is employed to steady the head in the erect position. It is through the combination of the joints of the atlas and epistropheus, and occiput and epistropheus (consisting of two pairs of joints placed symmetrically on either side of the median line, while through the median line there passes a pivot, also with a pair of joints), that the head enjoys such freedom and celerity of action, remarkable strength, and almost absolute security against violence, which could only be obtained by a ball-and-socket joint; but the ordinary ball-and-socket joints are too prone to dislocations by even moderate twists to be reliable enough when the life of the individual depends on the perfection of the articulation: hence the importance of this combination of joints.

THE ARTICULATIONS OF THE TRUNK

These may be divided into the following sets:—

1. Those of the vertebral column. Joints and ligaments connecting:
   - (*a*) The bodies.
   - (*b*) The articular processes.
   - (*c*) The laminæ.
   - (*d*) The spinous processes.
   - (*e*) The transverse processes.
2. Vertebral column with the pelvis.
3. Pelvis.
   - (*a*) Sacroiliac
   - (*b*) Sacrococcygeal.
   - (*c*) Intercoccygeal.
   - (*d*) Symphysis pubis.
4. Ribs with the vertebral column.
5. The articulations at the front of the thorax.
   - (*a*) Costal cartilages with the sternum.
   - (*b*) Costal cartilages with the ribs.
   - (*c*) Sternal.
   - (*d*) Certain costal cartilages with each other.

1. THE ARTICULATIONS OF THE VERTEBRAL COLUMN

There are two distinct sets of articulations in the vertebral column:—

- (*a*) Those between the bodies and intervertebral disks which form synchondroses and which are amphiarthrodial as regards movement.
- (*b*) Those between the articular processes which form arthroidal joints.

The ligaments which unite the various parts may also be divided into two sets, viz.—**immediate,** or those that bind together parts which are in contact; and **intermediate,** or those that bind together parts which are not in contact.

Immediate.

- (*a*) Those between the bodies and disks.
- (*b*) Those between the articular processes.

Intermediate.

- (*c*) Those between the laminæ.
- (*d*) Those between the spinous processes.
- (*e*) Those between the transverse processes.

(*a*) The Articulations of the Bodies of the Vertebræ

Class.—*False Synchondrosis.*

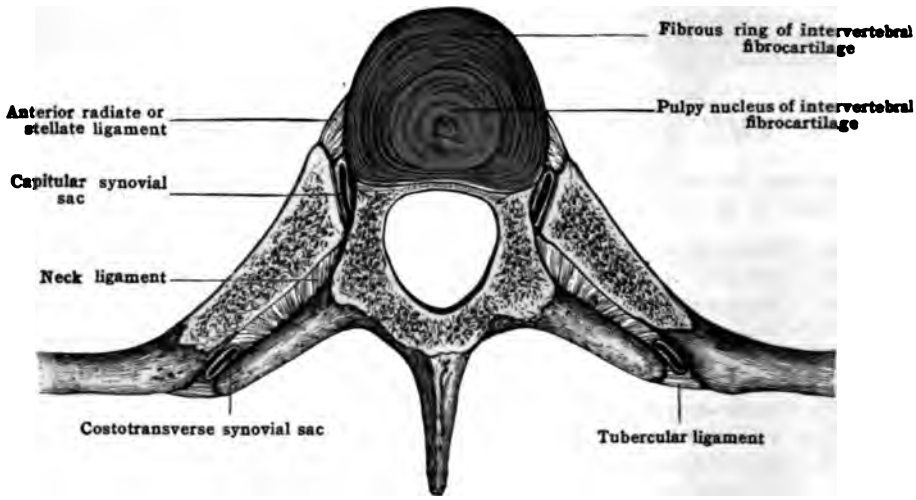
The ligaments which unite the bodies of the vertebræ are:—

Intervertebral fibrocartilages.	Anterior longitudinal.
Short lateral ligaments.	Posterior longitudinal.

The **intervertebral fibrocartilages** (figs. 294, 298) are tough, but elastic and compressible disks of composite structure, which serve as the chief bond of union between the vertebræ. They are twenty-three in number, and are interposed between the bodies of all the vertebræ from the epistropheus to the sacrum (figs. 294 and 304). Similar disks are found between the segments of the sacrum and coccyx in the younger stages of life, but they undergo ossification at their surfaces and often throughout their whole extent.

Each disk is composed of two portions—a circumferential laminar, and a central pulpy portion; the former tightly surrounds and braces in the latter, and forms somewhat more than half the disk. The **fibrous ring** [annulus fibrosus] or laminar portion consists of layers of fibrous tissue and fibrocartilage; the component fibers of these layers are firmly connected with two vertebræ, those of one passing obliquely down and to the right, those of the next down and to the left, making an X-shaped arrangement of the alternate layers. A few of the superficial

Fig. 298.—Horizontal Section Through an Intervertebral Fibrocartilage.



lamellæ project beyond the edges of the bodies, their fibers being connected with the edges of the anterior and lateral surfaces; and some do not completely surround the rest, but terminate at the intervertebral foramina, so that on horizontal section the circumferential portion is seen to be thinner posteriorly. The more central lamellæ are incomplete, less firm, and not so distinct as the rest; and as they near the pulp they gradually assume its characters, becoming more fibrocartilaginous and less fibrous, and have cartilage cells in their structure.

The **pulpy nucleus** [nucleus pulposus] or central portion is situated somewhat behind the center of the disk, forming a ball of very elastic and tightly compressed material, which bulges freely when the confining pressure of the laminar portion is removed by either horizontal or vertical section. Thus, it has a constant tendency to spring out of its confinement in the direction of least resistance, and constitutes a pivot round which the bodies of the vertebræ can twist, tilt, or incline. It is yellowish in color, and is composed of fine white and elastic fibers amidst which are ordinary connective-tissue cells, and peculiar cells of various sizes which contain one or more nuclei. Together with the most central laminæ, it is separated from immediate contact with the bone by a thin plate of articular cartilage. The central pulp of the intervertebral substance is the persistent part of the notochord.

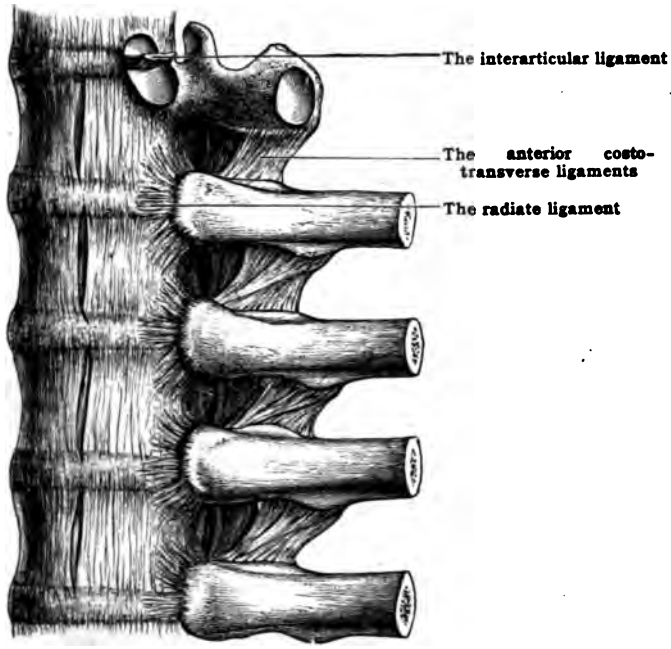
The intervertebral substances vary in shape with the bodies of the vertebræ they unite, and are widest and thickest in the lumbar region. In the cervical and lumbar regions they are thicker in front than behind, thus causing the convexity forward of the cervical, and increasing that of the lumbar region. The curve in the thoracic region, almost entirely due to the shape of the bodies, is, however, somewhat increased by the disks. Without the disks the column loses, a quarter of its length, and assumes a curve with the concavity forward, most marked a little below the midthoracic region. Such is the curve of old age, which is due to the shrinking and drying up of the intervertebral substances. The disk between the epistropheus and third cervical is the thinnest of all (fig. 294); that between the fifth lumbar and sacrum is the thickest, and is much thicker in front than behind (fig. 304). The intervertebral disks are in relation, in

front with the anterior longitudinal ligament; behind, with the posterior longitudinal ligament; laterally, with the short lateral; and in the thoracic region, with the interarticular and radiate ligaments.

In the cervical region lateral diarthrodial joints are placed one on each side of the intervertebral disks. They are of small extent and are confined to the intervals between the prominent lateral lips of the upper surface of the body below and the bevelled lateral edges of the lower surface of the body above.

The **anterior longitudinal ligament** (figs. 293, 299) commences as a narrow band attached to the inferior surface of the occipital bone in the median line, just in front of the atlanto-occipital ligament, of which it forms the thickened central portion. Attached firmly to the tubercle of the atlas, it passes down as the central portion of the atlantoepistrophic ligament, in the midline, to the front of the body of the epistropheus. It now begins to widen out as it descends, until it is nearly 5 cm. wide in the lumbar region. Below, it is fixed to the upper segment of the sacrum, becoming lost in periosteum about the middle of that bone; but is again distinguishable in front of the sacrococcygeal joint, as the anterior sacrococcygeal ligament.

FIG. 299.—THE ANTERIOR LONGITUDINAL LIGAMENT, THE RADIATE, THE INTERARTICULAR, AND THE ANTERIOR COSTOTRANSVERSE LIGAMENTS.



Its structure is bright, pearly-white, and glistening. Its lateral borders are separated from the lateral bands by clefts through which blood-vessels pass; they are frequently indistinct and are best marked in the thoracic region. It is thickest in the thoracic region, and thicker in the lumbar than the cervical. It is firmly connected with the bodies of the vertebræ, and is composed of longitudinal fibers, of which the superficial extend over several, while the deeper pass over only two or three vertebræ. It is connected with the tendinous expansion of the prevertebral muscles in the cervical, and the crura of the diaphragm are closely attached to it in the lumbar region.

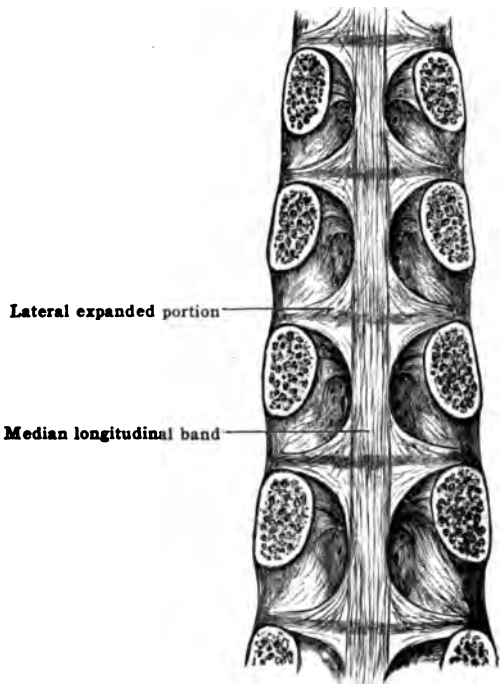
The **posterior longitudinal ligament** (figs. 297, 300, 307) extends from the occipital bone to the coccyx. It is wider above than below, and commences by a broad attachment to the cranial surface of the basioccipital. In the cervical region it is of nearly uniform width, and extends completely across the bodies of the vertebræ, upon which it rests quite flat. It does, however, extend slightly further laterally on each side opposite the intervertebral disks. In the thoracic and lumbar regions it is distinctly dentated, being broader over the intervertebral substances and the edges of the bones than over the middle of the bodies, where it is a narrow band stretched over the bones without resting on them, the anterior internal vertebral venous plexus being interposed. The narrow median portion consists of longitudinal fibers, some of which are super-

ficial and pass over several vertebræ; and others are deeper, and extend only from one vertebra to the next but one below.

The dentated or broader portions (fig. 307) are formed by oblique fibers which, springing from the bodies near the intervertebral foramina, take a curved course downward and backward over an intervertebral fibrocartilage, and reach the narrow portion of the ligament on the center of the vertebra next below; they then diverge to pass over another intervertebral disk to end on the body of the vertebra beyond, near the intervertebral notch. They thus pass over two disks and three vertebræ. Deeper still are other fibers thickening these expansions of the longitudinal ligament, and extending from one bone to the next.

The last well-marked expansion is situated between the first two segments of the sacrum: below this, the ligament becomes a delicate central band with rudimentary expansions, being more pronounced again over the sacrococcygeal joint, and losing itself in the ligamentous tissue at the back of the coccyx. The dura mater is tightly attached to it at the margin of the foramen magnum and behind the bodies of the upper cervical vertebræ, but is separated from it in the rest of its extent by loose cellular tissue which becomes condensed in the sacral region to form the sacrodural ligament. The filum terminale becomes blended with it at the lower part of the sacrum and back of the coccyx.

FIG. 300.—POSTERIOR LONGITUDINAL LIGAMENT. (Thoracic region.)
(Pedicles cut through, and posterior arches of vertebræ removed.)



The **lateral** (or short) **vertebral ligaments** (fig. 299) consist of numerous short fibers situated between the anterior and posterior longitudinal ligaments, and passing from one vertebra over the intervertebral disk, to which it is firmly adherent, to the next vertebra below.

The more superficial fibers are more or less vertical, but the deeper decussate and have a crucial arrangement. They are connected with the deep surface of the anterior longitudinal ligament, and so tie it to the edges of the bodies of the vertebræ and to the intervertebral disks. They blend behind with the expansions of the posterior longitudinal ligament, and so complete the casing round each amphiarthrodial joint. In the thoracic region, they overlie the radiate ligament, and in the lumbar they radiate toward the transverse processes. In the cervical region they are less well marked.

(*b*) THE LIGAMENTS CONNECTING THE ARTICULAR PROCESSES

Class.—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

The **articular capsules** (fig. 293) which unite these processes are composed partly of yellow elastic tissue and partly of white fibrous tissue. In the cervical

region only the medial side of the capsule is formed by the ligamenta flava, which in the thoracic and lumbar regions, however, extend anteriorly to the margins of the intervertebral foramina.

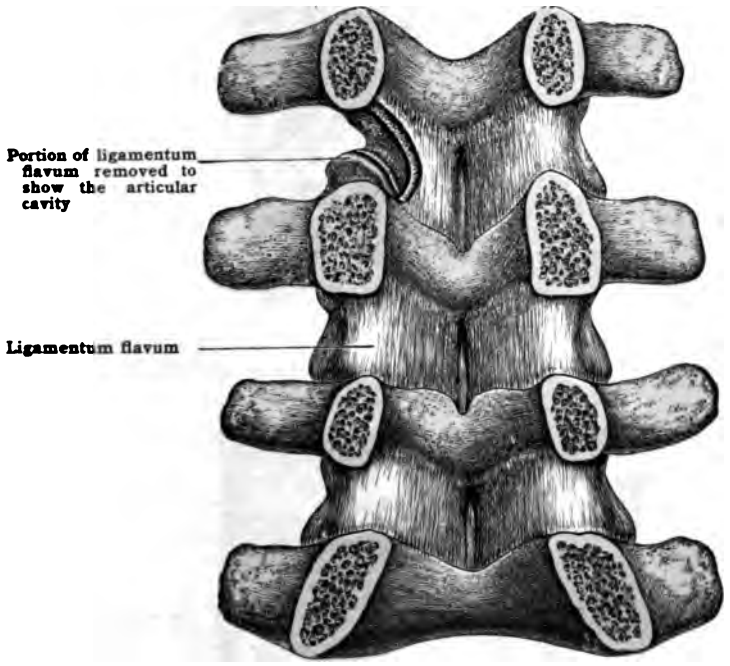
The part formed of white fibrous tissue consists of short, well-marked fibers, which in the cervical region pass obliquely downward and forward over the joint, between the articular processes and the posterior roots of the transverse processes of two contiguous vertebræ. In the thoracic region the fibers are shorter, and vertical in direction, and are attached to the bases of the transverse processes; in the lumbar, they are obliquely transverse. The articular capsules in the cervical region are the most lax, those in the lumbar region are rather tighter and those in the thoracic region are the tightest.

There is one **synovial membrane** to each capsule.

(*c*) The Ligaments uniting the Laminæ

The **ligamenta flava** (fig. 301) are thick plates of closely woven yellow elastic tissue, interposed between the laminæ of two adjacent vertebræ. The first connects the epistropheus with the third cervical, and the last the fifth lumbar with the sacrum. Each ligament extends from the medial and posterior edge of the

Fig. 301.—Ligamenta Flava in the Lumbar Region seen from within the vertebral Canal.



intervertebral foramen on one side to a corresponding point on the other; above, it is attached close to the inner margin of the inferior articular process and to a well-marked ridge on the inner surface of the lamina as far as the root of the spine; below, it is fixed close to the inner margin of the superior articular process and to the dorsal aspect of the upper edge of the lamina.

Thus each ligamentum flavum, besides filling up the interlaminar space, enters into the formation of two articular capsules; they do so to a greater extent in the thoracic and lumbar regions than in the cervical, where the articular processes are placed wider apart. When seen from the front after removing the bodies of the vertebræ, they are concave from side to side, but convex from above downward; they make a more decided transverse curve than the arches between which they are placed. This concavity is more marked in the thoracic, and still more in the lumbar region than in the cervical; in the lumbar region the ligamenta flava extend a short distance between the roots of the spinous process, blending with the interspinous ligament, and making a median sulcus when seen from the front; there is, however, no separation between the two parts. In the cervical region, where the spines are bifid, there is a median fissure in the yellow tissue which is filled up by fibroareolar tissue. The ligaments are thickest and strongest in the lumbar region; narrow but strong in the thoracic; thinner, broader, and more membranous in the cervical region.

(*d*) The Ligaments connecting the Spinous Processes

These include the supraspinous ligament, interspinous ligaments, and the li
mentum nuchæ.

Fig. 302.—Side View of Ligamentum Nuchæ.

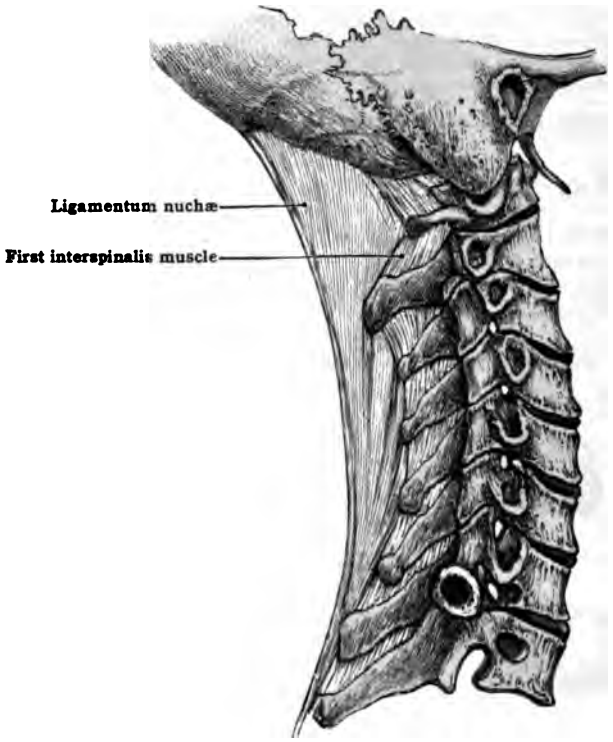


Fig. 303.—The Interspinous and Supraspinous Ligaments in the Lumbar Re

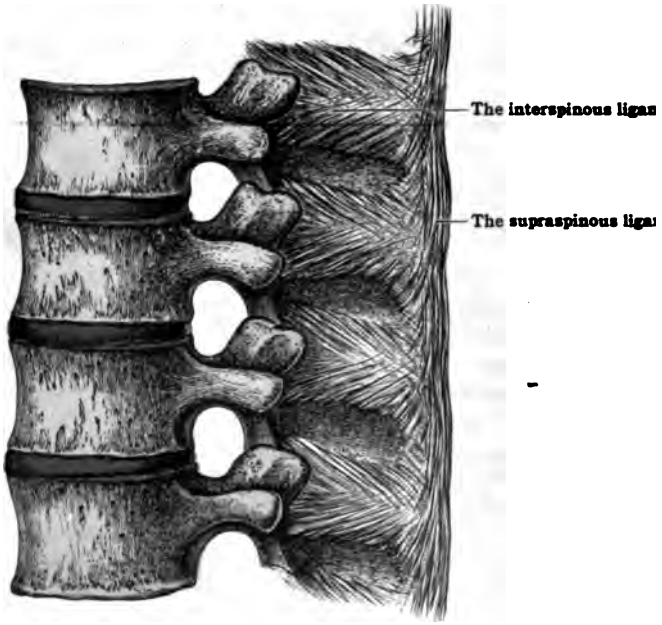

The **supraspinous ligament** (fig. 303) extends without interruption
well-marked band of longitudinal fibers along the tips of the spines of the vert
from that of the seventh cervical downward till it ends on the median sacral c

Its more superficial fibers are much longer than the deep. The deeper fibers pass over adjacent spines only, while the superficial overlie several. It is connected laterally with the aponeurotic structures of the back; indeed, in the lumbar region, where it is well marked, it appears to result from the interweaving of the tendinous fibers of the several muscles which are attached to the tips of the spinous processes. In the dorsal region it is a round slender cord which is put on the stretch in flexion and relaxed in extension of the back.

The **ligamentum nuchæ**, or the posterior cervical ligament (fig. 302), is the continuation in the neck of the supraspinous ligament, from which, however, it differs considerably. It is a slender vertical septum of an elongated triangular form, extending from the seventh cervical vertebra to the external protuberance and the crest of the occipital bone. Its anterior border is firmly attached to the tips of the spines of all the cervical vertebræ, including the posterior tubercle of the atlas, as well as to the occiput. Its posterior border gives origin to the trapezii, with the tendinous fibers of which muscle it blends. Its lateral, triangular surfaces afford numerous points of attachment for the posterior muscles of the head and neck.

In man it is rudimentary, and consists of elastic and white fibrous tissues. As seen in the horse, elephant, ox, and other pronograde mammals, it is a great and important elastic ligament, which even reaches along the thoracic part of the spinal column. In these animals it serves to support the head and neck, which otherwise from their own weight would hang down. Its rudimentary state in man is probably correlated with his erect position.

The **interspinous ligaments** (fig. 303) are thin membranous structures which extend between the spines, and are connected with the ligamenta flava in front, and the supraspinous ligament behind.

The fibers pass obliquely from the root of one spine to the tip of the next; they thus decussate. They are best marked in the lumbar region, and are replaced by the well-developed interspinales muscles in the cervical region.

(*e*) The Ligaments connecting the Transverse Processes

The **intertransverse ligaments** are but poorly developed.

In the thoracic region they form small rounded bundles, and in the lumbar they are flat membranous bands, unimportant as bonds of union. They consist of fibers passing between the apices of the transverse processes. In the cervical region they are replaced by the intertransversarii muscles.

Vessels, Nerves and Movements

The **arterial supply** for the articulations of the vertebral column comes from twigs of the vertebral, ascending pharyngeal, ascending cervical, superior and aortic intercostals, lumbar, iliolumbar, and lateral sacral.

The **nerve-supply** comes from the spinal nerves of each region.

Movements (Cf. p. 536).—The vertebral column is so formed of a number of bones and intervertebral disks as to serve many purposes. It is the axis of the skeleton; upon it the skull is supported; and with it the walls and viscera of the trunk and the limbs are connected. As a fixed column it is capable of bearing great weight, and, through the elastic intervertebral substances, of resisting and breaking the transmission of shocks. Moreover, it is flexible. While the movements between any two vertebræ are slight, the range of movements for the column as a whole is very considerable.

The amount of motion is everywhere limited by the common vertebral ligaments, but depends partly upon the width of the bodies of the vertebræ, and partly upon the depth of the disks, so that in the loins, where the bodies are large and wide, and the disks very thick, free motion is permitted; in the cervical region, though the disks are thinner, yet, as the bodies are smaller, almost equally free motion is allowed. The influence of the articular processes in limiting the direction of inclination will appear from a study of the movements in the three regions of the spine. Were it not for these processes, the column, instead of being steady, endowed with the capacity of movement by muscular agency, would be tottering, requiring muscles to steady it.

In the **neck** all movements are permitted and are free, except between the second and third cervical vertebræ, where they are slight, owing to the shallow intervertebral disk and the great prolongation of the anterior lip of the inferior surface of the body of the epistropheus, which checks forward flexion considerably. On the whole, however, extension and lateral inclination are more free than in any other region of the column, whilst flexion is more limited than in the lumbar region. Rotatory movements are also free, but take place, on account of the position and inclination of the articular facets, not, as in the thoracic region, round a vertical axis, but round an oblique axis, the articular process of one side gliding upward and forward and that of the opposite side downward and backward.

In the **thoracic region**, especially near its middle, anteroposterior flexion and extension are very slight; and, as the concavity of the curve here is forward, the flat and nearly vertical surfaces of the articular processes prevent anything like sliding in a curvilinear manner of the

ocesses over the sharp upper edges of the other, whi
on. A fair amount of lateral inclination would be per
by the ribs; while the position and direction of the artic
vertical axis which passes through the centers of the bod
t very great, and is freer in the upper than in the lower p
nbar region, extension and flexion are very free, especial
ourth and fifth vertebræ, where the lumbar curve is sha
ee between these same vertebræ. It has been stated tha
ar processes of the lumbar and the lower two or three dors
in these regions; but, owing to the fact that the inferior ar
ced by the superior, so that the two sets of articular proc
of the bodies at the same time, there is always some spa
ccur round an axis drawn through the central part of the
t it is very slight. Thus, the motions are most free in thos
convex curve forward, due to the shape of the intervertel
walls surrounding solid viscera, where the spinal canal is la
y attached, and where the pedicles and articular processes
rel with the posterior surface of the bodies of the vertebræ.

2. THE SACROVERTEBRAL ARTICULATIONS

(*a*) **Class.**—*False Synchondrosis.*

(*b*) **Class.**—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

ie intervertebral articulations, so in the union of the first portio
ih the last lumbar vertebra, there are two sets of joints—viz.
osis, between the bodies and intervertebral disk; and (*b*) a p
joints, between the articular processes. The union is effected l
igaments, which are common to the vertebral column:—(1) ant
osterior longitudinal; (3) lateral or short vertebral; (4) capsular
flava; (6) supraspinous and (7) interspinous ligaments. Two sp
ligaments on either side, viz., the sacrolumbar and the iliolum
e pelvis with the fourth and fifth lumbar vertebræ.
crolumbar ligament (fig. 304) is strong, and triangular in shape.
ove and medial, being attached to the whole of the lower border a
ce of the transverse process of the fifth lumbar vertebra, as well as
and body. It is intimately blended with the iliolumbar ligamen
as a wide, fan-shaped attachment, extending from the edge of the ili
ament forward to the brim of the minor (true) pelvis; blending with th
on the base of the sacrum and in the iliac fossa, and with the superio
igament.

arp medial border it limits laterally the foramen for the last lumbar nerve. It
wo large foramina, which transmit arteries to the sacroiliac synchondrosis. Thi
n series with the intertransverse ligaments of the spinal column. It is sometime
a part of the iliolumbar ligament.

disk here than elsewhere, the movements permitted at this joint are very free, being freer than those between any two lumbar vertebræ. As the diameter of the two contiguous bones is less in the sagittal than in the frontal plane, the forward and backward motions are much freer than those from side to side. The backward and forward motions take place every time the sitting is exchanged for the standing position, and the standing for the sitting posture; in rising, the back is extended on the sacrum at the sacrolumbar union; in sitting down it is flexed.

The articular processes provide for the gliding movement incidental to the extension, flexion, and lateral movements; they also allow some horizontal movement, necessary for the rotation of the vertebral column on the pelvis, or pelvis on the column. The inferior articular processes of the fifth differ considerably from the inferior processes in the rest of the lumbar vertebræ, and in direction they resemble somewhat those of the cervical vertebræ; while the superior articular processes of the sacrum differ in a similar degree from the superior processes of the lumbar vertebræ. This difference allows for the freer rotation which occurs at this joint.

The sacrovertebral angle averages 117° in the male, and 130° in the female; while the pelvic inclination averages 155° in the male, and 150° in the female.

As already stated, the movements at the sacrovertebral joint are the same as those in other parts of the spinal column, but more extensive, and the muscles which produce the movements are those mentioned in the preceding groups which cross the plane of the articulation.

3. THE ARTICULATIONS OF THE PELVIS

This group may again be subdivided into—

(*a*) The **sacroiliac articulation** and **sacrosciatic ligaments.**
(*b*) The **sacrococcygeal.**
(*c*) The **intercoccygeal.**
(*d*) The **symphysis pubis** and **obturator membrane.**

(*a*) The Sacroiliac Articulation and Sacrosciatic Ligaments

Class.—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

It is now generally admitted that the sacroiliac joint is a diarthrosis, the articular surface of each bone being covered with a layer of cartilage, whilst the cavity of the joint is a narrow cleft and the capsule is extremely thick posteriorly. The cartilage on the sacrum is much thicker than that on the ilium and the cartilages are sometimes bound together here and there by fibrous strands. The different character of the joint in the two sexes should be noted. Briefly, the female joint has strong ligamentous bonds with but little bony apposition, while the male joint gains its strength by virtue of extensive areas of bony contact and a slighter development of ligaments. This difference is, of course, a physiological one; for some laxity of the joint is demanded during pregnancy and labour. The bones which enter the joint are the sacrum and ilium, and they are bound together by the following ligaments:—

Anterior sacroiliac.
Posterior sacroiliac.
Interosseous.

The **anterior sacroiliac ligament** (figs. 304, 305) consists of well-marked glistening fibers which unite the ala and the first three bones of the sacrum to the ilium, blending with the periosteum of the sacrum and ilium as it passes away from the united edges of the bones.

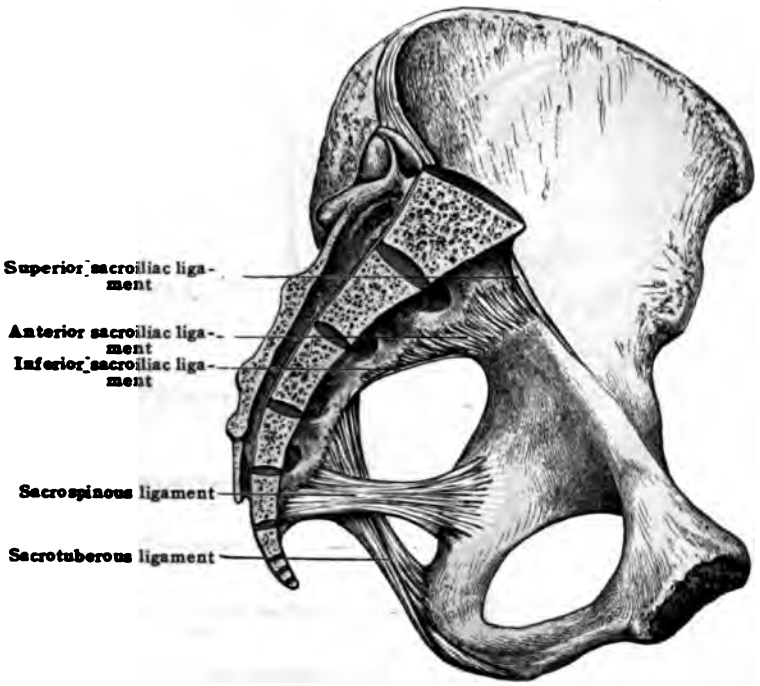
The upper anterior portion of the sacroiliac ligament, extending from the ala to the iliac fossa, is sometimes called the *superior sacroiliac ligament.* A band of fibers from the lateral part of the ala and adjacent ilium to the transverse process of the fifth lumbar vertebra forms the *sacrolumbar ligament* (fig. 304). The lowermost fibers of the anterior sacroiliac ligament, adjacent to the great sciatic notch, are sometimes termed the *inferior sacroiliac ligament* (fig. 305).

The **posterior sacroiliac ligament** (fig. 306) is extremely strong and consists essentially of two sets of fibers, deep and superficial, forming the short and long *posterior sacroiliac ligament* respectively. The *short posterior sacroiliac ligament* [lig. sacroiliacum posterius breve] passes downward and medialward from the rough area of the ilium behind the auricular surface to the back of the lateral mass of the sacrum, and to the upper sacral articular process, and the area between it and the first sacral foramen. The *long posterior sacroiliac ligament* [lig. sacroiliacum posterius longum] passes downward from the posterior superior iliac spine to the second third, and fourth tubercles on the back of the sacrum, and is continuous below with the sacrotuberous ligament.

The **interosseous ligament** is the strongest of all, and consists of fibers of different lengths passing in various directions between the two bones. It extends from the rough surface of the iliac tuberosity to the corresponding surface on the lateral aspect of the sacrum above and behind the auricular surface. Immediately above the interspinous notch of the ilium the fibers of this ligament are very strong, and form an open network, in the interstices of which is a quantity of fat in which the articular vessels ramify.

The ear-shaped **cartilaginous plate,** which unites the bones firmly, is accurately applied to the auricular surfaces of the sacrum and ilium. It is about 2 mm. thick in the center, but becomes thinner toward the edges. Though closely adherent to the bones, it tears away from one entirely, or from both partially, on the application of violence, sometimes breaking irregularly so that the greater portion remains connected with one bone, leaving the other bone rough and bare. It consists of two layers of fibrocartilage, separated by a more or less extensive imperfect synovial cavity. Testut mentions certain folds of synovial membrane filling up gaps which here and there occur at the margin of the fibrocartilage but they are not usually seen.

FIG. 305.—MEDIAN SAGITTAL SECTION OF THE PELVIS, SHOWING LIGAMENTS.



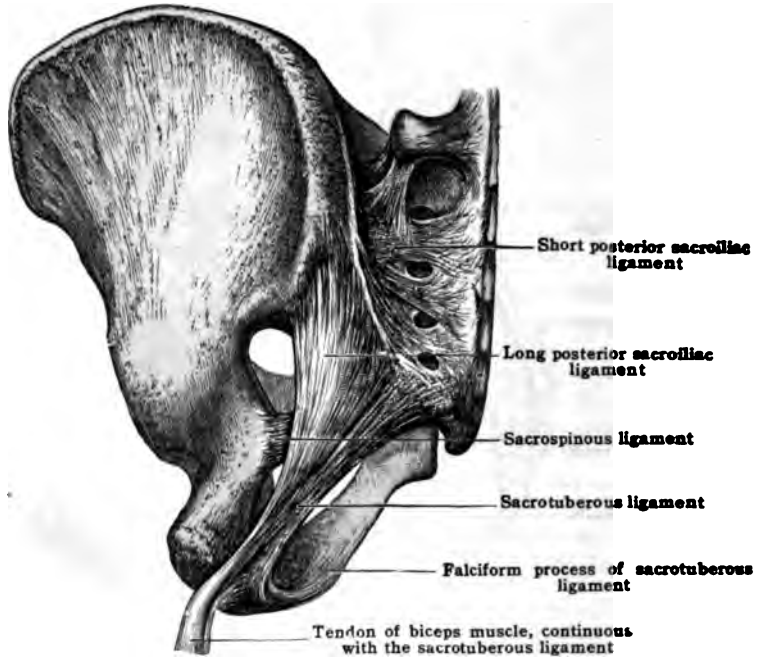
The **sacrotuberous** (great sciatic) **ligament** (figs. 304–306) is attached above to the posterior extremity of the crest of the ilium and the lateral aspect of the posterior iliac spines, in common with the long posterior sacroiliac ligament. From this attachment some of its fibers pass downward and backward to be attached to the lateral borders and posterior surfaces of the lower three sacral vertebræ and upper two segments of the coccyx; while others, after passing for a certain distance backward, curve forward and downward to the ischium, forming the anterior free margin of the ligament where it limits posteriorly the sciatic foramina. These fibers are joined by others which arise from the posterior surfaces of the lower three sacral vertebræ and upper pieces of the coccyx. At the ischium it is fixed to the medial border of the tuberosity, and sends a thin sharp process upward along the ramus of the ischium which is called the **falciform process** (fig. 306), and is a prolongation of the posterior edge of the ligament.

A great many fibers pass on directly into the tendon of the biceps muscle, so that traction on this muscle braces up the whole ligament, and the coccyx is thus made to move on the sacrum. The ligament may not unfairly be described as a tendinous expansion of the muscle, whereby its action is extended and a more advantageous leverage given. It is broad and flat at its attached ends, but narrower and thicker in the center, looking like two triangular expansions joined by a flat band, the larger triangle being at the ilium, and the smaller at the ischium. The fibers of the ligament are twisted upon its axis at the narrow part, so that some of the superior fibers pass to the lower border.

The posterior surface gives origin to the gluteus maximus muscle, and on it ramify the loops from the posterior branches of the sacral nerves; its anterior surface is closely connected at its origin with the sacrospinous ligament, and some fibers of the piriformis muscle arise from it; below, the obturator internus passes out of the pelvis under its cover, and the internal pudic vessels and nerve pass into the perineum. At the ilium, its posterior edge is continuous with the vertebral aponeurosis; while to the anterior edge is attached the thick fascia covering the gluteus medius. The obturator fascia is attached to its falciform edge. It is pierced by the coccygeal branches of the inferior gluteal (sciatic) artery and the inferior clunial (perforating cutaneous) nerve from the second and third sacral.

The **sacrospinous** (small sciatic) **ligament** (figs. 304–306) is triangular and thin, springing by a broad base from the lateral border of the sacrum and coccyx, from the front of the sacrum both above and below the level of the fourth sacral foramen, and from the coccyx nearly as far as its tip. By its apex it is attached to the front surface and the borders of the ischial spine as far outward as its base. Its fibers decussate so that the lower ones at the coccyx become the highest at the ischial spine; muscular fibers are often seen intermingled with the ligamentous.

FIG. 306.—POSTERIOR SACROILIAC, SACROTUBEROUS AND SACROSPINOUS LIGAMENTS.



Short posterior sacroiliac ligament
Long posterior sacroiliac ligament
Sacrospinous ligament
Sacrotuberous ligament
Falciform process of sacrotuberous ligament
Tendon of biceps muscle, continuous with the sacrotuberous ligament

The sacrospinous ligament is situated in front of the sacrotuberous ligament, with which it is closely connected at the sacrum, and separates the greater from the lesser sciatic foramen [foramen ischiadicum majus; foramen ischiadicum minus]. These are subdivisions of a large space intervening between the sacrotuberous ligament and the hip-bone. The piriformis muscle passes out of the pelvis into the thigh by way of the greater sciatic foramen, and is accompanied by the gluteal and sciatic vessels and nerves. The internal pudendal vessels and nerve and the nerve to the obturator internus muscle also leave the pelvis by this foramen to enter the perineal region through the lesser sciatic opening, by which also the obturator internus muscle passes from the pelvis to its insertion on the femur.

Anteriorly, the sacrospinous ligament gives attachment to the coccygeus muscle, which overlies it. Behind, it is connected with, and hidden by, the sacrotuberous ligament, so that only the lateral inch or less (2 cm.) and a small part of its attachment to the coccyx can be seen; the internal pudic nerve also passes over the posterior surface.

The **arterial supply** of the sacroiliac joint comes from the superior gluteal, iliolumbar, and lateral sacral.

The **nerve supply** is from the superior gluteal, sacral plexus, and external twigs of the posterior divisions of the first and second sacral nerves.

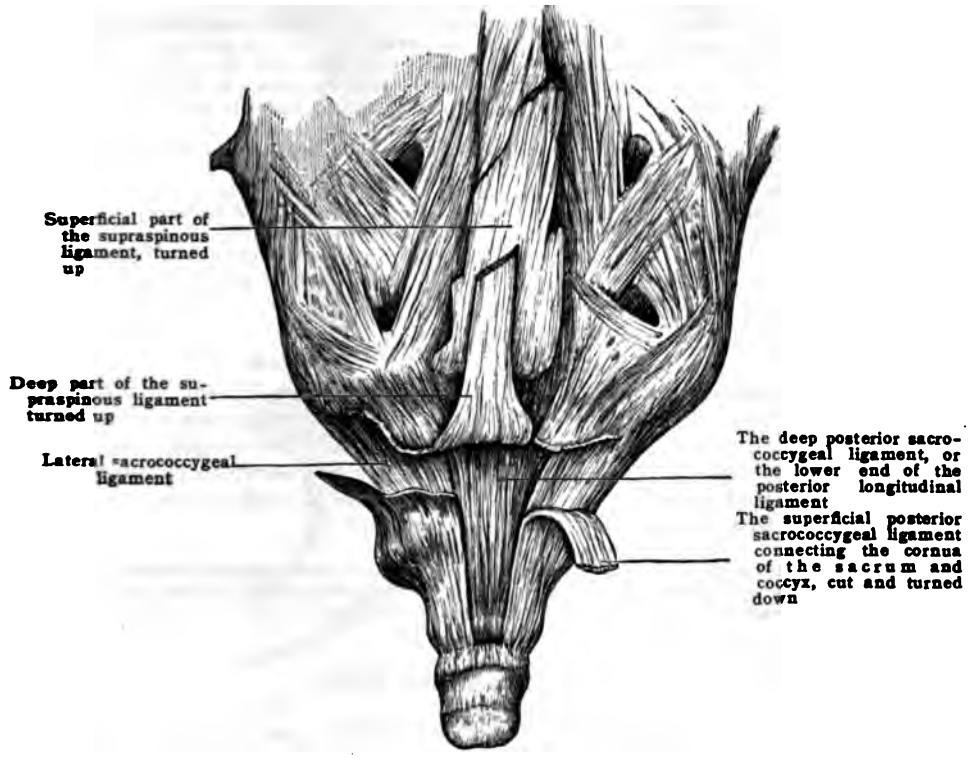
Movements.—Investigations have shown that in spite of the interlocking of the articular surfaces and the strong ligaments connecting the bones together a slight amount of movement, both a gliding and rotatory, does occur at the sacroiliac joint. The gliding movement is both up and down, and forward and backward, and the latter is associated with a slight rotation round a transverse axis which passes through the upper tubercles on the back of the sacrum. The movement is but small in extent, nevertheless as the base of the sacrum moves downward and forward the conjugate (anteroposterior) diameter of the pelvic inlet is diminished and at

the same time, as the coccyx moves up and back, the conjugate diameter of the outlet is increased. This rotatory movement is limited principally by the sacrosciatic (sacrotuberous and sacrospinous) ligaments which prevent any extensive upward and backward movement of the coccyx and lower part of the sacrum.

Downward displacement of the sacrum when the body is in the sitting posture is prevented not only by the surrounding ligaments, but also by the wedge-like character of the sacrum, which is broader above than below. Downward and forward displacement of the sacrum in the erect posture is prevented by the ligaments and more particularly by the posterior sacroiliac bands, while backward displacement would be hindered by the breadth of the anterior as contrasted with the posterior part of the sacrum as well as by the anterior ligaments.

Relations.—The sacroiliac joint is in relation above with psoas and iliacus. In front it is in relation at its upper part with the hypogastric vessels and obturator nerve, and at its lower part with the piriformis muscle.

FIG. 307.—LIGAMENTS CONNECTING SACRUM AND COCCYX POSTERIORLY.



Superficial part of the supraspinous ligament, turned up
Deep part of the supraspinous ligament turned up

(*b*) THE SACROCOCCYGEAL ARTICULATION

Class.—*False Synchondrosis*

The last piece of the sacrum and first piece of the coccyx enter into this union [symphysis sacrococcygea] and are bound together by the following ligaments:–

Anterior sacrococcygeal. Deep posterior sacrococcygeal.
Superficial posterior sacrococcygeal. Lateral sacrococcygeal.
Intervertebral fibrocartilage.

The **intervertebral fibrocartilage** is a small oval disk, about 2 cm. wide, and a little less from before backward, closely connected with the surrounding ligaments. It resembles the other disks in structure, but is softer and more jelly-like, though the laminæ of the fibrous portion are well marked.

The **anterior sacrococcygeal ligament** is a prolongation of the glistening fibrous structure on the front of the sacrum. It is really the lower extremity of the anterior longitudinal ligament, which is thicker over this joint than over the central part of either of the bones.

The **posterior sacrococcygeal ligament** (fig. 307) is divided into two layers of which one (the **deep**) is a direct continuation of the posterior longitudinal ligament of the column, consisting of a narrow band of closely packed fibers,

which become blended at the lower border of the first segment of the coccyx with the filum terminale and deep posterior ligament.

The **superficial layer** of the posterior sacrococcygeal ligament (or supracornual ligament), (fig. 307) is the prolongation of the supraspinous which becomes inseparably blended with the aponeurosis of the sacrospinalis (erector spinæ) opposite the laminæ of the third sacral vertebra, and is thus prolonged downward upon the back of the coccyx, passing over and roofing in the lower end of the spinal canal where the laminæ are deficient.

The median fibers (the **supraspinous ligament**) extend over the back of the coccyx to its tip, blending with the deep fibers of the posterior sacrococcygeal ligament and filum terminale; the deeper fibers run across from the stunted laminæ on one side to the next below on the opposite side, and from the sacral cornu on one side to the coccygeal on the opposite, some passing between the two cornu of the same side, and bridging the aperture through which the fifth sacral nerve passes. Its posterior surface gives origin to the gluteus maximus muscle.

The **lateral sacrococcygeal** or **intertransverse ligament** (fig. 307) is merely a quantity of fibrous tissue which passes from the transverse process of the coccyx to the lateral edge of the sacrum below its angle. It is connected with the sacrosciatic ligaments at their attachments, and the fifth sacral nerve escapes behind it. It is perforated by twigs from the lateral sacral artery and the coccygeal nerve.

The **arterial supply** of the sacrococcygeal joint is from the lateral sacral and middle sacral arteries.

The **nerves** come from the fourth and fifth sacral and coccygeal nerves.

The **movements** permitted at this joint are of a simple forward and backward, or hinge-like character. In the act of defecation, the bone is pushed back by the fecal mass, and, in parturition, by the fetus; but this backward movement is controlled by the upward and forward pull of the levator ani and coccygeus. The external sphincter also tends to pull the coccyx forward.

(*c*) Intercoccygeal Joints

The several segments of the coccyx are held together by the anterior and posterior longitudinal ligaments, which completely cover the bony nodules on their anterior and posterior aspects. Laterally, the sacrosciatic ligaments, being attached to nearly the whole length of the coccyx, serve to connect them. Between the first and second pieces of the coccyx there is a very perfect amphiarthrodial joint, with a well-marked intervertebral disk.

Movements.—But little movement occurs as a rule at the sacrococcygeal and intercoccygeal joints, but when the head of the child is passing through the pelvic outlet at birth, the tip of the coccyx is displaced backward, it may be to the extent of one inch.

(*d*) The Symphysis Pubis

Class.—*False Synchondrosis*

The bones entering into this joint are the pubic portions of the hip-bones. This joint is shorter and broader in the female than in the male. The ligaments, which completely surround the articulation, are:—

Superior.	Anterior.
Arcuate.	Interpubic cartilage.

The **superior ligament** (figs. 308, 309) is a well-marked stratum of yellowish fibers which extends lateralward along the crest of the pubis on each side, blending in the middle line with the interosseous cartilage. It gives origin to the rectus abdominis tendon.

The **anterior ligament** (figs. 308, 309) is thick and strong, and is closely connected with the fascial covering of the muscles arising from the body of the pubis. It consists of several strata of thick, decussating fibers of different degrees of obliquity, the superficial being the most oblique, and extending lowest over the joint.

The most superficial descending fibers extend from the upper border of the pubis, cross others from the opposite side about the middle of the symphysis, and are attached to the ramus of the opposite bone. The most superficial ascending fibers come from the arcuate ligament, arch upward, and decussate with other fibers across the middle line, and are lost on the opposite side beneath the descending set. There is another deeper set of descending fibers which arise below the angle, but do not descend so far as the superficial; and a deeper set of ascending, which decussate, and reach higher than the superficial set, and are connected with the arcuate

ligament. Some few transverse fibers pass from side to side, especially above and below the points of decussation.

The **arcuate** (inferior or subpubic) **ligament** (figs. 308, 310) is a thick, arch-like band of closely packed fibers which fills up the angle between the pubic rami, and forms a smooth, rounded summit to the pubic arch. It is yellowish in color and is inseparably connected with the interpubic cartilage.

FIG. 308.—ANTERIOR VIEW OF THE MALE SYMPHYSIS PUBIS, SHOWING THE DECUSSATION OF THE FIBERS OF THE ANTERIOR LIGAMENT.

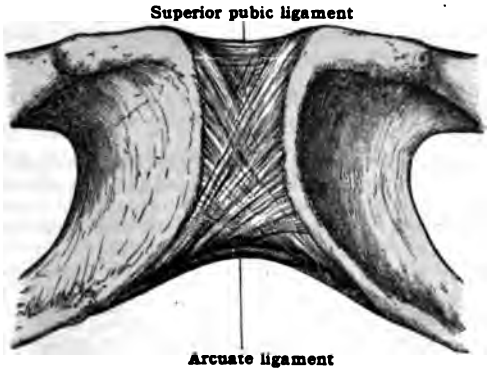

FIG. 309.—ANTERIOR VIEW OF THE FEMALE SYMPHYSIS PUBIS, SHOWING GREATER WIDTH.

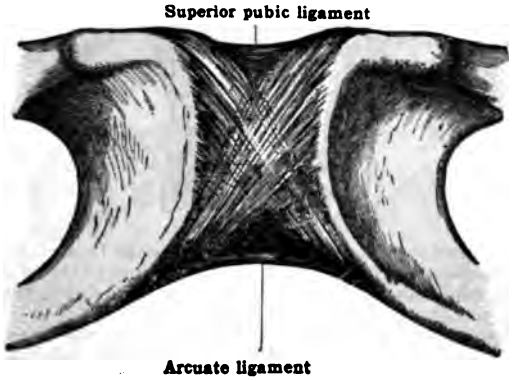

FIG. 310.—POSTERIOR VIEW OF THE SYMPHYSIS PUBIS, SHOWING THE DECUSSATION OF THE FIBERS FROM THE ARCUATE LIGAMENT.

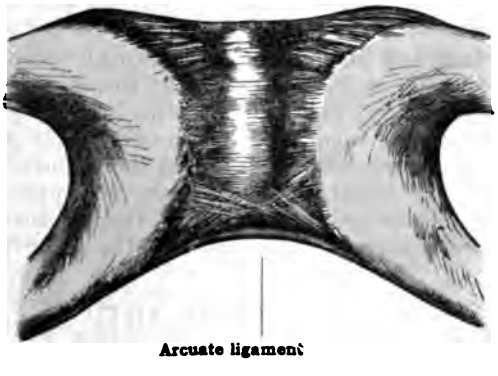


Both on the front and back aspects of the joint it gives off decussating fibers, which, by their interlacement add very materially to the strength of the joint. In fact, the ligament may be said to split superiorly into two layers, one passing over the front, and the other over the back, of the articulation.

The interpubic fibrocartilage [lamina fibrocartilaginea interpubica] varies in different subjects, but is thicker in the female than in the male. It is thicker in front than behind, and projects beyond the edges of the bones, especially

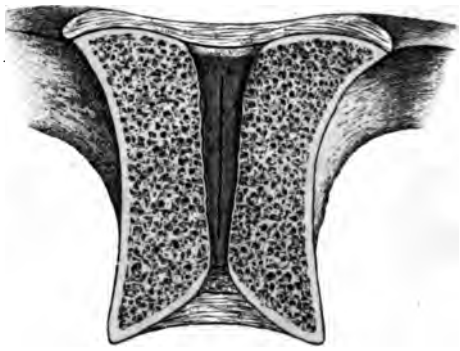
posteriorly (see fig. 310), blending intimately with the ligaments at its margins. It is sometimes uninterruptedly woven throughout, but often presents an elongated narrow fissure, partially dividing the cartilage into two plates, with a little fluid in the interspace (fig. 311). This rudimentary synovial cavity generally extends about half the length of the cartilage.

When this cavity is large, especially if it reaches or approaches very near to the circumference of the cartilage (which, however, it very rarely does), it is thought by some anatomists that it more nearly resembles a diarthrodial than an amphiarthrodial joint, and it is then classed with the sacroiliac joint under similar conditions, as 'diarthroamphiarthrosis.' The interosseous cartilage is intimately adherent to the layer of hyaline cartilage which covers the medial surface of each pubic bone; the osseous surface is ridged to give a firmer attachment; and, on forcing the bones apart, it does not frequently split into two plates, but is torn from the bone on one side or the other.

The **arterial supply** of the interpubic joint is from twigs of the internal pudic, pubic branches of the obturator and epigastric, and ascending branches of the internal circumflex and superficial external pudic.

The **movements** amount only to a slight yielding of the cartilage; neither muscular force nor extrinsic forces produce any appreciable movement in the ordinary condition. Occasionally, as the result of child-bearing, the joint becomes unnaturally loose, and then walking and standing are painfully unsteady. It is known that, during pregnancy and parturition, the

FIG. 311.—SECTION OF SYMPHYSIS TO SHOW THE RUDIMENTARY SYNOVIAL CAVITY.



symphyseal cartilage becomes softer and more vascular, so as to permit the temporary enlargement of the pelvis; but it must be remembered that the fibers of the oblique muscles decussate and thus, during labor, while they force the head of the fetus down, they strengthen the joint by bracing the bones more tightly together.

Relations.—The interpubic joint is in relation above with the linea alba; behind with the prostate and the anterior border of the bladder; in front with the suspensory ligament of the penis or clitoris; and below with the dorsal vein of the penis or clitoris and the upper border of the urogenital diaphragm (triangular ligament).

OBTURATOR MEMBRANE

The **obturator membrane** [membrana obturatoria], composed of fibers having various directions, fills the thyroid (obturator) foramen, its attachment being upon the pelvic side of the bony margin of the opening. Superiorly, it is deficient and a notch remains, which, together with the obturator groove forms a canal traversed by the obturator vessels and nerve in their course from the pelvis into the thigh. Through this canal, the membrane is continuous with the pelvic fascia covering the obturator internus muscle. Both obturator muscles in large part arise from the membrane, one from its outer, the other from its inner surface.

4. THE COSTOVERTEBRAL ARTICULATIONS

These consist of two sets, viz.:—

(*a*) The **capitular** (costocentral): i. e., the articulation of the head of the rib with the vertebræ.

(*b*) The **costotransverse,** or the articulation of the tubercle (of each of the first ten ribs) with the transverse process of the lower of the two vertebræ, with which the head of the rib articulates: i. e., the one bearing its own number, as the first rib with the first thoracic vertebra, the second rib with the second thoracic vertebra, and so on.

(*a*) The Capitular Articulation

Class.—*Diarthrosis.* **Subdivision.**—*Condylarthrosis.*

It is a very perfect joint, into the formation of which the head of the rib and two vertebræ, with the intervertebral disk between them, enter. The articular surfaces of the bones are covered with cartilage. In the case of the first, tenth, eleventh, and twelfth ribs, the capitular joint is formed by the head of the rib articulating with a single vertebra.

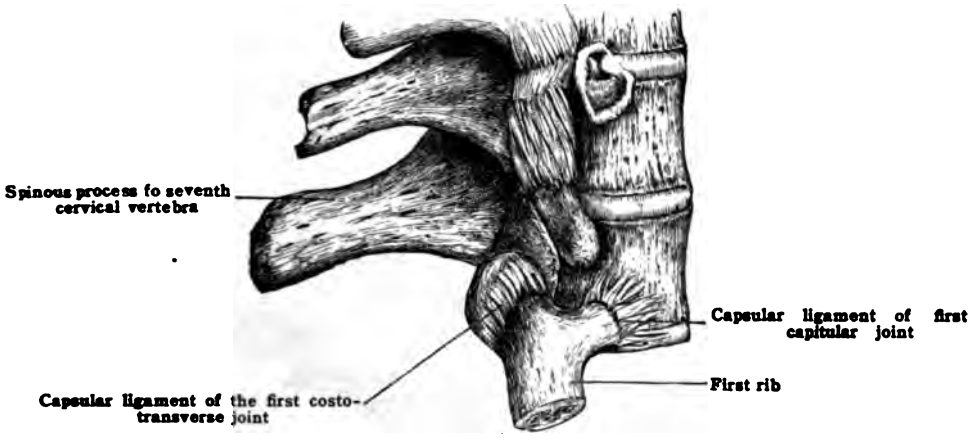
The ligaments are:—

Articular capsule. Interarticular.
Radiate.

The articular capsule (fig. 312) consists of short, strong fibers, completely surrounding the joint, which are attached to the bones and intervertebral disks, a little beyond their articular margins.

At its upper part it reaches through the intervertebral foramen toward the back of the bodies of the vertebræ, being strengthened here by fibers which at intervals connect the anterior with the posterior longitudinal ligaments. The lower fibers extend downward nearly to the demifacet (costal pit) of the rib below; behind, it is continuous with the neck ligament, and in front is overlaid by the radiate.

Fig. 312.—The Capsular Ligaments of the Costovertebral Joints.



Spinous process to seventh cervical vertebra
Capsular ligament of first capitular joint
First rib
Capsular ligament of the first costo-transverse joint

The interarticular ligament (fig. 313) consists of short, strong fibers, closely interwoven with the outermost ring of the intervertebral disk, and attached to the transverse ridge separating the articular facets on the head of the rib. It completely divides the articulation into two parts, but does not brace the rib tightly to the spine, being loose enough to allow a moderate amount of rotation on its own axis. There is no interarticular ligament in the costovertebral joints of the first, tenth, eleventh, and twelfth ribs.

The radiate (or stellate) **ligament** [lig. capituli costæ radiatum], a thickening of the anterior part of the capsule (figs. 313, 314), is the most striking of all, and consists of bright, pearly-white fibers attached to the anterior surface, and upper and lower borders of the neck of the rib, a little way beyond the articular facet; from this they radiate upward, forward, and downward, so as to form a continuous layer of distinct and sharply defined fibers.

The middle fibers run straight forward to be attached to the intervertebral disk, the upper ascend to the lower half of the lateral surface of the vertebra above, and the lower descend to the upper half of the vertebra below. The radiate ligament is overlapped on the vertebral bodies by the lateral (short) vertebral ligaments.

In the case of the first, tenth, eleventh, and twelfth ribs, each of which articulates with one vertebra, the ligament is not quite so distinctly radiate, but even in these the ascending fibers reach the vertebra above that with which the rib articulates.

The synovial membranes of the capitular articulation (fig. 314) consist of two closed sacs which do not communicate: one above, and the other below, the interarticular ligament. In the case of the first, tenth, eleventh, and twelfth

articulations, there is but one synovial membrane, as these joints have no interarticular ligament.

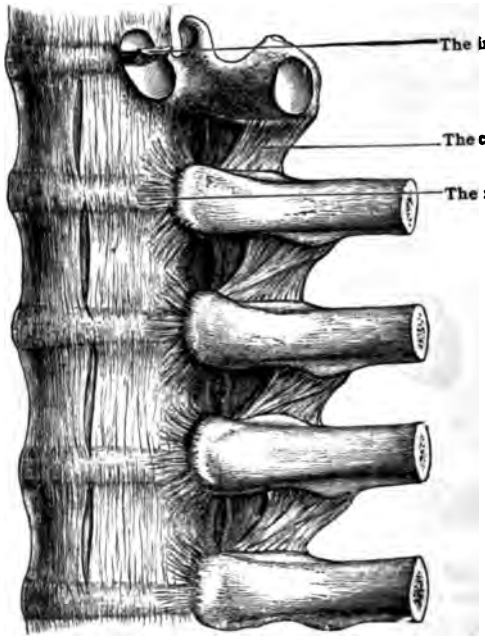
The **arterial supply** of the capitular articulations is from the intercostal arteries, the twigs piercing the radiate and capsular ligaments.

The **nerve-supply** comes from the anterior primary branches of the intercostal nerves.

Movements (Cf. p. 538).—These joints approach most nearly in their movements to the condylarthroses. The movements are ginglymoid in character, consisting of a slight degree of elevation and depression around an obliquely horizontal axis corresponding with the interarticular ligament; there is also a slight amount of forward and backward gliding; and a slight degree of screwing or rotatory movement is also possible. There is a considerable difference in the degree of mobility of the different ribs, for while the first rib is almost immobile except in a very deep inspiration, the mobility of the others increases from the second to the last; the two floating ribs being the most mobile of all. The head of the rib is the most fixed point of the costal arch, and upon it the whole arch rotates; the interarticular ligament allows only a very limited amount of flexion and extension (i. e., elevation and depression), and of gliding. Gliding is checked by the radiate ligament.

In inspiration, the rib is elevated, and glides forward in its socket, too great elevation being checked not only by the ligaments, but also by the overhanging upper edge of the cavity itself. In expiration, the rib is depressed, and glides backward in its cavity.

FIG. 313.—ANTERIOR LONGITUDINAL LIGAMENT, AND THE CONNECTION OF THE RIBS WITH THE VERTEBRÆ.



(*b*) THE COSTOTRANSVERSE ARTICULATION

Class.—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

This joint is formed by the tubercle of the rib articulating with the anterior part of the tip of the transverse process. The eleventh and twelfth ribs are devoid of these joints, for the tubercles of these ribs are absent, and the transverse processes of the eleventh and twelfth thoracic vertebræ are rudimentary.

The ligaments of the union are:—

Articular capsule.	Tubercular ligament.
Neck ligament.	Costotransverse ligaments.

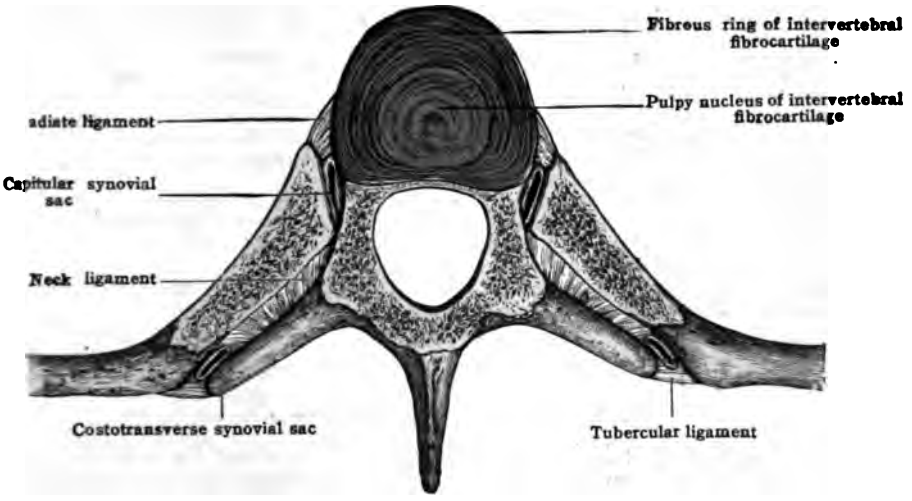
The **articular capsule** (figs. 312, 314) forms a thin, loose, fibrous envelope to the synovial membrane. Its fibers are attached to the bones just beyond the articular margins, and are thickest below, where they are not strengthened by any other structure. It is connected medially with the neck ligament, above with the costotransverse, and laterally with the tubercular (posterior costotransverse) ligaments. The eleventh and twelfth ribs are unprovided with costotransverse capsules.

The neck ligament [lig. colli costæ] (middle costotransverse, or interosseous ligament) (fig. 314), consists of short fibers passing between the back of the neck of the rib and front of the transverse process, with which the tubercle articulates. It extends from the capsule of the capitular joint to that of the costotransverse. It is best seen on horizontal section through the bones filling the costotransverse foramen. In the **eleventh** and **twelfth** ribs this ligament is rudimentary.

The **tubercular ligament** [lig. tuberculi costæ] (fig. 314) is a short but thick, strong, and broad ligament, which extends laterally and upward from the extremity of the transverse process to the non-articular surface of the tubercle of the corresponding rib. The **eleventh** and **twelfth** ribs have no posterior ligament.

The **costotransverse ligament** (fig. 313) is a strong, broad band of fibers which ascends laterally from the crest on the upper border of the neck of the rib, to the lower border of the transverse process above. A few scattered posterior fibers pass upward and medially from the neck to the transverse process. The costotransverse ligament is subdivided into a stronger anterior portion, **anterior costotransverse ligament,** best seen from the front (fig. 313), and a weaker posterior portion, **posterior costotransverse ligament.** Its medial border bounds the foramen through which the posterior branches of the intercostal vessels and nerves

FIG. 314.—HORIZONTAL SECTION THROUGH THE INTERVERTEBRAL DISK AND RIBS.



pass. To the lateral border is attached the thin aponeurosis covering the external intercostals. Its anterior surface is in relation with the intercostal vessels and nerve; the posterior with the longissimus dorsi. The **first** rib has no costotransverse ligament. The twelfth rib is firmly bound down by the **lumbocostal ligament,** a specially strong mass of fibers in the anterior layer of the lumbodorsal fascia connected medially with the tips of the transverse processes of the first two lumbar vertebræ.

The **synovial membrane** (fig. 314) of the costotransverse articulation is a single sac.

The **arterial** and **nerve supplies** come from the posterior branches of the intercostal arteries and nerves.

The **movements** which take place at these joints are limited to a gliding of the tubercle of the rib upon the transverse process. The exact position of the facet on the transverse process varies slightly from above downward, being placed higher on the processes of the lower vertebræ. The plane of movement in most of the costotransverse joints is inclined upward and backward in inspiration, and downward and forward in expiration. The point round which these movements occur is the head of the rib, so that the tubercle of the rib glides upon the transverse process in the circumference of a circle, the center of which is at the capitular joint.

5. THE ARTICULATIONS AT THE FRONT OF THE THORAX

These may be divided into four sets, viz.:—

(*a*) The **intersternal joints,** or the union of the several parts of the sternum with one another.

(*b*) The **costochondral joints,** or the union of the ribs with their costal cartilages.

(*c*) The **chondrosternal joints,** or the junction of the costal cartilages with the sternum.

(*d*) The **interchondral joints,** or the union of five costal cartilages (sixth, seventh, eighth, ninth, and tenth) with one another.

(*a*) The Intersternal Joints

The sternum being composed, in the adult, of three distinct pieces—the manubrium, body, and the xiphoid process—has two articulations, viz., the superior, which unites the manubrium with the body (gladiolus), and the inferior, which unites the body with the xiphoid.

1. The Superior Intersternal Articulation

Class.—*False Synchondrosis.*

The lower border of the manubrium and the upper border of the body of the sternum present oval-shaped, flat surfaces, with their long axes transverse, and covered with a thin layer of hyaline cartilage. An **interosseous fibrocartilage** is interposed between the bony surfaces; it corresponds exactly in shape and intimately adheres to them. At each lateral border this fibrocartilage enters into the formation of the second chondrosternal articulation (fig. 315).

In consistence it varies, being in some cases uniform throughout, in others softer in the center than at the circumference, and in others again an oval-shaped synovial cavity is found toward its anterior part. When such a cavity exists in the fibrocartilage this joint has a remote resemblance to the diarthroses, and is classed, with the sacroiliac joint and the symphysis pubis under similar conditions, as 'diarthroamphiarthrosis.'

The periosteum passes uninterruptedly over the joint from one segment of the sternum to the other, forming a kind of capsular ligament [membrana sterni]. This capsule is strengthened, especially on its posterior aspect, by longitudinal ligamentous fibers as well as by the radiating and decussating fibers of the chondrosternal ligaments.

In some instances the fibrocartilage is replaced by short bundles of fibrous tissue which unite the cartilage-coated articular bone surfaces.

2. The Inferior Intersternal Articulation

Class.—*False Synchondrosis*

The body (gladiolus) is joined to the xiphoid cartilage by a thick investing membrane, by anterior and posterior longitudinal fibers, and by radiating fibers of the sixth and seventh chondrosternal ligaments. The **costoxiphoid ligament** also connects the xiphoid with the anterior surface of the sixth and seventh costal cartilages, and thus indirectly with the gladiolus; and some fine fibroareolar tissue also connects the xiphoid with the back of the seventh costal cartilage.

The junction of the xiphoid with the sternum is on a level somewhat posterior to the junction of the seventh costal cartilage with the sternum. The union is a synchondrosis, each bone being covered by hyaline cartilage which is connected with the intervening fibrocartilage plate.

(*b*) The Costochondral Joints

Class.—*Synarthrosis.*

The extremity of the costal cartilage is received into a cup-shaped depression at the end of the rib, which is somewhat larger than the cartilage. The two are joined together by the continuity of the investing membranes, the periosteum of the rib being continuous with the perichondrium of the cartilage.

(*c*) The Sternocostal Articulations

Class.—*Diarthrosis.* **Subdivision.**—*Ginglymus.*

These articulations are between the lateral borders of the sternum and the ends of the costal cartilages. The union of the first rib with the sternum is *synchondrodial*, and therefore forms an exception to the others. From the second

the seventh inclusive, the articulations have the following ligaments, which gether form a complete capsule:—

Radiate (anterior) sternocostal. Posterior sternocostal.

The **radiate** (anterior) **sternocostal ligament** (fig. 315) is a triangular band omposed of strong fibers which cover the medial one centimeter of the front of the ostal cartilage, and radiate upward and downward upon the front of the sternum. Some of the fibers decussate across the middle line with fibers of the opposite ligament.

The **posterior sternocostal ligament** consists of little more than a thickening of the fibrous envelopes of the bone and cartilage, the joint being completed behind by a continuity of perichondrium with periosteum. The periosteum of the sternum, augmented by the fibers of the anterior and posterior ligaments forms a dense layer enveloping the sternum and has been termed the **membrana sterni.**

Deeper than the fibers of these ligaments are short fibers passing from the margins of the sternal facets to the edges of the facets on the cartilages; they are most distinct in the front and lower part of the joint, and may encroach so much upon the synovial cavity as to reduce it to a very small size, or almost obliterate it. This occurs mostly in the case of the sixth and seventh joints, especially the latter.

The interarticular ligament (fig. 315) is by no means constant, but is usually resent in the second joint on one, if not on both sides of the same subject. It onsists of a strong transverse bundle of fibers passing from the ridge on the facet n the cartilage to the fibrous substance between the manubrium and body; ometimes the upper part of the synovial cavity is partially or entirely obliterated y short, fine, ligamentous fibers.

The costoxiphoid ligament (fig. 315) is a strong flat band of fibers passing bliquely upward and laterally from the front surface of the xiphoid cartilage to he anterior surface of the sternal end of the seventh costal cartilage, and most requently to that of the sixth also. It is not always present.

Synovial membranes.—The union of the first cartilage with the sternum, being synchondroal, has no synovial membrane; the second has usually two, separated by the interarticular pament. The rest usually have one synovial membrane, which may occasionally be subivided into two (fig. 315).

The arterial supply is derived from perforating branches of the internal mammary; and ie **nerves** come from the anterior branches of the intercostals.

Movements.—Excepting the first, the chondrosternal joints are ginglymoid, but the motion which they are capable is very limited. It consists of a hinge-like action in two directions: rst, there is a slight amount of elevation and depression which takes place round a transverse cis, and, secondly, there is some forward and backward movement round an obliquely vertical cis. In inspiration the cartilage is elevated, the lowest part of its articular facet is pressed to the sternal socket, and the sternum is thrust forward so that the upper and front edges the articular surfaces separate a little; in expiration the reverse movement takes place. Thus e two extremities of the costal arches move in their respective sockets in opposite directions. This difference results necessarily from the fact that the costal arch moves upon the vertebral column, and, having been elevated, it in its turn raises the sternum by pushing it upward id forward.

The costoxiphoid ligament tends to prevent the xiphoid cartilage from being drawn backard by the action of the diaphragm.

(*d*) The Interchondral Articulations

Class.—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

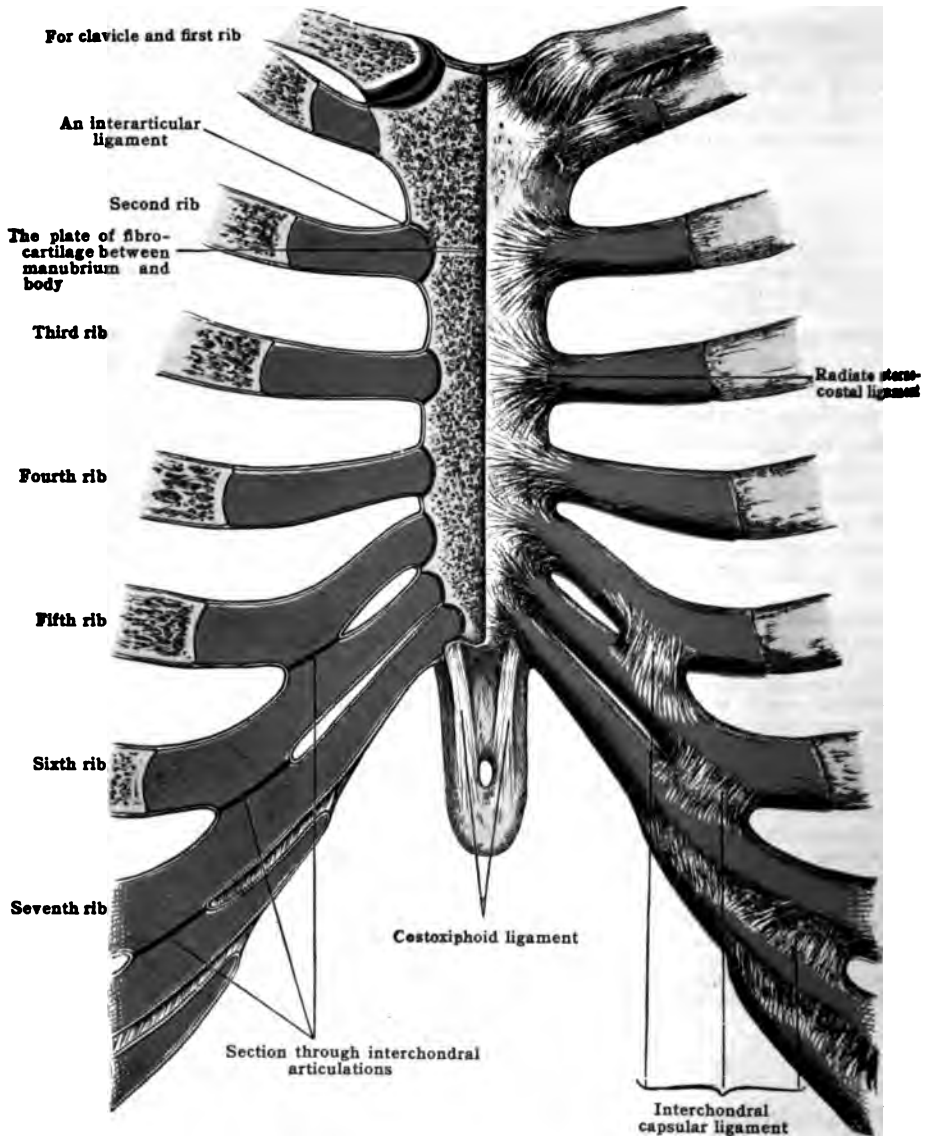
A little in front of the point where the costal cartilages bend upward toward ie median line (fig. 315) the sixth is united with the seventh, the seventh with the ghth, the eighth with the ninth, and the ninth with the tenth.

At this point each of the cartilages from the sixth to the ninth inclusive is deeper than sewhere, owing to the projection downward from its lower edge, of a broad blunt process, hich comes into contact with the cartilage next below. Each of the apposed surfaces is nooth, and they are connected at their margins by ligamentous tissue, which forms a complete psule for the articulation, and is lined by a synovial membrane (fig. 315). The largest of ese cavities is between the seventh and eighth; those between the eighth and ninth, and ninth id tenth are smaller, and are not free to play upon each other in the whole of their extent, being eld together by ligamentous tissue at their anterior margins. Sometimes this fibrous tissue mpletely obliterates the synovial cavity.

The arteries are derived from the musculophrenic, and the nerves from the intercostals.

Movements.—By means of the costal cartilages and interchondral joints, strength with elasticity is given to the wall of the trunk at a part where the cartilages are the only firm structures in its composition; while a slight gliding movement is permitted between the costal cartilages themselves, which takes place round an axis corresponding to the long axis of the cartilages. By this means, the outward projection of the lower part of the thoracic wall is increased by deep inspiration.

FIG. 315.—THE ARTICULATIONS AT THE FRONT OF THE THORAX.
(Left side, showing ligaments; right side, the articular cavities.)

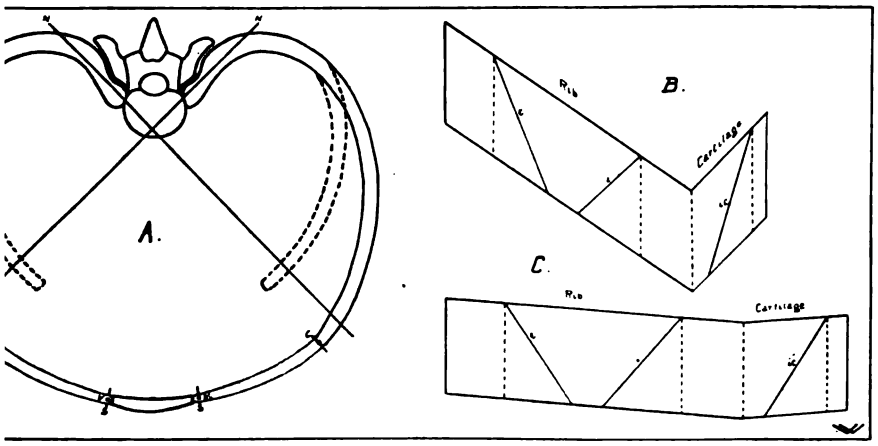


MOVEMENTS OF THE THORAX AS A WHOLE

Each rib above the tenth moves on an axis which passes through the costotransverse and capitular articulations approximately parallel with the direction of the neck of the rib, fig. 316. The axes of rotation of the pairs of ribs converge in front to intersect in the mid-plane, in angles which diminish from above downward, following the differences in form of rib and vertebra in the upper and lower ends of the series. The movements which take place in the upper ribs for the same cause differ from those occurring in the pairs of lower ribs. During inspiration and expiration, the anterior extremities of the first pair of costal arches play up and down, the tubercles and the heads of the ribs acting in a hinge-like manner, around an axis whose direction tends to approach a right angle with the sagittal plane. By this movement the anterior ends of these costal arches are simply raised or depressed, and the sternum pushed a little forward (Cf. p. 538).

ovements of the other ribs, particularly in the midregion of the thorax, are more
the axes of rotation tending to pass in a sagittal direction; for, besides the elevation
erior extremities, the bodies and angles of the ribs rise nearly as much as the extremities
s. In this movement the tubercles of the ribs glide upward and backward in inspira-
downward and forward in expiration.
g inspiration the cavity of the thorax is increased in every direction. The **antero-**
diameter is increased by the thrusting forward of the sternum, caused by the eleva-
e costal cartilages and fore part of the ribs, whereby they are brought to nearly the
l as the heads of the ribs. The **transverse diameter** is increased: (1) Behind, by the
of the middle part of the ribs; for when at rest the midpart of the rib is on a lower
l either the costovertebral or chondrosternal articulations. Owing to this obliquity
verse diameter is increased when the rib is raised, and the increase is proportionate
gree of obliquity. (2) By the eversion of the lower border of the costal arch, which
ward as the arch is raised. (3) The transverse diameter is increased in front by the
l of the anterior extremity of the rib at the same time as it is elevated and thrust

—Horizontal Projection of the Costal Ring Formed by the Fifth Ribs (After Luciani.)



crease in the vertical diameter of the thorax is due to the elevation of the ribs, espe-
l **upper ones**, and the consequent widening of the intercostal spaces; but the chief
n **this direction** is due to the descent of the diaphragm.
reatest increase both in the anteroposterior and transverse diameters takes place

the posterior fibers of the external oblique also helping to fix the lower ribs. (*b*)
nary inspiration: The superior extremities are raised and fixed. The cervical part of
bral column and the head are extended, and in addition to the muscles of ordinary
n, the following muscles also come into play: The pectoralis minor, the muscles which
e head and the cervical part of the vertebral column, the sternomastoid and the supra-
hyoid muscles, the lower fibers of the pectoralis major, some of the lower fibers of the
nterior, and, when the clavicle is fixed, the subclavius.
tion is produced by the elasticity of the lungs and the weight of the thorax, aided
stic reaction and contraction of the external (?) and internal oblique **muscles**, the recti
midales, the transversus abdominis, and the levatores ani and coccygei. In forcible
l all muscles which depress the ribs and reduce the dimensions of the abdomen are
to action. The internal intercostals probably tend to contract the thorax, excepting
chondral parts, which tend to expand the thorax.

THE ARTICULATIONS OF THE UPPER EXTREMITY

The articulations of the upper extremity are the following:—

1. The **sternocostoclavicular.**
2. The **scapuloclavicular union.**
3. The **shoulder-joint.**
4. The **elbow-joint.**
5. The **radioulnar union.**
6. The **radiocarpal** or **wrist-joint.**
7. The **carpal joints.**
8. The **carpometacarpal joints.**
9. The **intermetacarpal joints.**
10. The **metacarpophalangeal joints.**
11. The **interphalangeal joints.**

1. THE STERNOCOSTOCLAVICULAR ARTICULATION

Class.—*Diarthrosis.* **Subdivision.**—*Condylarthrosis.*

At this joint (figs. 315, 317, 318) the large medial end of the clavicle is united to the superior angle of the manubrium sterni, the first costal cartilage also assisting to support the clavicle. It is the only joint between the upper extremity and the trunk, and takes part in all the movements of the pectoral girdle. Looking at the bones, one would say that they were in no way adapted to articulate with one another, and yet they assist in constructing a joint of security, strength, and freedom of movement. The bones are nowhere in actual contact, being completely separated by an articular disk. The interval between the joints of the two sides varies from 2.5 to 4 cm. The ligaments of this joint are:—

Articular capsule.	Articular disk.
Interclavicular.	Costoclavicular.

The **articular capsule** (fig. 317) consists of fibers, having varying directions and being of various strength and thickness, which completely surround the articulation, and are firmly connected with the edges of the articular disk.

The fibers at the back of the joint, sometimes styled the **posterior sternoclavicular ligament,** are stronger than those in front or below, and consist of two sets: a superficial, passing upward and laterally from the manubrium sterni, to the projecting posterior edge of the end of the clavicle, a few being prolonged onward upon the posterior surface of the bone. A deeper set of fibers, especially thick and numerous below the clavicle, connect the interarticular cartilage with the clavicle and with the sternum, but do not extend from one bone to the other. The fibers in front, the **anterior sternoclavicular ligament,** are well marked, but more lax and less tough than the posterior, and are overlaid by the tendinous sternal origin of the sternomastoid, the fibers of which run parallel to those of the ligament. They extend obliquely upward and laterally from the margin of the sternal facet to the anterior surface of the clavicle some little distance from the articular margin. The fibers which cover in the joint below are short, and consist more of fibroareolar tissue than true fibrous tissue; they extend from the upper border of the first costal cartilage to the lower border of the clavicle just lateral to the articular margin, and fill up the gap between it and the costoclavicular ligament. The superior portion consists of short tough fibers passing from the sternum to the articular disk and of others binding the fibrocartilage to the upper edge of the clavicle, only a few of them passing from the clavicle direct to the sternum.

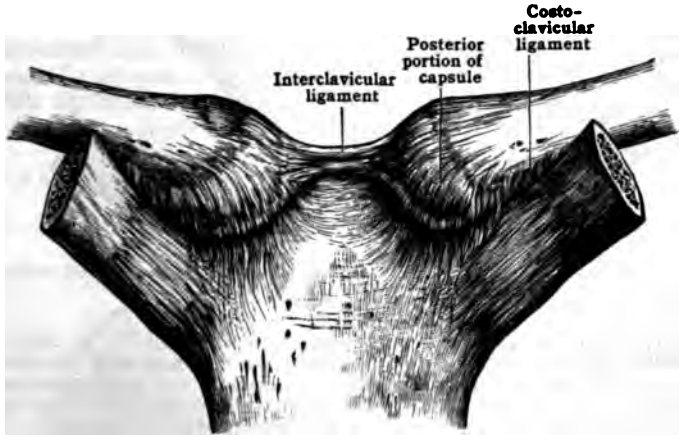
The **interclavicular ligament** (fig. 317) is a strong, concave band, materially strengthening the superior portion of the capsule. It is about 6 mm. deep with a concavity upward, its upper border tapering to a narrow, almost sharp edge. It is connected with the posterior superior angle of the sternal extremity of each clavicle, and with the fibers which bind the articular disk to the clavicle; and then passes across from clavicle to clavicle along the posterior aspect of the upper border of the manubrium sterni. The lowest fibers are attached to the sternum, and join the posterior fibers of the capsule of each joint. In the midline, between the ligament and the sternum, there is an aperture for the passage of a small artery and vein.

In addition to the interclavicular ligament, Carwardine (Journal of Anatomy and Physiology, vol. 7, n.s., p. 232) has described a special band of the upper portion of the sternoclavicular capsule which he proposes to name the 'suprasternal ligament.' It descends from the upper border of the sternal end of the clavicle to the upper border of the sternum, and is of special importance as it encloses the suprasternal bones, when these rudiments are present.

The **costoclavicular** (or rhomboid) **ligament** (fig. 317) is a strong dense band, composed of fine fibers massed together into a membranous structure. It extends from the upper (medial) border of the first costal cartilage (and rib), upward, backward, and distinctly laterally to the costal tuberosity on the under surface of the medial extremity of the clavicle, to which it is attached just lateral to the lower part of the capsule. Frequently some of the lateral fibers pass upward and medially behind the rest, and give the appearance of decussating. It is from 1.5 to 2 cm. broad.

The **articular disk** (fig. 318) is a flattened disk of nearly the same size and outline as the medial articular end of the clavicle, which it fairly accurately fits. It is attached above to the upper border of the posterior edge of the clavicle; and below to the cartilage of the first rib at its union with the sternum, where it assists in forming the socket for the clavicle. At its circumference it is connected with the articular capsule, and this connection is very strong behind, and still stronger above, where it is blended with the interclavicular ligament.

FIG. 317.—POSTERIOR VIEW OF THE STERNOCLAVICULAR JOINT.



The disk is usually thinnest below, where it is connected with the costal cartilage. It varies in thickness in different parts, sometimes being thinner in the center than at the circumference, sometimes the reverse, and is occasionally perforated in the center. It divides the joint into two compartments.

There are two **synovial membranes** (fig. 318); a lateral one, which is reflected from the clavicle and capsule over the lateral aspect of the disk and is looser than the medial one; the medial is reflected from the sternum over the medial side of the articular disk, costal cartilage, and capsule. Occasionally a communication takes place between them.

The arterial supply of the sternoclavicular joint is derived from branches—(1) from the internal mammary; (2) from the superior thoracic branch of the axillary; (3) twigs of a muscular branch often arising from the subclavian artery pass over the interclavicular notch; (4) twigs of the transverse scapular (suprascapular) artery.

The nerve-supply is derived from the nerve to the subclavius and sternal descending branch of the cervical plexus.

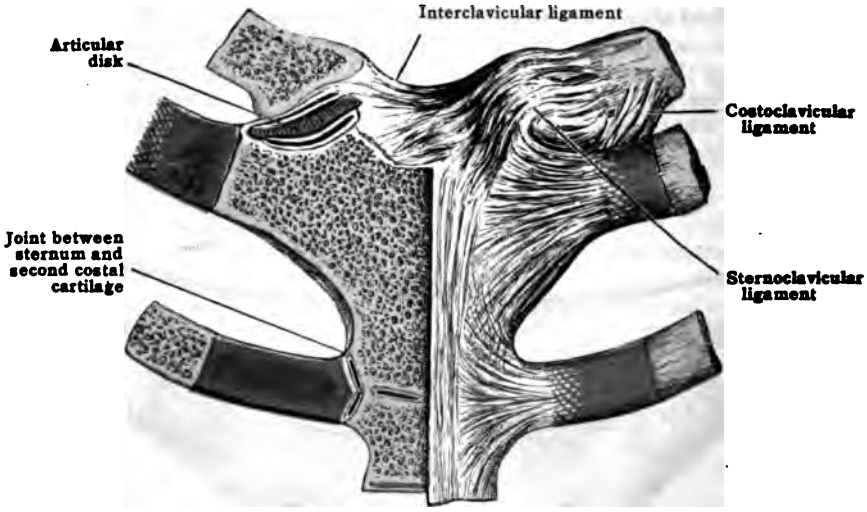
Relations.—In front of the joint is the sternal head of the sternomastoid. Behind it are the sternohyoid and sternothyroid muscles. Still further back, on the right side, are the innominate and internal mammary arteries, and, on the left side, the left common carotid, the left subclavian, and the internal mammary arteries. Above and behind, between the sternomastoid and sternohyoid muscles, the anterior jugular vein passes back and laterally toward the posterior triangle.

The movements (cf. p. 539) permitted at this joint are various though limited, owing to the capsular ligament being moderatly tense in every position of the clavicle. Motion takes place in nearly every direction—viz., upward, downward, forward, backward, and in a circumductory path. The upward and downward motions occur between the clavicle and the articular disk; during elevation of the corner, the upper edge of the clavicle with its attached articular disk

is pressed into the sternal socket, and the lower edge glides away from the disk; during depression of the limb, the lower edge of the clavicle presses on to the disk, while the rest of the articular surface of the clavicle inclines laterally, bringing with it to a slight degree the upper edge of the articular disk. These movements occur on an anteroposterior axis drawn through the outer compartment of the joint. The forward and backward motions take place between the articular disk and sternum, the clavicle with the disk gliding backward upon the sternum when the shoulder is brought forward, and forward when the shoulder is forced backward; these movements occur round an axis drawn nearly vertically through the sternal socket.

The articular disk serves materially to bind the bones together, and to prevent the medial and upward displacements of the clavicle. It also forms an elastic buffer which tends to break shocks. The capsule, by being moderately tight, tends to limit movements in all directions, while the interclavicular ligament is a safeguard against upward displacement during depression of the arm. The costoclavicular ligament prevents dislocation upward during elevation of the arm, and resists displacements backward.

FIG. 318.—ANTERIOR VIEW OF STERNOCOSTOCLAVICULAR JOINT, WITH SECTION SHOWING CAVITIES OPENED ON THE RIGHT SIDE.



Muscles which move the clavicle at the sternoclavicular joint (cf. p. 539).—*Elevators.*—Trapezius, clavicular part of sternomastoid, levator scapulæ, omohyoid, rhomboids. *Depressors.*—Subclavius, pectoralis minor, lower fibers of trapezius and serratus anterior (magnus). Depression is aided by the weight of the upper extremity. *Protractors.*—Pectoralis major and minor, serratus anterior (magnus). *Retractors.*—Latissimus dorsi, trapezius.

2. THE SCAPULOCLAVICULAR UNION

The scapula is connected with the clavicle by a synovial joint with its ligaments at the acromioclavicular articulation; and also by a set of ligaments passing between the coracoid process and the clavicle. So that we have to consider—

(*a*) The **acromioclavicular articulation.**

(*b*) The **coracoclavicular ligaments.**

(*c*) The **proper scapular ligaments** are also best described in this section—viz., the **coracoacromial** and **transverse.**

(*a*) THE ACROMIOCLAVICULAR JOINT

Class.—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

The acromioclavicular joint is surrounded by an articular capsule and frequently contains an articular disk.

The **articular capsule** (figs. 320, 323) completely surrounds the articular margins and is composed of strong, coarse fibers arranged in parallel fasciculi, of fairly uniform thickness, which are attached to the borders as well as the surfaces of the bones. It is somewhat lax in all positions of the joint, so that the clavicle is not tightly braced to the acromion. The fibers extend about 2 cm. along the clavicle posteriorly, but only 6 mm. anteriorly. Superiorly, they are attached to an oblique line joining these two points, while inferiorly they reach to the ridge for the trapezoid ligament with which they blend.

At the acromion they extend half way across the upper and lower surfaces, but at the anterior and posterior limits of the joint they are attached close to the articular facet. The anterior fibers become blended with the insertion of the coracoacromial ligament. The fibers are strengthened above by the aponeuroses of the trapezius and deltoid muscles; and all run from the acromion to the clavicle medially and backward. The upper portion of the capsule has been designated the acromioclavicular ligament.

The **articular disk** is occasionally present, but is usually imperfect, only occupying the upper part of the joint; it may completely divide the joint into two cavities, or be perforated in the center. It is usually thicker at the edge than in the center, and some of the fibers of the articular capsule are blended with its edges. The **synovial membrane** lining the joint is accordingly either partially or entirely divided into two by the articular disk.

Relations.—Superiorly skin and fascia and the tendinous intersection between the deltoid and the trapezius. Inferiorly, the coracoacromial ligament and supraspinatus. Anteriorly, part of the origin of the deltoid. Posteriorly, part of the insertion of the trapezius.

Movements.—A certain amount of gliding movement occurs at this joint, but the most important movement is a rotation of the scapula whereby the glenoid cavity is turned forward and upward, or downward. As these movements occur the inferior angle of the scapula moves forward as the glenoid cavity turns upward and the superior angle recedes.

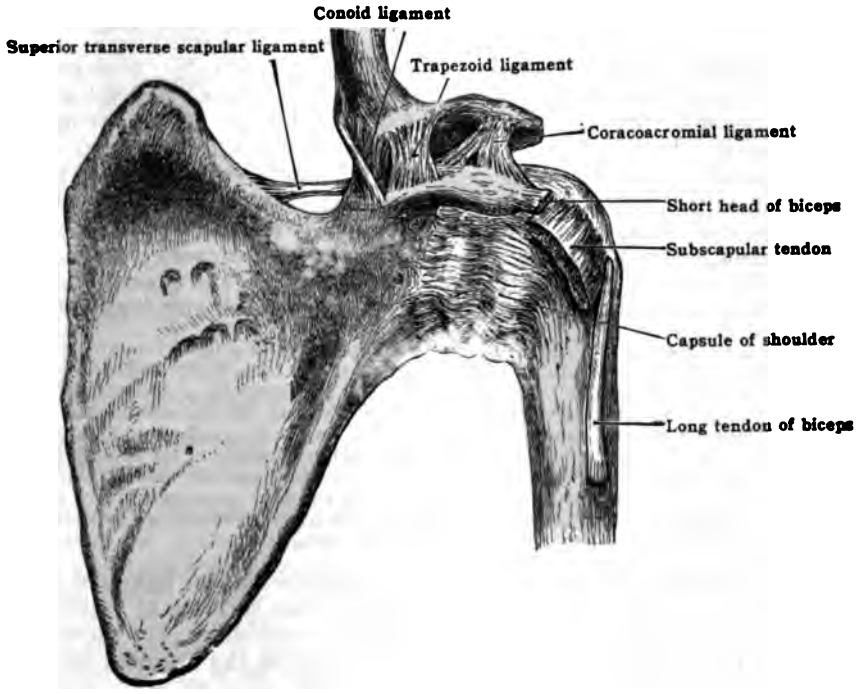
The forward movement of the inferior angle is produced mainly by the inferior fibers of the serratus anterior (magnus), aided by the inferior fibers of the trapezius, and it is by this movement that the arm is raised above the level of the shoulder. The reverse movement is produced mainly by the rhomboideus major aided by the latissmus dorsi.

(*b*) The Coracoclavicular Union

The **coracoclavicular ligament** (figs. 319, 320, 323) consists of two parts, the conoid and the trapezoid ligaments.

The **conoid ligament** is the medial and posterior portion, and passes upward and laterally from the coracoid process to the clavicle.

Fig. 319.—Anterior View of Shoulder, showing also Coracoclavicular and Coracoacromial Ligaments.



It is a very strong and coarsely fasciculated band of triangular shape, the apex being fixed to the medial and posterior edge of the root of the coracoid process just in front of the scapular notch, some fibers joining the transverse ligament. Its base is at the clavicle, where it widens out, to be attached to the posterior edge of the inferior surface, as well as to the coracoid tubercle. It is easily separated from the trapezoid, without being absolutely distinct. A small bursa often exists between it and the coracoid process; medially, some of the fibers of the subclavius muscle are often attached to it.

The **trapezoid ligament** is the anterior and lateral portion of the coraco-clavicular ligament. It is a strong, flat, quadrilateral plane of closely woven fibers, the surfaces of which look upward and medially toward the clavicle, and downward and laterally over the upper surface of the coracoid process.

At the coracoid it is attached for about 2.5 cm. to a rough ridge which runs forward from the angle, along the anterior border of the process. At the clavicle it is attached to the oblique ridge which runs laterally and forward from the coracoid tubercle, reaching as far as, and blending with the inferior part of the acromioclavicular ligament. Its anterior edge is free, and overlies the coracoacromial ligament; the posterior edge is shorter than the anterior, and is in contact with the posterior and lateral portions of the conoid ligament.

The **arterial supply** is derived from the transverse scapular (suprascapular), acromial branches of the thoracoacromial, and the anterior circumflex.

The **nerve-supply** is derived from the suprascapular and axillary (circumflex) nerves.

Movements (cf. p. 539).—In the movements of the shoulder girdle, the scapula moves upon the lateral end of the clavicle, and the clavicle, in turn, carried by the uniting ligaments, moves upon the sternum; so that the entire scapula moves in the arc of a circle whose center is at the sternoclavicular joint, and whose radius is the clavicle. The scapula, in moving upon the clavicle, also moves upon the thorax forward and backward, upward and downward, and also in a rotatory direction upon an axis drawn at right angles to the center of the bone. Throughout these movements the inferior angle and base of the scapula are kept in contact with the ribs by the latissimus dorsi, which straps down the former, and the rhomboids and serratus anterior (magnus), which brace down the latter. By means of the acromioclavicular joint, the scapula can be forcibly advanced upon the thorax, the glenoid cavity all the time keeping its face duly forward. Thus the muscles of the shoulder and forearm can be with advantage combined, as, for example, in giving a direct blow. The acromioclavicular joint also permits the lower angle of the scapula to be retained in contact with the chest wall during the rising and falling of the shoulder, the scapula turning in a hinge-like manner round the horizontal axis of the joint.

There are no actions in which the scapula moves on a fixed clavicle, or the clavicle on a fixed scapula; the two bones, bound together by their connecting ligament, must move in unison

(*c*) The Proper Scapular Ligaments

There are three proper ligaments of the scapula, which pass between different portions of the bone, viz.—

Coracoacromial. Superior transverse.
Inferior transverse.

The **coracoacromial ligament** (figs. 319, 323) is a flat, triangular band with a broad base, attached to the lateral border of the coracoid process, and a blunt apex which is fixed to the tip of the acromion. It is made up of two broad marginal bands, and a smaller and thinner intervening portion. The **anterior band,** which arises from the anterior portion of the coracoid process, is the stronger, and some of its marginal fibers can often be traced into the short head of the biceps, which can then make tense this edge of the ligament. The **posterior band,** coming from the posterior part of the coracoid process, is also strong. The intermediate part, of variable extent, is thin and membranous; it is often incomplete near the coracoid process, leaving a small gap (fig. 319).

The superior surface of the ligament looks upward and a little forward, and is covered by the deltoid muscle; the inferior looks downward and a little backward, and is separated from the capsule of the shoulder-joint by a bursa and the tendons of the supraspinatus and subscapularis muscles. At the coracoid process it overlies the coracohumeral ligament. It is barely 8 mm. above the capsule of the shoulder, and in the undissected state there is scarcely a 6 mm. interval. The anterior band projects over the center of the head of the humerus, and is continued into a tough fascia under the deltoid; the posterior band is continuous with the fascia over the supraspinatus muscle. It binds the two processes firmly together, and so strengthens each; it holds the deltoid off the capsule of the shoulder, and protects the joint from slight injuries directed downward and backward against it.

The **superior transverse** (coracoid, or suprascapular) **ligament** (figs. 319, 321) is a small triangular band of fibrous tissue, the surfaces of which look forward and backward; and its edges, which are thin and sharp, are turned upward and downward. It continues the superior border of the scapula, bridging over the scapular notch.

It is broader medially, where it springs from the upper border of the scapula on its dorsal surface; and narrow laterally, where it is attached to the base of the coracoid process; some of its fibers are inserted under the edge of the trapezoid ligament, and others pass upward with the conoid to reach the clavicle. The transverse scapular (suprascapular) artery passes over it, and the suprascapular nerve beneath it. Medially, some fibers of the omohyoid muscle arise from it.

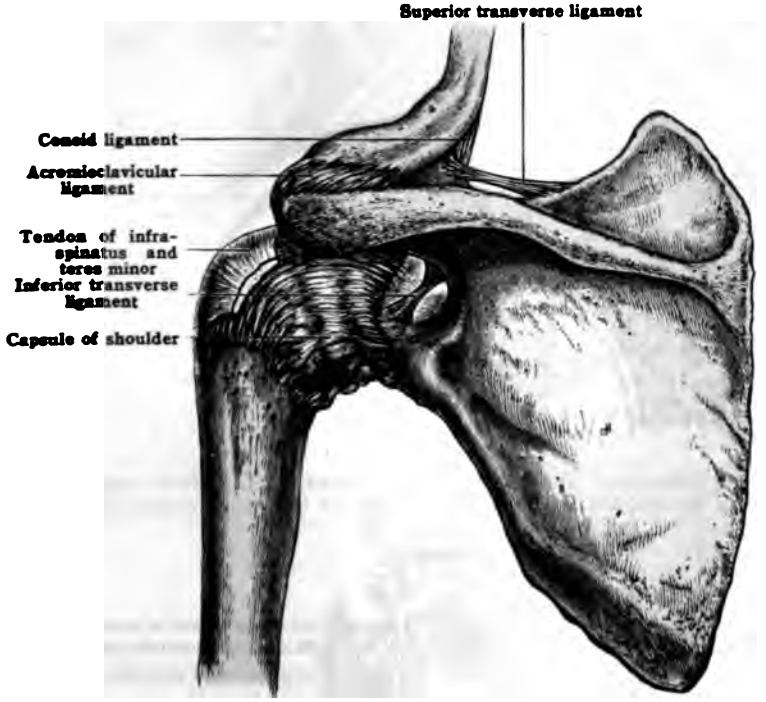
The inferior transverse (spinoglenoid) **ligament** (fig. 320) reaches from the lateral border of the spine of the scapula to the margin of the glenoid cavity, and so forms a foramen under which the transverse scapular (suprascapular) vessels and suprascapular nerve gain the infraspinous fossa. It is usually a weak membranous structure.

3. THE SHOULDER-JOINT

Class.—*Diarthrosis.* **Subdivision.**—*Enarthrodia.*

The shoulder-joint [articulatio humeri] is one of the most perfect and most movable of joints, the large upper end of the humerus playing upon the shallow glenoid cavity. Like the hip, it is a ball-and-socket joint. It is retained in position much less by ligaments than by muscles, and, owing to the looseness of its capsule, as well as to all the other conditions of its construction and position, it is exceedingly liable to be displaced; on the other hand, it is sheltered from violence by the two projecting processes—the acromion and coracoid.

FIG. 320.—POSTERIOR VIEW OF THE SHOULDER-JOINT, SHOWING ALSO THE ACROMIOCLAVICULAR JOINT AND THE SPECIAL LIGAMENTS OF THE SCAPULA.



The ligaments of the shoulder-joint are:—

Articular capsule.	Coracohumeral.
Glenohumeral.	Glenoid.

The articular capsule (figs. 319–321, also 1118) is a loose sac, insufficient in itself to maintain the bones in contact. It consists of fairly distinct but not coarse fibers, closely woven together, and directed, some straight, others obliquely, between the two bones, a few circular ones being interwoven amongst them. At the scapula, it is fixed on the dorsal aspect to the prominent rough surface around the margin of the glenoid cavity, reaching as far as the neck of the bone. Superiorly, it is attached to the root of the coracoid process; anteriorly, to the ventral surface, at a variable distance from the articular margin, often reaching 12 mm. upon the neck of the bone, and thus allowing the formation of a pouch; it may not, however, extend for more than 6 mm. beyond the articular margin; inferiorly, it blends with the origin of the long head of the triceps. At the humerus, the superior half is fixed to the anatomical neck, sending a prolongation downward between the two tuberosities which attenuates as it descends, and

covers the transverse humeral ligament. The lower half of the capsule descends upon the humerus further from the articular margin, some of the deeper fibers being reflected upward so as to be attached close to the articular edge, thus forming a kind of fibrous investment for the neck of the humerus. This ligament is more uniform in thickness than that of the hip.

Glenohumeral bands of the capsule (figs. 321, 322).—There are three accessory bands, known as the *superior*, *middle* and *inferior glenohumeral bands*, which project toward the interior of the joint from the fore part of the capsule and are consequently best seen when the joint is opened from behind.

FIG. 321.—VERTICAL SECTION THROUGH THE SHOULDER-JOINT TO SHOW THE GLENOHUMERAL LIGAMENT.
(The joint is opened from behind.)

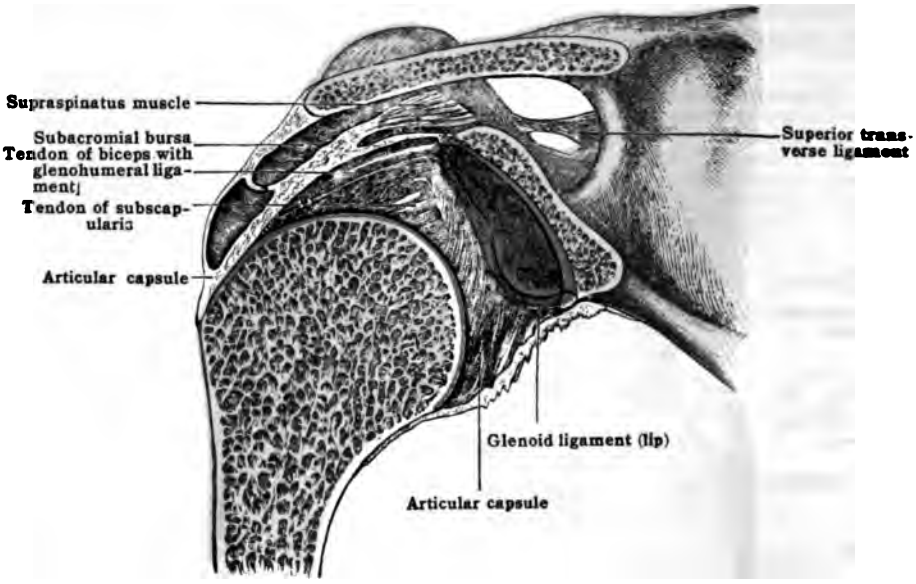


FIG. 322.—FETAL SHOULDER-JOINT, SHOWING THE GLENOHUMERAL LIGAMENT, AND ALSO THE SHORT HEAD OF THE BICEPS, BEING CONTINUOUS WITH THE CORACOACROMIAL LIGAMENT.

Short tendon of biceps running on into anterior band of coracoacromial ligament
Long tendon of biceps
Glenohumeral ligament
Capsule of shoulder, turned back
Subscapularis tendon, cut and turned laterally

The middle band reaches from the anterior margin of the glenoid cavity along the lower border of the subscapularis tendon to the lower border of the lesser tuberosity, and the inferior band from the inferior part of the glenoid cavity to the inferior part of the neck of the humerus. The superior band, known also as the glenohumeral ligament, runs from the edge of the glenoid cavity at the root of the coracoid process, just medial to the origin of the long tendon of the biceps, and, passing laterally and downward at an acute angle to the tendon, for which it forms a slight groove or sulcus, is fixed to a depression, the fovea capitis humeri, above the lesser tuberosity of the humerus. It is a thin, ribbon-like band, of which the superior surface is attached to the capsule, while the inferior is free and turned toward the joint. In the fetus it is often, and in the adult occasionally, quite free from the capsule, and may be as thick as the long tendon of the biceps (fig. 322).

The tendons of the supra- and infraspinatus, teres minor, and subscapularis muscles strengthen and support the capsule, especially near their points of insertion, and can be with difficulty dissected off from it. The long head of the triceps supports and strengthens the

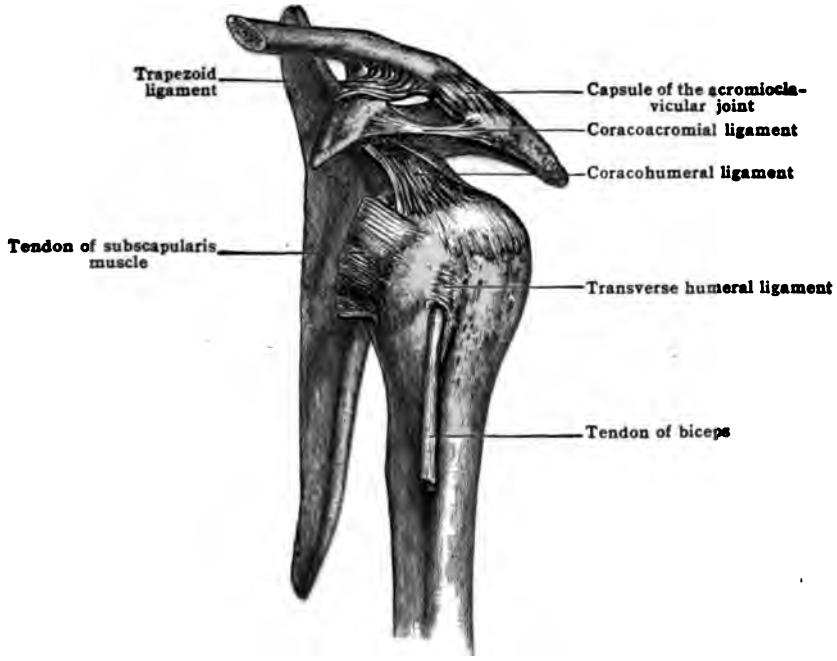
capsule below. The capsule also receives an upward slip from the pectoralis major. The supraspinatus often sends a slip into the capsule from its upper edge (fig. 321).

The **coracohumeral ligament** (fig. 323) is a strong broad band, which is attached above to the lateral edge of the root and horizontal limb of the coracoid process nearly as far as the tip. From this origin it is directed backward along the line of the biceps tendon to blend with the capsule, and is inserted into the greater tuberosity of the humerus.

Seen from the back, it looks like an uninterrupted continuation of the capsule, while from the front it looks like a fan-shaped prolongation from it overlying the rest of the ligament. At its origin there is sometimes a bursa between it and the capsule.

The **glenoid ligament** or **lip** [labrum glenoidale] (figs. 323, 325) is a narrow rim of dense fibrocartilage, which surrounds the edge of the glenoid socket and

FIG. 323.—LATERAL VIEW OF THE SHOULDER-JOINT, SHOWING THE CORACOHUMERAL AND TRANSVERSE HUMERAL LIGAMENTS.



deepens it. It is about 6 mm. wide above and below, but less at its sides. Its peripheral edge is inseparably attached, near the bone, with the articular capsule. Its structure is almost entirely fibrous, with but few cartilage cells intermixed. At the upper part of the fossa the **biceps tendon** is prolonged into the glenoid ligament, the tendon usually dividing and sending fibers right and left into the ligament, which may wind round nearly the whole circumference of the socket. It may, however, send fibers into one side only, usually into the lateral.

The **articular cartilage** covering the glenoid cavity is thicker at the circumference than in the center, thus tending to deepen the cavity. It is usually thickest at the lower part of the fossa; over the head of the humerus the cartilage is thickest at and below the center.

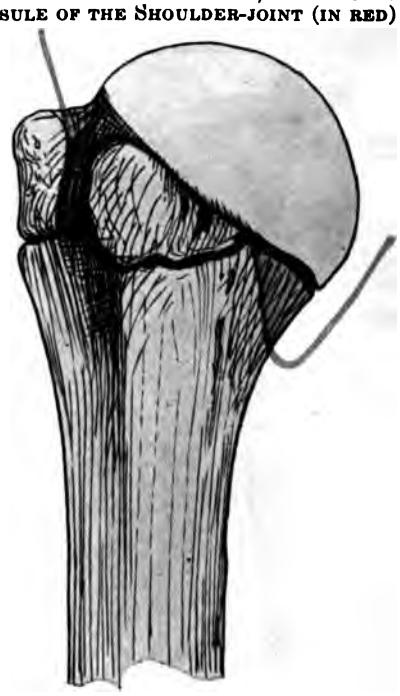
The **synovial membrane** lines the glenoid ligament, and is then reflected over the capsule as far as its attachment to the humerus, from which it ascends as far as the edge of the articular cartilage. The tendon of the biceps receives a long tubular sheath, which is continuous with the synovial membrane, both at its attached extremity and at the bicipital groove, but is free in the rest of its extent. The synovial cavity almost always communicates with the bursa under the subscapularis, and sometimes with one under the infraspinatus muscle.

It also sends a pouch-like prolongation beneath the coracoid process when the fibrous capsule is attached wide of the margin of the glenoid fossa. A few fringes are seen near the edge of the glenoid cavity, and there is often one which runs down the medial edge of the biceps tendon, extending slightly below it and making a slight groove for the tendon to lie in.

The **transverse humeral ligament** (fig. 323) is so closely connected with the capsule of the shoulder that, although it is a proper ligament of the humerus, it may well be described here. It is a strong band of fibrous tissue, which extends between the two tuberosities, roofing in the intertubercular (bicipital) groove. It is covered by a thin expansion of the capsule. It is limited to the portion of the bone above the line of the epiphysis.

Relations.—The following muscles are in contact with the capsule of the shoulder-joint. In front, the subscapularis; above, the supraspinatus; above and behind, the infraspinatus; behind, the teres minor; below, the long head of the triceps and the teres major. In the interval between the subscapularis and the supraspinatus the subacromial bursa is close to the capsule and occasionally its cavity communicates with the cavity of the joint.

FIG. 324.—THE UPPER EXTREMITY OF THE HUMERUS, ANTERIOR VIEW, TO SHOW THE RELATION OF THE ARTICULAR CAPSULE OF THE SHOULDER-JOINT (IN RED) TO THE EPIPHYSIAL LINE.



The axillary (circumflex) nerve and posterior circumflex artery pass beneath the capsule in the interval between the long head of the triceps, the humerus, and the teres major. When the arm is abducted, the long head of the triceps and the teres major are drawn into closer relation with the capsule and help to prevent dislocation of the humerus.

The axillary vessels, the great nerves of the axilla, the short head of the biceps, and the coracobrachialis are separated from the joint by the subscapularis, whilst the deltoid forms a kind of cap, which extends from the front to the back over the more immediate relations.

The **arterial supply** is derived from the transverse scapular (suprascapular), anterior and posterior circumflex, subscapular, circumflex scapular (dorsalis scapulæ), and a branch from the second portion of the axillary artery.

The **nerve-supply** is derived from the suprascapular, by branches in both fossæ; and from the axillary (circumflex) and subscapular nerves.

The **movements** (cf. p. 540) of the shoulder-joint consist of flexion, extension, adduction, abduction, rotation and circumduction.

Flexion is the swinging forward, *extension* the swinging backward, of the humerus; *abduction* is the raising of the arm from, and *adduction* depression of the arm to, the side. In flexion and extension the head of the humerus moves upon the center of the glenoid fossa round an oblique line corresponding to the axis of the head and neck of the humerus, flexion being more free than extension, and in extreme flexion the scapula follows the head of the humerus, so as to keep the articular surfaces in apposition. In extension the scapula moves much less, if at all. In abduction and adduction the scapula is fixed, and the humerus rolls up and down upon the glenoid fossa; during abduction the head descends until it projects beyond the lower edge of the glenoid cavity, and the greater tuberosity impinges against the arch of the acromion; during adduction, the head of the humerus ascends in its socket, the arm at length reaches the side, and the capsule is completely relaxed.

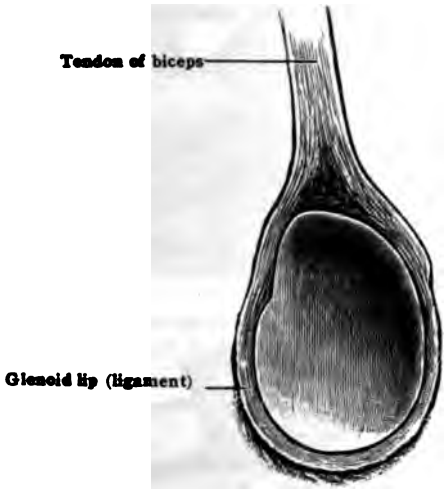
In *circumduction*, the humerus, by passing quickly through these movements, describes a cone, whose apex is at the shoulder-joint, and the base at the distal extremity of the bone. *Rotation* takes place round a vertical axis drawn through the extremities of the humerus from

the center of the head to the medial condyle; in rotation forward (that is, medialward) the head of the bone rolls back in the socket as the great tuberosity and shaft are turned forward; in rotation backward (that is, lateralward) the head of the bone glides forward, and the tuberosity and shaft of the humerus are turned backward, i. e., lateralward.

Great freedom of movement is permitted at the shoulder, and this is increased by the mobility of the scapula. Restraint is scarcely exercised at all upon the movements of the shoulder by the ligaments, but chiefly by the muscles of the joint. In abduction, the lower part of the capsule is somewhat, and in extreme abduction considerably, tightened; and in rotation medialward and lateralward, the upper part of the capsule is made tense, as is also, in the latter movement, the coracohumeral ligament.

The movements of abduction and extension have a most decided and definite resistance offered to them other than by muscles and ligaments, for the greater tuberosity of the humerus, by striking against the acromion process and coracoacromial ligament, stops short any further advance of the bone in these directions, and thus abduction ceases altogether as soon as the arm is raised to a right angle with the trunk, and extension shortly after the humerus passes the line of the trunk.

FIG. 325.—BICEPS TENDON, BIFURCATING AND JOINING THE GLENOID LIP.



Further elevation of the arm beyond the right angle, in the abducted or extended position, is effected by the rotation of the scapula round its own axis by the action of the trapezius and serratus anterior muscles upon the sternoclavicular and acromioclavicular joints respectively.

The acromion and coracoid process, together with the coracoacromial ligament, form an arch, which is separated by a bursa and the tendon of the supraspinatus from the capsule of the shoulder. Beneath this arch the movements of the joint take place, and against it the head and tuberosities are pressed when the weight of the trunk is supported by the arms; the greater tuberosity and the upper part of the shaft impinge upon it when abduction and extension are carried to their fullest extent.

No description of the shoulder-joint would be complete without a short notice of the peculiar relation which the biceps tendon bears to the joint. It passes over the head of the humerus a little to the medial side of its summit, and lies free within the capsule, surrounded only by a tubular process of synovial membrane. It is flat, with the surfaces looking upward and downward, until it reaches the intertubercular (bicipital) groove, when it assumes a rounded form. It strengthens the articulation along the same course as the coracohumeral ligament, and tends to prevent the head of the humerus from being pulled upward too forcibly against the inferior surface of the acromion. It also serves the purpose of a ligament by steadying the head of the humerus in various movements of the arm and forearm; it is let into a groove at the upper end of the bone, from which it cannot escape on account of the abutting tuberosities and the strong transverse humeral ligament which binds it down. Further, it acts like the four shoulder muscles which pass over the capsule, to keep the head of the humerus against the glenoid socket; and, moreover, it resists the tendency of the pectoralis major and latissimus dorsi muscles, in certain actions when the arm is away from the side of the body, to pull the head of the humerus below the lower edge of the cavity.

Muscles which act upon the shoulder-joint (cf. p. 397).—*Flexors or protractors.*—Deltoid (anterior fibers), pectoralis major (clavicular fibers), coracobrachialis, biceps (short head), subscapularis (upper fibers). *Extensors or retractors.*—Latissimus dorsi, deltoid (posterior fibers), teres major, teres minor, infraspinatus (lower fibers). *Abductors.*—Deltoid, supraspinatus, biceps (long head). *Adductors.*—Pectoralis major, latissimus dorsi, subscapularis, infraspinatus, teres major, teres minor, coracobrachialis, biceps (short head), triceps (lower head). *Medial rotators.*—Pectoralis major, latissimus dorsi, teres major, subscapularis, deltoid (anterior fibers). *Lateral rotators.*—Deltoid (posterior fibers), infraspinatus, teres minor. *Circumductors.*—The above groups acting consecutively.

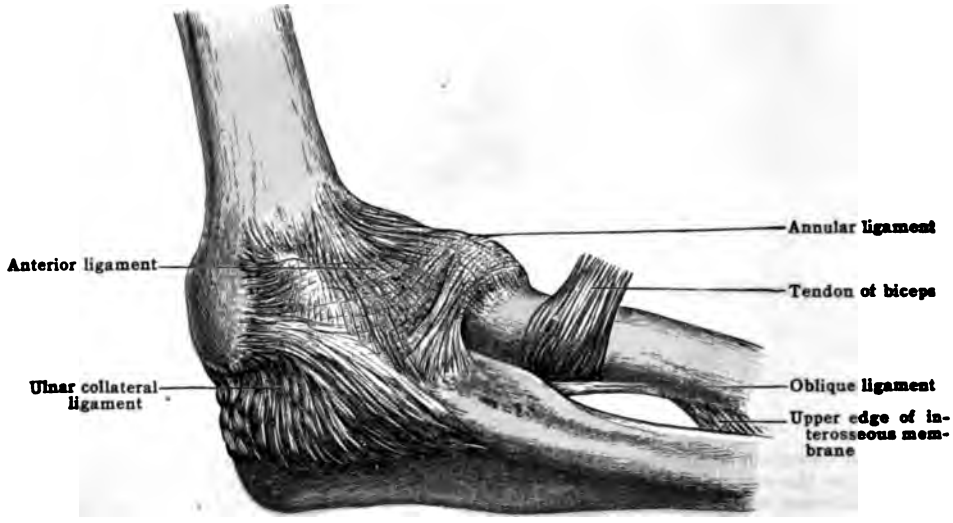
4. THE ELBOW-JOINT

Class.—*Diarthrosis.* **Subdivision.**—*Ginglymus.*

The elbow-joint [articulatio cubiti] is a complete hinge, and, unlike the knee, depends for its security and strength upon the configuration of its bones rather than on the number, strength, or arrangement of its ligaments. The bones composing it are the lower end of the humerus above, and the upper ends of the radius and ulna below; the articular surface of the humerus being received partly within the semilunar notch (great sigmoid cavity) of the ulna, and partly upon the cup-shaped area (fovea) of the radial head. Thus it will be noted that the elbow includes two articulations: the **humeroulnar** and **humeroradial joints.** Besides these which enter into the mechanism of the hinge movement, there is also present within the capsule of the elbow, the **proximal radioulnar articulation,** concerned in the movements of pronation and supination.

The ligaments of the elbow form one large and capacious capsule [capsula articularis], which, by blending with the annular ligament, and then passing on to

FIG. 326.—MEDIAL VIEW OF THE ELBOW-JOINT.



be attached to the neck of the radius, embraces the elbow and the superior radioulnar joints, uniting them into one (fig. 330). Laterally, it is considerably strengthened by superadded fibers arising from the epicondyles of the humerus and inseparably connected with the capsule. For convenience of description it will be spoken of as consisting of four portions:—

Anterior.	Medial.
Posterior.	Lateral.

The **anterior portion** (fig. 326) is attached to the front of the humerus above the articular surface and coronoid fossa, in an inverted V-shaped manner, to two very faintly marked ridges which start from the front of the medial and lateral epicondyles, and meet a variable distance above the coronoid fossa. Below, it is fixed, just beyond the articular margin, to the front of the coronoid process and it is intimately blended with the front of the annular ligament, a few fibers passing on to the neck of the radius.

It varies in strength and thickness, being sometimes so thin as barely to cover the synovial membrane; at others, thick and strong, and formed of coarse decussating fibers, the majority of which descend from the medial side laterally to the radius.

The **posterior portion** (fig. 327), thin and membranous, is attached superiorly to the humerus, in much the same inverted V-shaped way as the anterior; ascending from the medial epicondyle, along the medial side of the olecranon fossa nearly to the top; then, crossing the bottom of the fossa, it descends on the lateral

side, skirting the lateral margin of the trochlear surface, and turns laterally along the posterior edge of the capitulum. Inferiorly, it is attached to a slight groove along the superior and lateral surfaces of the olecranon, and the rough surface of the ulna just beyond the radial notch, and to the annular ligament, a few fibers passing on to the neck of the radius.

FIG. 327.—LATERAL VIEW OF THE ELBOW-JOINT.

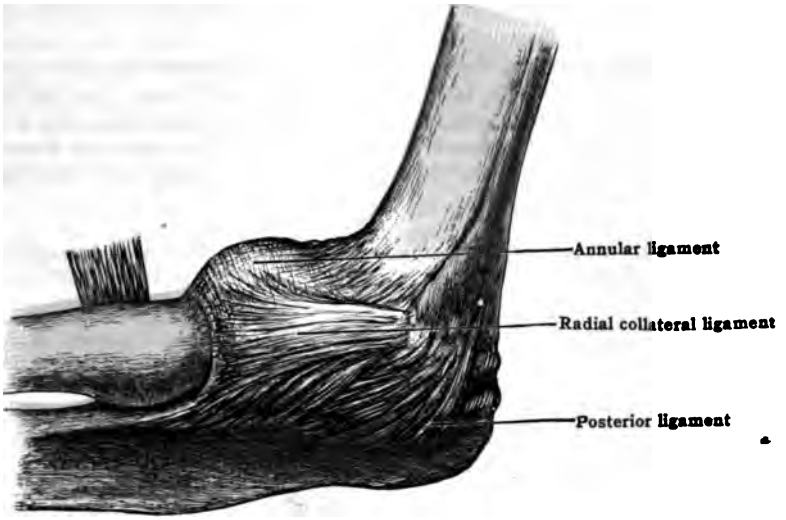


FIG. 328.—LOWER EXTREMITY OF THE HUMERUS, TO SHOW THE RELATION OF THE ARTICULAR CAPSULE OF THE ELBOW-JOINT (IN RED) TO THE EPIPHYSIAL LINES.

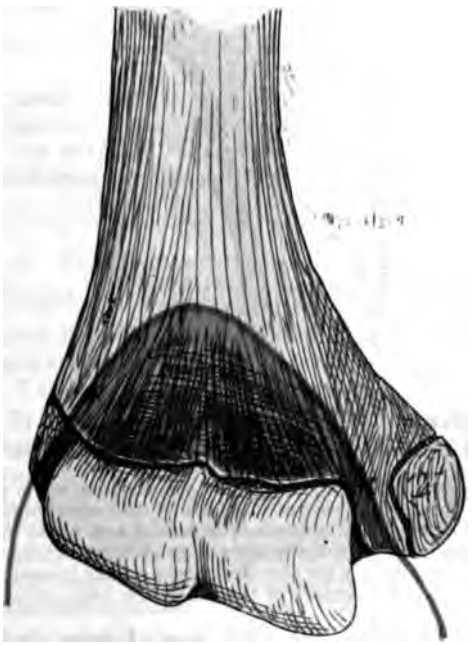


It is composed of decussating fibers, most of which pass vertically or obliquely downward, a few taking a transverse course at the summit of the olecranon fossa where the ligament is usually thinnest.

The medial portion, the ulnar collateral ligament (fig. 326), is thicker, stronger, and denser than either the anterior or posterior portions. It is triangular in form, its apex being attached to the anterior and inferior aspect of the medial epicondyle, and to the condyloid edge of the groove between the trochlea and the

condyle. The fibers radiate downward from this attachment, the anterior passing forward to be fixed to the rough overhanging medial edge of the coronoid process; the middle descend less obliquely to a ridge running between the coronoid and olecranon processes, while the posterior pass obliquely backward to the medial edge of the olecranon just beyond the articular margin.

An oblique band (the *oblique ligament* of Sir Astley Cooper) connects the margin of the olecranon process with the margin of the coronoid process. It lies superficial to the posterior fibers of the ulnar collateral ligament. Tne anterior fibers are the thickest, strongest, and most pronounced.

The **lateral portion,** the **radial collateral ligament** (fig. 327), is attached above to the lower part of the lateral epicondyle, and from this the fibers radiate to their attachment into the lateral side of the annular ligament, a few fibers being prolonged to reach the neck of the radius. The anterior fibers reach further forward than the posterior do behind. It is strong and well-marked, but less so than the medial portion.

FIG. 329.—THE UPPER EXTREMITY OF THE ULNA, TO SHOW THE RELATION OF THE ARTICULAR CAPSULE OF THE ELBOW-JOINT (IN RED) TO THE EPIPHYSIAL LINES.

The **synovial membrane** lines the whole of the capsule of the elbow-joint, and extends into the superior radioulnar joint, lining the annular ligament.

Outside the synovial membrane, but inside the capsule, are often seen some pads of fatty tissue; one is situated on the medial side at the base of the olecranon, another is seen on the lateral side projecting into the cavity between the radius and ulna; this latter, with a fold of synovial membrane opposite the front of the lateral lip of the trochlea, suggests the division of the joint into two parts—one medially for the ulna, and another laterally for the radius. There are also pads of fatty tissue at the bottom of the olecranon and coronoid fossæ, and at the tip of the olecranon process.

The **arterial supply** is derived from each of the vessels forming the free anastomosis around the elbow, and there is also a special branch to the front and lateral side of the joint, from the brachial artery, and the arterial branch to the brachialis also feeds the front of the joint.

The **nerve-supply** comes chiefly from the musculocutaneous; the ulnar, median, and radial (musculospiral) also gives filaments to the joint.

Relations.—In front of the joint, and in immediate relation with the capsule, are the brachialis, the superficial and deep branches of the radial (musculospiral) nerve, the radial recurrent artery, and the brachioradialis. The brachial artery, the median nerve, and the pronator teres are separated from the capsule by the brachialis. Directly behind the capsule are the triceps, the anconeus, and the posterior interosseous recurrent artery. On the medial side are the ulnar nerve, the superior ulnar collateral (inferior profunda) artery, and the upper

darts of the flexor carpi ulnaris and flexor digitorum sublimis. On the lateral side lie the extensor carpi radialis longus and the upper part of the common tendon of origin of the superficial extensors of the wrist and fingers.

The movements permitted at the elbow (cf. p. 541) are those of a true hinge-joint, viz., flexion and extension. These movements are oblique, so that the forearm is inclined medially in flexion, and laterally in extension; they are limited by the contact respectively of the coronoid and olecranon processes of the ulna with their corresponding fossæ on the humerus, and their extent is determined by the relative proportion between the length of the processes and depth of the fossæ which receive them, rather than by the tension of the ligaments, or the bulk of the soft parts over them. The anterior and posterior portions of the capsule, together with the corresponding portions of the collateral ligament, are not put on the stretch during flexion and extension; but, although they may assist in checking the velocity, and thus prevent undue force of impact, they do not control or determine the extent of these movements. The limit of extension is reached when the ulna is nearly in a straight line with the humerus; and the limit of flexion when the ulna describes an angle of from 30° to 40° with the humerus.

The obliquity of these movements is due to the lateral inclination of the upper and back part of the trochlear surface, and the greater prominence of the medial lip of the trochlea below; thus the plane of motion is directed from behind forward and medially, and carries the hand toward the middle third of the clavicle. The obliquity of the joint, the twist of the shaft of the humerus, and the backward direction of its head, all tend to bring the hand toward the midline of the body, under the immediate observation of the eye, whether for defence, employment, or nourishment. This is in striking contrast to the lower limb, where the direction of the foot diverges from the median axis of the trunk, thus preventing awkardness in locomotion. In flexion and extension, the cup-like depression of the radial head glides upon the capitulum, and the medial margin of the radial head travels in the groove between the capitulum and the trochlea. This allows the radius to rotate upon the humerus while following the ulna in all its movements. In full extension and supination, the head of the radius is barely in contact with the inferior surface of the capitulum, and projects so much backward that its posterior margin can be felt as a prominence at the back of the elbow. In full flexion the anterior edge of the radial head is received into, and checked against, the depression above the capitulum; while in midflexion the cup-like depression is fairly received upon the capitulum, and in this position, the radius being more completely steadied by the humerus than in any other, pronation and supination take place most perfectly.

Muscles which act upon the elbow-joint (cf. p. 411ff).—*Flexors.*—Brachialis, biceps, brachioradialis, pronator teres, flexor carpi radialis, palmaris longus, flexor digitorum sublimis, flexor carpi ulnaris. *Extensors.*—Triceps, anconeus, and the muscles from the lateral epicondyle.

5. THE UNION OF THE RADIUS WITH THE ULNA

The radius is firmly united to the ulna by two joints, and an intermediate fibrous union, viz.:—

(*a*) **The superior radioulnar**—whereat the head of the radius *rotates* within the radial notch and annular ligament.

(*b*) The **union of the shafts**—the **mid-radioulnar union.**

(*c*) The **inferior radioulnar**—whereat the lower end of the radius *rolls round* the head of the ulna.

(*a*) The Superior Radioulnar Joint

Class.—*Diarthrosis.* **Subdivision.**—*Trochoides.*

The bones which enter into this joint (which is often included with the elbow-joint) are the ulna by its radial notch and the radius by the smooth vertical border or rim on its head. There is but one ligament special to the joint, viz.:—

Annular ligament of the radius.

The annular ligament (fig. 330) consists of bands of strong fibers, somewhat thicker than the capsule of the elbow-joint, which encircle the head of the radius, retaining it against the side of the ulna. The bulk of these fibers forms about three-fourths of a circle, and they are attached to the anterior and posterior margins of the radial notch; some few are continued round below the radial notch, and form a complete ligamentous circle.

The ligament is inseparably connected along its upper edge and lateral (i. e., its nonarticular) surface with the anterior, posterior, and lateral portions of the capsule of the elbow, a few of the fibers of these portions, especially of the lateral, descending to be attached to the neck of the radius. The lower part of the articulation is covered in anteriorly, posteriorly, and laterally by a thin independent membranous layer, which passes from the lower edge of the annular ligament to the neck of the radius, strengthened on the lateral side by those fibers passing down from the capsule. They are loose enough to allow the bone to rotate upon its own axis (fig. 330). Medially and below the cavity is closed in by a loose membrane, the ligamentum quadratum, which passes from the lower border of the radial notch to the neck of the radius.

The **synovial membrane** is a continuation of that of the elbow-joint, and, after lining the annular ligament, passes on to the neck of the radius, and thence up to the lower margin of the articular cartilage. It forms the *recessus sacciformis.*

The arterial and nerve-supply are the same as those to the lateral part of the elbow-joint. **Relations.**—Behind lies the anconeus and in front the lateral border of the brachialis.

(*b*) The Mid-Radioulnar Union

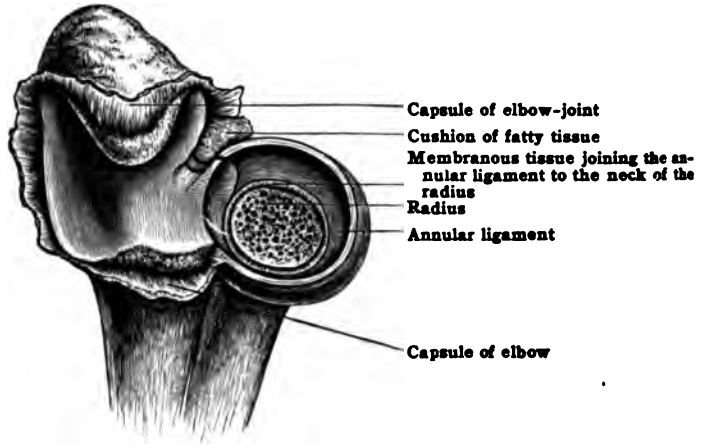
Class.—*Synarthrosis.* **Subdivision.**—*Syndesmosis.*

There are two interosseous ligaments which pass between the shafts of the bones and unite them firmly together, viz.:—

Oblique cord. Interosseous membrane.

The **oblique cord** [chorda obliqua] (figs. 326, 331) is a fairly strong, narrow band, which passes from the lower end of the rough lateral border of the coronoid process, downward and laterally to be attached to the posterior edge of the lower end of the tuberosity of the radius and the vertical ridge running from it to the medial border of the bone.

Fig. 330.—Annular Ligament and Capsule of the Elbow-joint.
(The head of the radius removed to show the membranous connection of the annular ligament with the radius.)



Capsule of elbow-joint
Cushion of fatty tissue
Membranous tissue joining the annular ligament to the neck of the radius
Radius
Annular ligament
Capsule of elbow

Some of its fibers blend with the fibers of insertion of the biceps tendon; behind, it is in close contact with the *supinator;* below, a thin membrane passes off from it to the upper edge of the interosseous membrane; the posterior interosseous vessels pass in the space between it and the interrosseous membrane; occasionally a slip is continued into the annular ligament of the superior radioulnar articulation (see fig. 331).

The **interosseous membrane** (fig. 326) is attached to the ulna at the lowest part of the ridge in front of the depression for the supinator, and along the whole length of the interosseous border as far as the inferior radioulnar articulation, approaching the front of the bone in the lower part of its attachment. To the radius it is attached along the interosseous border, from 2.5 cm. below the tuberosity to the ulnar notch for the lower end of the ulna.

It is strongest and broadest in the center, where the fibers are dense and closely packed; it is also well marked beneath the pronator quadratus, and thickens considerably at the lower end, forming a strong band of union between the two bones. Its fibers pass chiefly downward and medially, from the radius to the ulna, though some take the opposite direction; at the lower end some are transverse. On the posterior surface are one or two bands, which pass downward and laterally from the ulna to the radius, and frequently there is a strong bundle as large as the oblique cord; this, which may be called the **inferior oblique ligament** (fig. 336), stretches from the ulna, an inch and a half above its lower extremity, downward and laterally to the ridge above and behind the ulnar notch of the radius.

At its attachment to the bones, the interosseous membrane blends with the periosteum. Its upper border is connected with the oblique cord by a thin membrane, which is pierced by the posterior interosseous vessels; and the lower border, which stretches across between the two bones just above the inferior radioulnar articulation, assists in completing the capsule of that

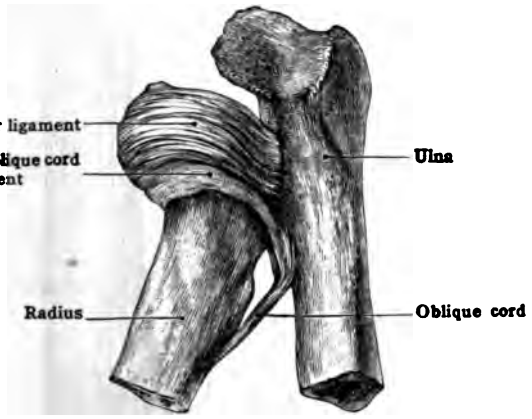
int. Its anterior surface is in relation with the flexor digitorum profundus and flexor pollicis ngus in the upper three-quarters, the lower fourth being in relation with the pronator quad- tus. The anterior interosseous vessels and nerve descend along the middle of the membrane, e artery being bound down to it. About an inch from the lower end it is pierced by the nterior interosseous artery. The posterior surface is in relation with the supinator, abductor ollicis longus, extensor pollicis longus and brevis, and the extensor indicis proprius; at its lower art, also with the posterior branch of the anterior interosseous artery, and the deep branch of the adial nerve (posterior interosseous).

(*c*) The Inferior Radioulnar Joint

Class.—*Diarthrosis.* **Subdivision.**—*Trochoides.*

This is, in one respect, the reverse of the superior; for the radius, instead of presenting a circular head to rotate within a concavity of the ulna, presents a concave surface which rolls round the head of the ulna. The articulation may be said to consist of two parts at right angles to each other; one between the radius and ulna, and the other between the ulna and the articular disk (triangular fibrocartilage).

Fig. 331.—Upper Portions of Left Ulna and Radius, to show an Occasional Slip from the Oblique Cord to the Lower Part of the Annular Ligament.
(From a dissection by Mr. W. Pearson, Royal College of Surgeons, England.)



The ligaments are:—

Anterior radioulnar. Posterior radioulnar.

Articular disk

The **articular disk** (triangular fibrocartilage) (figs. 336, and 337) assists the adius in forming an arch under which is received the first row of carpal bones. ts base is attached to the margin of the radius, separating the ulnar notch from he articular surface for the carpus, while its apex is fixed to the fossa at the base f the styloid process of the ulna. It gradually and uniformly diminishes in vidth from base to apex, becoming rounded where it is fixed to the ulna; it is oined by fibers of the ulnar collateral ligament of the wrist.

The articular disk measures about 1 cm. from side to side and from before backward. It s thicker at the circumference than in the center; smooth and concave above to adapt itself o the ulna, and smooth and slightly concave below to fit over the triquetral bone. Its anterior nd posterior borders are united to the anterior and posterior radioulnar and radiocarpal liga- nents. It is the most important structure in the inferior radiocarpal articulation, as it is a ery firm bond of union between the lower ends of the bones, and serves to limit their movements pon one another more than any other structure in either the upper or lower radioulnar joints. ts structure is fibrous at the circumference, while in the center there is a preponderance of cells. t differs from all other fibrocartilages in entering into two distinct articulations; and separates ntirely the synovial membrane of the radioulnar joint from that of the wrist.

The lower end of the **interosseous membrane** extends between the ulna and adius immediately above their points of contact. Transverse fibers between the wo bones form a sort of arch above the concave articular facet of the radius, and, oining the anterior and posterior radioulnar ligaments, complete the **articular apsule** of the inferior radioulnar joint. The ligaments represent merely hickenings of the capsule.

The **anterior radioulnar ligament** (fig. 333) is attached by one end to the anterior edge of the ulnar notch of the radius, and by the other to the rough bone above the articular surface of the ulna as far medially as the notch, as well as into the anterior margin of the triangular cartilage from base to apex.

The **posterior radioulnar ligament** (fig. 334) is similarly attached to the posterior margin of the ulnar notch at one end, and at the other to the rough bone above the articular surface of the extremity of the ulna as far medially as the groove for the extensor carpi ulnaris, with the sheath of which it is connected, as well as into the whole length of the posterior margin of the articular disk. Both the radioulnar ligaments consist of thin, almost scattered, fibers.

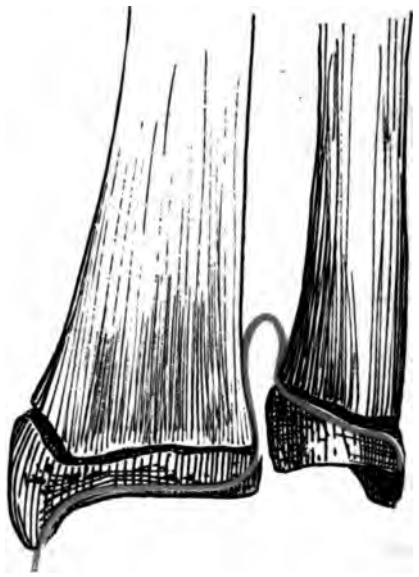
The **synovial membrane** is large and loose in proportion to the size of the joint reaching upward between the radius and ulna above the level of their articular surfaces to form the **recessus sacciformis.** The synovial cavity extends between the terminal articular surface of the ulna and the upper surface of the articular disk.

The **arterial supply** is derived from the volar interosseous artery and branches of the volar carpal rete.

The **nerve-supply** comes from the volar interosseous of the median, and the deep branch of the radial (posterior interosseous).

Relations.—Behind lies the tendon of the extensor digiti quinti proprius and in front the flexor digitorum profundus.

FIG. 332.—LOWER EXTREMITIES OF THE RADIUS AND ULNA TO SHOW THE RELATION OF THE ARTICULAR CAPSULE OF THE WRIST JOINT (IN RED) TO THE EPIPHYSIAL LINES. Note the upward extension of the membrana sacciformis.



The movements of the radius (cf. p. 541).—The upper end of the radius rotates upon an axis drawn through its own head and neck within the collar formed by the radial notch and the annular ligament, while the lower end, retained in position by the articular disk rolls round the head of the ulna. This rotation is called *pronation*, when the radius from a position nearly parallel to the ulna turns medialward so as to lie obliquely across it; and *supination*, when the radius turns back again, so as to uncross and lie nearly parallel with the ulna. In these movements the radius carries with it the hand, which rotates on an axis passing along the ulnar side of the hand; thus, the hand when pronated lies with its dorsum upward, as in playing the piano, while when supinated, the palm lies upward—the attitude of a beggar asking alms. Ward thus expresses the relations of the two extremities of the radius in pronation and supination: 'The head of the radius is so disposed in relation to the sigmoid cavity (ulnar notch) at the lower end that the axis of the former if prolonged falls upon the center of the circle of which the latter is a segment;' the axis thus passes through the lower end of the ulna at a point at which the articular disk is attached, and if prolonged further, passes through the ring finger. Thus the radius describes, in rotating, a blunt-pointed cone whose apex is the center of the radial head, and whose base is at the wrist; partial rotation of the bone being unaccompanied by any hinge-like or anteroposterior motion of its head, and pronation and supination occurring without disturbance to the parallelism of the bones at the superior radioulnar joint. Associated with this rotation in the ordinary way, there is some rotation of the humeroulnar shaft, which causes lateral shifting of the hand from side to side; thus, with pronation there is some abduction, and with supination some adduction combined, so that the hand can keep on the same superficies in both pronation and supination. The power of supination in man is much greater than pronation, owing to the immense power and leverage obtained by the curve of the radius, and by the attachment of the biceps tendon to the back of the tuberosity. For this reason all our screw-driving and boring tools are made to be used by supination movements.

In the undissected state, the amount of rotation it is possible to obtain is about 135°, so t neither the palm nor the fore part of the lower end of the radius can be turned completely pposite directions; yet in the living subject this amount can be greatly increased by rotation he humeroulnar shaft at the shoulder-joint.

Pronation is checked in the living subject by (a) the posterior inferior radioulnar ligament, ch is strengthened by the connection of the sheath of the extensor tendons with it; (b) the ermost fibers of the interosseous membrane; (c) the back part of the ulnar collateral and scent fibers of the posterior ligament of the wrist, and (d) the meeting of the soft parts on front of the forearm.

Supination is checked mainly (a) by the medial ulnar collateral ligaments of the wrist, but tly also by (b) the oblique cord; (c) the anterior inferior radioulnar ligament, and (d) the est fibers of the interosseous membrane.

The interosseous membrane serves, from the direction of its fibers downward and medially m the radius to the ulna, to transmit the weight of the body from the ulna to the radius in extended position of the elbow, as in pushing forward with the arms extended, or in support- one's own weight on the hands, the ulna being in intimate contact with the humerus, but t at all with the carpus; while the area of contact of the radius with the humerus is small, d that of the radius with the carpus large. Hence the weight transmitted by the ulna is mmunicated to the radius by the tightening of the interosseous membrane. Conversely, in ls upon the hand with the arm extended, the interosseous membrane acts as a sling to break e violence of the shock, and prevents the whole force of the impact from expending itself rectly upon the capitulum.

Muscles which act upon the radioulnar joints (cf. p. 416).—*Pronators.*—Pronator teres, onator quadratus, flexor carpi radialis, palmaris longus. *Supinators.*—Biceps, supinator, tensor pollicis longus. The brachioradialis is chiefly a flexor of the elbow-joint, but it takes art in the initiation of the movements of supination, when the hand is fully pronated, and of ronation when the hand is fully supinated.

6. THE RADIOCARPAL OR WRIST-JOINT

Class.—*Diarthrosis.* **Subdivision.**—*Condylarthrosis.*

The wrist-joint is formed by the union of the radius and articular disk above, rticulating with the navicular, lunate, and triquetral bones below; the ulna eing excluded by the intervention of the articular disk. The radius and disk ogether present a smooth surface, slightly concave both from before backward, nd from side to side, whilst the three bones of the carpus present a smooth, onvex surface, made uniformly even by the interosseous ligaments which bind hem together.

The capsule of the wrist-joint has been usually described as four separate liga- nents, and it will be convenient for the sake of a complete description to follow his method; but it must be understood that these four portions are continuous round the joint, extending from styloid process to styloid process on both its spects.

The four portions are:—

Volar radiocarpal.	Ulnar collateral.
Dorsal radiocarpal.	Radial collateral.

The **volar** (or anterior) **radiocarpal** [lig. radiocarpeum volare] (fig. 333) is a hick strong ligament, attached superiorly to the radius immediately above the nterior margin of the terminal articular facet, to the curved ridge at the root of he styloid process of the radius, and to the anterior margin of the articular disk, blending with some fibers of the capsule of the inferior radioulnar joint. It passes lownward and in a medial direction to be attached to both rows of carpal bones, specially the second, and to the volar intercarpal ligament.

The strongest and most oblique fibers arise from the root of the styloid process of the radius, nd pass obliquely over the navicular, with which only a few fibers are connected, to be inserted nto the lunate, capitate, and triquetral bones. Another set, less oblique, passes from the nargin of the facet for the lunate to be attached to the adjacent parts of the capitate, hamate, nd triquetral bones. Between the two sets of fibers, small vessels pass into the joint.

The **dorsal** (or posterior) **radiocarpal ligament** [lig. radiocarpeum dorsale] fig. 334) is attached above to the dorsal edge of the lower end of the radius, the ack of the styloid process, and the posterior margin of the fibrocartilage. It asses downward and in a medial direction to be connected with the first row of f the carpal bones, chiefly with the lunate and triquetral, and the dorsal inter- arpal ligament. This ligament is thin and membranous.

It is strengthened by (i) strong fibers passing from the back of the articular disk where hey are blended with the posterior inferior radioulnar ligament, and, from the edge of the radius

just behind the ulnar notch, to the triquetral bone; (ii) from the ridge and groove for the extensor pollicis longus to the back of the lunate and triquetral bones; and (iii) from the groove for the radial extensors to the back of the navicular and lunate. It is in relation with, and strengthened by, the extensor tendons which pass over it.

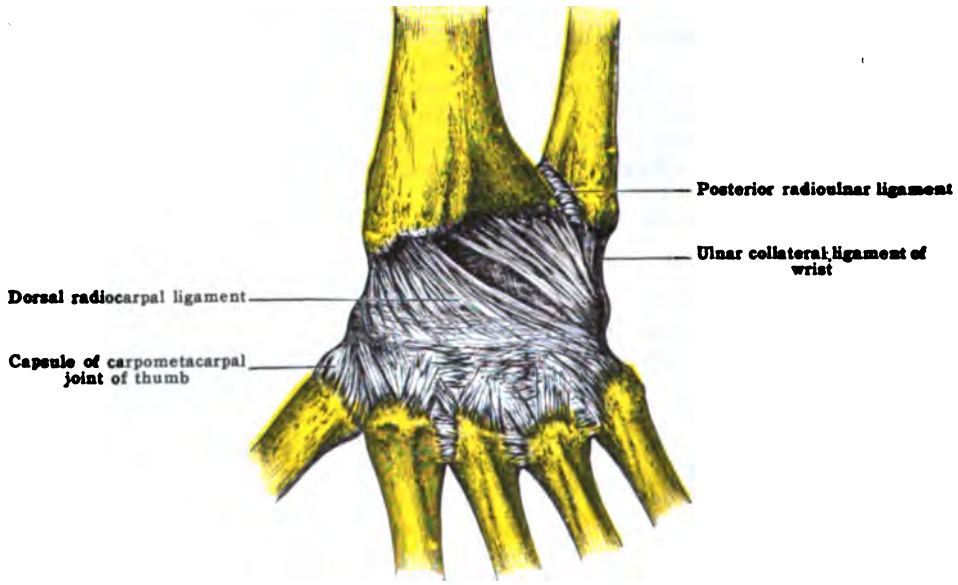
FIG. 334.—POSTERIOR VIEW OF WRIST-JOINT.



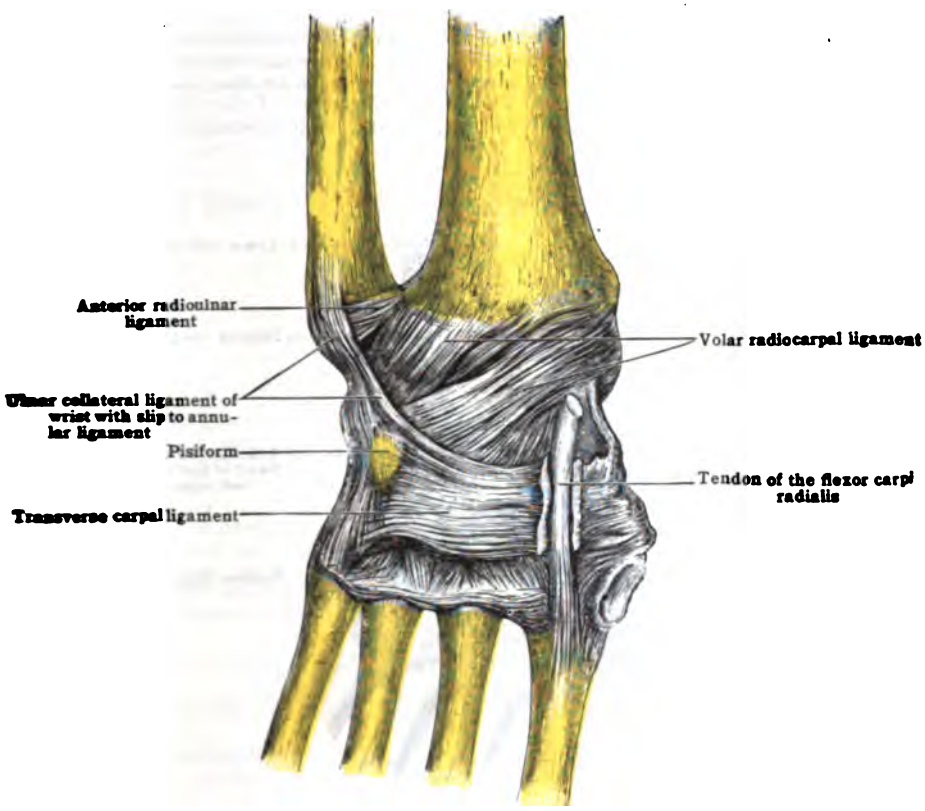
Posterior radioulnar ligament
Ulnar collateral ligament of wrist
Dorsal radiocarpal ligament
Capsule of carpometacarpal joint of thumb

The **ulnar collateral ligament** (fig. 334) is fan-shaped, with its apex above, at the styloid process of the ulna, to which it is attached on all sides, blending with the apex of the articular disk. Some of the fibers pass forward and laterally to the base of the pisiform bone and to the medial part of the upper border of the transverse carpal ligament, where it is attached to the pisiform bone; they form a thick, rounded fasciculus on the front of the wrist. Other fibers descend vertically to the medial side of the triquetral bone, and others again laterally to the dorsal surface of the triquetral. The tendon of the extensor carpi ulnaris is posterior to, and passes over, part of the fibers of the ligament.

The radial collateral ligament (fig. 333) consists of fibers which radiate from the fore part and tip of the styloid process of the radius. Some pass downward and medially, in front, to the navicular and adjacent edge of the capitate; some downward, a little forward and medially, to the tubercle of the navicular and ridge of the greater multangular; and others downward and laterally to the rough dorsal surface of the navicular.

The fibers of this ligament are not so long and strong, nor do they radiate so much as those of the ulnar collateral ligament. It is in relation with the radial artery, and the abductor pollicis longus and extensor pollicis brevis, the artery separating the tendons from the ligament.

FIG. 335.—FRONT OF WRIST WITH TRANSVERSE CARPAL LIGAMENT.



Anterior radioulnar ligament
Volar radiocarpal ligament
Ulnar collateral ligament of wrist with slip to annular ligament
Pisiform
Tendon of the flexor carpi radialis
Transverse carpal ligament

The **synovial membrane** is extensive, but does not usually communicate with the synovial membrane of the inferior radioulnar joint, being shut out by the articular disk. It is also excluded, in almost every instance, from that of the carpal joints by the interosseous ligaments between the first row of carpal bones. The styloid process of the radius is cartilage-covered medially, and forms part of the articular cavity, while that of the ulna does not.

The arterial supply is derived from the anterior and posterior carpal rami, the dorsal division of the volar interosseous, and from twigs direct from the radial and ulnar arteries.

The nerve-supply is derived from the ulnar and median in front, and the deep branch of the radial (posterior interosseous) behind.

Relations.—In front of the radiocarpal joint are the tendons of the flexor muscles of the wrist and fingers, the synovial sheaths associated with them, the radial and ulnar arteries, and the median and ulnar nerves.

Behind the joint are the majority of the tendons of the extensor muscles of the wrist and fingers, with their synovial sheaths, the terminal part of the anterior and posterior interosseous arteries, and the deep branch of the radial nerve (posterior interosseous). On the radial side lie the tendons of the abductor pollicis longus and the extensor pollicis brevis. On the ulnar side the joint is subcutaneous and is crossed by the dorsal cutaneous branch of the ulnar nerve.

Movements (cf. p. 541).—The wrist is a condyloid joint, the carpus forming the condyle. It allows of movements upon a transverse axis, i. e., flexion and extension; and around an antero-posterior axis, i. e., abduction and adduction; together with a combination of these in quick succession—circumduction. Lacking only rotation on a vertical axis, it thus possesses most of the movements of a ball-and-socket joint, without the weakness and liability to dislocation

which are peculiar to these joints. This deficiency of rotation is compensated for by the movements of the radius at the radioulnar joints, viz., supination and pronation. Its strength depends chiefly upon the number of tendons which pass over it, and the close connection which exists between the fibrous tissue of their sheaths and the capsule of the wrist; also upon the proximity of the mediocarpal and carpometacarpal joints, which permits shocks and jars to be shared and distributed between them; another source of strength is the absence of any long bone on the distal side of the joint. In flexion and extension the carpus rolls backward and forward, respectively, beneath the arch formed by the radius and articular disk; flexion being limited by the dorsal ligament and dorsal portions of the collateral; extension by the volar, and volar portions of the collateral ligaments. In adduction and abduction the carpal bones glide from the ulnar to the radial side and from the radial to the ulnar side, respectively. Abduction is more limited than adduction, and is checked by the ulnar collateral ligament and by contact of the styloid process of the radius with the greater multangular; adduction is checked by the radial collateral ligament alone. One reason for adduction being more free than abduction is that the ulna does not reach so low down as the radius, and the yielding articular disk allows of greater movement upward of the ulnar end of the carpus. In circumduction the hand moves so as to describe a cone, the apex of which is at the wrist. These movements are made more easy and extensive by the slight gliding of the carpal bones upon one another, and the comparatively free motion at the mediocarpal joint. The oblique direction of the fibers of the collateral ligaments prevents any rotation at the radiocarpal joint, while it permits considerable freedom of abduction and adduction.

FIG. 336.—POSTERIOR VIEW OF THE WRIST, WITH CAPSULE CUT TO SHOW ARTICULAR SURFACES.

Muscles which act upon the radiocarpal joint (cf. p. 416).—*Flexors.*—The flexors of the carpus and the long flexors of the fingers and the thumb, and the palmaris longus. *Extensors.*—The extensors of the carpus and fingers. *Abductors.*—Extensor carpi radialis longus, the abductor pollicis longus. *Adductor.*—Flexor carpi ulnaris, extensor carpi ulnaris.

7. THE CARPAL JOINTS

The joints of the carpus [articulatio intercarpea] may be subdivided into:—

(*a*) The **joints of the first row.**
(*b*) The **joints of the second row.**
(*c*) The **mediocarpal**, or junction of the two rows with each other.

(*a*) THE JOINTS OF THE FIRST ROW OF CARPAL BONES

Class.—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

The bones of the first row, the pisiform excepted, are united by two sets of ligaments and two interosseous fibrocartilages.

Dorsal. Interosseous. Volar.

The **two dorsal intercarpal ligaments** extend transversely between the bones, and connect the navicular with the lunate, and the lunate with the triquetral. Their posterior surfaces are in contact with the posterior ligament of the wrist.

The two volar intercarpal ligaments extend nearly transversely between the bones connecting **the navicular** with the lunate, and the lunate with the triquetral. They are stronger than **the dorsal ligaments**, and are placed beneath the anterior ligament of the wrist.

The two interosseous intercarpal ligaments (fig. 337) are interposed between the navicular **and lunate**, and the lunate and triquetral bones, reaching from the dorsal to the volar surfaces, **and being** connected with the dorsal and volar ligaments. They are narrow fibrocartilages **which extend** between small portions only of the osseous surfaces. They help to form the **convex carpal** surface of the radiocarpal joint, and are somewhat wedge-shaped, their bases **being** toward the wrists, and their thin edges between the adjacent articular surfaces of the bones.

The synovial membrane is a prolongation from that of the mediocarpal joint.

The arterial and **nerve-supplies** are the same as for the mediocarpal joint.

The Joint of the Pisiform Bone with the Triquetral

This [articulatio ossis pisiformis] is an arthrodial joint which has a loose **fibrous capsule** attached to both the pisiform and triquetral bones just beyond the **margins** of their articular surfaces.

It is lined by a separate synovial membrane. Two strong rounded or flattened bands pass **downward** from the pisiform, one to the process of the hamate [lig. pisohamatum], and the **other** [lig. pisometacarpeum] to the bases of the third to fifth metacarpals; these are regarded as **prolongations** of the tendon of the flexor carpi ulnaris, and the pisiform bone may be looked **upon** in the light of a sesamoid bone developed in that tendon.

(*b*) The Joints of the Second Row of Carpal Bones

Class.—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

The four bones of this row are united by three dorsal, three volar, and three interosseous ligaments.

The three dorsal ligaments (fig. 336) extend transversely and connect the greater with the lesser multangular, the lesser multangular with the capitate, and the capitate with the hamate.

The three volar ligaments are stronger than the dorsal, and are deeply placed beneath the **mass** of flexor tendons; they extend transversely between the bones in a manner similar to that of the dorsal ligaments.

Three interosseous ligaments connect the bones of the lower row of the carpus together. Two are connected with the capitate, one uniting it with the hamate (fig. 337) and the other binding it to the lesser multangular. The third ligament joins the greater and lesser multangular.

The **synovial membrane** is a prolongation of that lining the mediocarpal joint.

The **arterial** and **nerve-supplies** are the same as for the mediocarpal joint.

(*c*) The Mediocarpal Joint between the Two Rows of the Carpus

Class.—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

The inferior surfaces of the bones of the first row are adapted to the superior articular surfaces of the bones of the second row. The line of this articulation is concavo-convex from side to side, and is sometimes described as having the course of a Roman S placed horizontally, ∽, a resemblance by no means strained. (i) The lateral part of the first row consists of the navicular alone; it is convex, and bears the greater and lesser multangulars. (ii) Then follows a transversely elongated socket formed by the medial part of the navicular, the lunate, and triquetral, into which are received—(*a*) the head of the capitate, which articulates with the navicular and lunate; (*b*) the upper and lateral angle of the hamate, which articulates with the navicular; and (*c*) the upper convex portion of the medial surface of the hamate, which articulates with the lateral and concave portion of the interior surface of the triquetral. (iii) The medial part of the inferior surface of the triquetral bone is convex, and turned a little backward to fit into the lower portion of the medial surface of the hamate, which is a little concave and turned forward to receive it. The central part, which forms a socket for the capitate and hamate, has somewhat the character of a condyloid joint, the capitate and hamate being the condyle, to fit into the cavity formed by the navicular, lunate, and triquetral; the other portions are typically arthrodial. The ligaments are:—(1) **radiate or anterior mediocarpal**; (2) **posterior mediocarpal**; (3) **transverse dorsal.**

The radiate, anterior or volar mediocarpal is a ligament of considerable strength, consisting **mostly of fibers which radiate from the capitate to the navicular, lunate, and triquetral; some few fibers connect the greater and lesser** multangular with the navicular, and others pass **between the hamate and triquetral.** It is covered over and thickened by fibrous tissue derived

from the sheaths of the flexor tendons and the fibers of origin of the small muscles of the thumb and little finger.

The posterior or **dorsal mediocarpal ligament**, consists of fibers passing obliquely from the bones of the first row to those of the second. It is stronger on the ulnar side than on the radial, but is not so strong as the volar ligament.

The **transverse dorsal ligament** (fig. 336) is an additional band, well marked and often of considerable strength, which passes across the head of the capitate from the navicular to the triquetral bone; besides binding down the head of the capitate, it serves to fix the upper and lateral angles of the hamate in the socket formed by the first row.

The dorsal ligamets, like the volar, are strengthened by a quantity of fibrous tissue belonging to the sheaths of the extensor tendons, and by an extension of some of the fibers of the capsule of the wrist. There are no proper collateral mediocarpal ligaments; they are but prolongations of the collateral ligaments of the wrist.

Synovial sac of the wrist-joint
Synovial sac of the carpometacarpal joint of the thumb
Collateral ligaments of the metacarpophalangeal and interphalangeal joints

The **synovial membrane** (fig. 337) of the carpus is common to all the joints of the carpus, and extends to the bases of the four medial metacarpal bones. Thus, besides lining the inter- or mediocarpal joint, it sends two processes upward between the three bones of the first row, and three downward between the contiguous surfaces of the lesser and greater multangular, the lesser multangular and capitate, and capitate and hamate. From these latter, prolongations extend to the four medial carpometacarpal joints and the three intermetacarpal joints.

The **arterial supply** is derived from—(*a*) the volar and dorsal carpal rami of the radial and ulnar arteries; (*b*) the carpal branch of the volar interosseous; (*c*) the recurrent branches from the deep volar arch. The terminal twigs of the volar and dorsal interosseous arteries supply the joint on its dorsal aspect.

The **nerve-supply** comes from the ulnar on the ulnar side, the median on the radial side, and the deep branch of the radial (posterior interosseous) behind.

Relations.—The relations of this joint are practically the same as those of the radiocarpal nt, except that the flexor carpi ulnaris does not cross the front, the ulnar artery is separated om it by the transverse carpal ligament, and the radial artery passes across its lateral border stead of in front.

The movements of the carpal articulations between bones of the same row are very limited d consist only of slight gliding upon one another; but, slight as they are, they give elasticity the carpus and break the jars and shocks which result from blows or falls upon the hand.

The movements of one row of bones upon the other at the mediocarpal joint are more tensive, especially in the direction of flexion and extension, so that the hand enjoys a greater nge of these movements than is permitted at the wrist-joint alone. At the wrist, extension is ore free than flexion; but this is balanced by the greater freedom of flexion than of extension the mediocarpal joint, and by flexion at the carpometacarpal joint, so that on the whole the nge of flexion of the hand is greater than that of extension.

A slight amount of side-to-side motion accompanied by a limited degree of rotation also kes place; this rotation consists in the head of the capitate and the superior and lateral angle f the hamate bone rotating in the socket formed by the three bones of the upper row, and in a liding forward and backward of the greater and lesser multangular upon the navicular.

In addition to the ligaments, the undulating outline and the variety of shapes of the apposed ccets render this joint very secure.

Bearing in mind the mobility of this mediocarpal joint and the carpometacarpal, we see t once the reason for the radial and ulnar flexors and extensors of the carpus being prolonged own to their insertion into the base of metacarpus, for they produce the combined effect f motion at each of the three transverse articulations:—(1) at the wrist; (2) at the mediocarpal; 3) at the carpometacarpal joints.

Muscles which act upon the midcarpal joint.—The muscles which act upon this joint are he same as those which act upon the radiocarpal joint.

8. THE CARPOMETACARPAL JOINTS

These may be divided into two sets, namely:—

(*a*) The **carpometacarpal joints of the four medial fingers.**
(*b*) The **carpometacarpal joints of the thumb.**

The inferior surfaces of the bones of the second row of the carpus present a omposite surface for the four medial metacarpal bones; the greater multangular resents in addition a distinct and separate saddle-shaped surface for the base of ıe metacarpal bone of the thumb.

(*a*) The Four Medial Carpometacarpal Joints

Class.—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

These joints exist between the greater and lesser multangular, capitate, and amate bones above, and the four medial metacarpal bones below. The liga- ents which unite them are, dorsal, volar and interosseous.

The dorsal ligaments (fig. 336).—Three dorsal ligaments pass to the second metacarpal ne: one from each of the carpal bones with which it articulates, viz., the greater and lesser ultangular, and capitate. Two dorsal bands pass from the capitate to the third metacarpal ne. Two dorsal bands pass to the fourth bone: viz., one from the hamate, and another from e capitate; the latter is sometimes wanting. The fifth bone has only one band passing to it om the hamate.

The volar ligaments (fig. 333).—One strong band passes from the second metacarpal bone the greater multangular medial to the ridge for the transverse carpal ligament; it is covered r the sheath of the flexor carpi radialis.

Three bands pass from the third metacarpal: one laterally to the greater multangular, a iddle one upward to the capitate, and a third medially over the fourth to reach the fifth meta- rpal and the hamate bones.

One ligament connects the fourth bone to the hamate.

One ligament connects the fifth bone to the hamate, the fibers extending medially, and con- ecting the dorsal and volar ligaments. The ligament to the fifth bone is strengthened in front r the prolonged fibers of the flexor carpi ulnaris and the strong medial slip of the ligament of e third metacarpal bone; and posteriorly, by the tendon of the extensor carpi ulnaris.

The interosseous ligament (fig. 337) is limited to one part of the articulation, and consists short fibers connecting the contiguous angles of the hamate and capitate with the third and urth metacarpal bones toward their volar aspect. There is, however, a thick strong ligament nnecting the edge of the greater multangular with the lateral border of the base of the second etacarpal bone; it helps to separate the carpometacarpal joint of the thumb from the common rpometacarpal joint, and to close in the radial side of the latter joint.

The synovial membrane is a continuation of the mediocarpal joint; occasionally there is separate membrane between the hamate and fourth and fifth metacarpal bones (fig. 337); hile that between the fourth and capitate is lined by the synovial sac of the common joint.

The arteries to the four medial carpometacarpal joints are as follows:—

(1) For the index finger: twigs are supplied by the trunk of the radial on the dorsal and volar pects, and by the dorsal and volar metacarpal branches. (2) For the middle finger: the first

dorsal metacarpal by the branch which passes upward to join the dorsal carpal arch, and a branch from the deep volar arch which joins the volar carpal arch. (3) For the ring finger: the deep volar arch and recurrent twigs from the second dorsal metacarpal in the same manner as for the middle finger. (4) For the little finger: the ulnar and its deep branch; also twigs from the second dorsal metacarpal.

The **nerves** are supplied to these joints by the deep volar branch of the ulnar, the deep branch of the radial (posterior interosseous), and the median.

Relations.—In front of the four medial carpometacarpal joints are the flexors of the fingers with their synovial sheath. The flexor carpi radialis crossing in front of the lateral part of the joint and the fibers of the oblique adductor pollicis which spring from the capitate and lesser multangular are also anterior relations. Behind the joints are the extensors of the wrist and fingers with their synovial sheaths and the dorsal metacarpal arteries. At the lateral border of the joints between the index and lesser multangular lies the radial artery.

The **movements** permitted at these joints (cf. p. 541), though slight, serve to increase those of the mediocarpal and wrist-joints. The joint between the fifth metacarpal and the hamate bones approaches somewhat in shape and mobility the first carpometacarpal joint; it has a greater range of flexion and extension, but its side-to-side movement is nearly as limited as that of the three other metacarpal bones; the process of the hamate bone limits its flexion. Motion toward the ulnar side is checked by the strong palmar band which unites the base of the fifth metacarpal to the base of the third, and the strong transverse ligament at the head of the bones. The mobility of the second, third, and fourth metacarpal bones is very limited, and consists almost entirely of a slight gliding upon the carpal bones, i. e., flexion and extension; that of the third and fourth bones is extremely slight, as there is no long flexor attached to either; but, owing to the close connection of the bases of the metacarpal bones, the radial and ulnar flexors and extensors of the carpus act on all by their pull on the particular bone into which they are inserted.

Abduction, or movement toward the radial side, is prevented by the impaction of the second bone against the greater multangular; a little adduction is permitted, and is favored by the slope given to the hamate and fifth metacarpal bones.

There is also a slight gliding between the fourth and fifth bones, when the concavity they present toward the palm is deepened to form the 'cup of Diogenes.'

Muscles which act upon the four medial carpometacarpal joints are the flexors and extensors of the wrist and fingers (cf. p. 437).

(*b*) The Carpometacarpal Joint of the Thumb

Class.—*Diarthrosis.* **Subdivision.**—*Ephippial.*

The bones entering into this joint are the base of the first metacarpal and the greater multangular. The first metacarpal bone diverges from the other four, contrasting very strongly with the position of the great toe. It is due to this divergence that the thumb is able to be opposed to each and all the fingers. The ligament which unites the bones is the

Articular capsule.

The **articular capsule** (figs. 333, 334) consists of fibers which pass from the margin of the articular facet on the greater multangular, to the margin of the articular facet at the base of the first metacarpal bone.

The fibers are stronger on the dorsal than on the volar aspect. They are not tense enough to hold the bones in close contact, so that while they restrict they do not prevent motion in any direction. The medial fibers are stronger than the lateral.

The **synovial membrane** is lax, and distinct from the other synovial membranes of the carpus.

The **arteries** of the carpometacarpal joint of the thumb are derived from the trunk of the radial, the first volar metacarpal, and the dorsalis pollicis.

The **nerves** are supplied by the branches of the median to the thumb.

Relations.—Behind are the long and short extensor tendons of the thumb, and behind and laterally the tendon of the abductor pollicis longus. The tendon of the flexor pollicis longus is in front and fibers of the flexor pollicis brevis and opponens pollicis muscles are also anterior relations. To the medial side is the radial artery as it passes forward into the palm of the hand.

The **movements** of this joint (cf. p. 541) are regulated by the shape of the articular surfaces, rather than by the ligaments, and consist of flexion, extension, abduction, adduction, and circumduction, but not rotation. In flexion and extension the metacarpal bone slides to and fro upon the multangular; in abduction and adduction it slides from side to side or, more correctly, revolves upon the anteroposterior axis of the joint. The power of opposing the thumb to any of the fingers is due to the forward and medial obliquity of its flexion movement, which is by far its most extensive motion. Abduction is very free, while adduction is limited on account of the proximity of the second metacarpal bone. The movement of the greater multangular upon the rest of the carpus somewhat increases the range of all the movements of the thumb.

Muscles which act upon the carpometacarpal joint of the thumb (cf. p. 437).—*Flexors.*—Flexor pollicis brevis, flexor pollicis longus, opponens pollicis. *Extensors.*—Extensores pollicis brevis and longus and abductor pollicis longus. *Abductors.*—Abductores pollicis longus and brevis. *Adductors.*—The transverse and oblique adductor pollicis, opponens, first dorsal interosseous. *Muscles producing opposition.*—Opponens, flexor brevis oblique adductor.

9. THE INTERMETACARPAL ARTICULATIONS

Class.—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

The metacarpal of the thumb is not connected with any other metacarpal bone. The second, third, fourth, and fifth metacarpal bones are in actual contact at their bases, and are held firmly together by the following ligaments (in addition to the articular capsule):—

Dorsal. Interosseous ligaments. Volar.

The dorsal ligaments (fig. 335) are layers of variable thickness of strong, short fibers, which pass transversely from bone to bone, filling up the irregularities on the dorsal surfaces.

The volar ligaments are transverse layers of ligamentous tissue passing from bone to bone; they cannot be well differentiated from the other ligaments and fibrous tissue covering the bones.

The interosseous ligaments (fig. 337) pass between the apposed surfaces of the bones, and are attached to the distal sides of the articular facets, so as to close in the synovial cavities on this aspect; where there are two articular facets, the fibers extend upward between them nearly as far as their carpal facets. That between the fourth and fifth is the weakest.

The synovial membrane is prolonged downward from the common carpal sac.

The arteries to the intermetacarpal joints are twigs from the volar and dorsal metacarpal arteries; the twigs pass upward between the interosseous muscles.

The nerves are derived from the ulnar and the deep branch of radial (posterior interosseous).

The Union of the Heads of the Metacarpal Bones

The distal extremities of these bones are connected together on their volar aspects by what is called the **transverse ligament** [ligg. capitulorum transversa]. This consists of three short bands of fibrous tissue, which unite the second and third, third and fourth, and the fourth and fifth bones. They are rather more than 6 mm. deep, and rather less in width, and limit the distance to which the metacarpal bones can be separated. They are continuous above with the fascia covering the interosseous muscles; below, they are connected with the subcutaneous tissue of the web of the hand. They are on a level with the front surface of the bones, and are blended on either side with the edges of the glenoid ligament in front, with the lateral ligaments of the metacarpophalangeal joint, and also with the sheaths of the tendons. In front, a lumbrical muscle passes with the digital arteries and nerves; while behind, the interossei muscles pass to their insertions.

10. THE METACARPOPHALANGEAL JOINTS

(*a*) The Metacarpophalangeal Joints of the Four Medial Fingers

Class.—*Diarthrosis.* **Subdivision.**—*Condylarthrosis.*

In these joints the cup-shaped extremity of the base of the first phalanx fits on to the rounded head of the metacarpal bone, and is united by the following ligaments (in addition to the articular capsule):—

Collateral. Volar accessory.

The volar accessory (or glenoid) **ligament** (fig. 338) is a fibrocartilaginous plate which seems more intended to increase the depth of the phalangeal articular facet in front, than to unite the two bones. It is much more firmly attached to the margin of the phalanx than to the metacarpal bone, being only loosely connected with the palmar surface of the latter by some loose areolar tissue which covers in the synovial membrane, here prolonged some little distance upon the surface of the bone. At the sides, it is connected with the collateral ligaments and the transverse metacarpal ligament. A sesamoid bone sometimes exists at the medial border of the joint of the little finger.

The collateral ligaments (337 and 338) are strong and firmly connect the bones with one another; each is attached above to the corresponding tubercle, and to a depression in front of the tubercle, of the metacarpal bone. From this point the fibers spread widely as they descend on either side of the base of the phalanx; the anterior fibers are connected with the accessory volar ligament; the posterior blend with the tendinous expansion at the back of the joint.

The joint is covered in **posteriorly** by the expansion of the extensor tendon, and some loose areolar tissue passing from its under surface to the bones (fig. 338).

The synovial membrane is loose and capacious, and invests the inner surface of the ligaments which connect the bones.

The arteries come from the digital or volar metacarpal vessels of the deep arch.

The nerves are derived from the digital branches, or from twigs of the branches of the ulnar to the interosseous muscles.

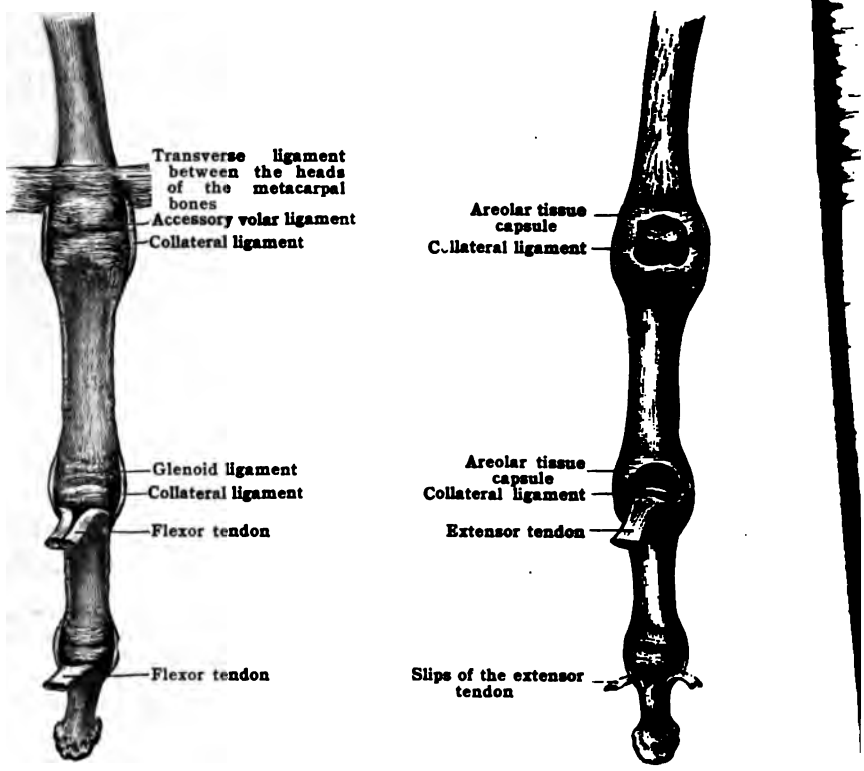
Relations.—1. The metacarpophalangeal joints of the middle three digits. In front the tendons of the flexor profundus and flexor sublimis digitorum. On the radial side, a lumbrical, an interosseous muscle, and digital nerves and vessels; on the ulnar side, an interosseous muscle and digital vessels and nerves. Behind, the common extensor tendon and in the case of the index digit the tendon of the extensor indicis.

2. The metacarpophalangeal joint of the little finger. In front, the flexor digiti quinti brevis and the tendons of the flexor profundus and sublimis digitorum muscle which go to

this digit. Behind, the extensor digiti quinti to a slip of the extensor digitorum communis sometimes. On the radial side, a lumbrical, the third palmar interosseous muscle, digital vessels and nerves. On the ulnar side, digital vessels and nerves.

The movements permitted at these joints (cf. p. 542) are flexion, extension, abduction, adduction, and circumduction. Flexion is the most free of all and may be continued until the phalanx is at a right angle with the metacarpal bone. This is in accord with the fact that the articular surface of the head of the bone is prolonged so much further on the volar aspect, and that the synovial membrane is here so loose and ample. Extension is the most limited of the movements, and can only be carried to a little beyond the straight line. Abduction and adduction are fairly free, but not so free as flexion. Flexion is associated with adduction, and extension with abduction. This may be proved by opening the hand, when the fingers involuntarily separate as they extend, while in closing the fist they come together again. The free abduction, adduction, and circumduction which are permitted at these joints are due to the fact that the long axes of the articular facets are at right angles to one another.

FIG. 338.—ANTERIOR AND POSTERIOR VIEWS OF LIGAMENTS OF THE FINGERS.



Muscles acting on the middle three digits.—*Flexors.*—Flexor digitorum profundus, flexor digitorum sublimis, lumbricales. *Extensors.*—Extensor digitorum communis and on the index digit the extensor indicis. *Abductors.*—Dorsal interossei. *Adductors.*—Volar interossei.

Muscles acting on the metacarpophalangeal joint of the little finger.—*Flexors.*—Flexor digiti quinti brevis, flexor digitorum sublimis, flexor digitorum profundus, lumbricalis. *Extensors.*—Extensor digitorum communis, extensor digiti quinti. *Abductor.*—Abductor digiti quinti. *Adductor.*—Third volar interosseous.

(*b*) THE METACARPOPHALANGEAL JOINT OF THE THUMB

Class.—*Diarthrosis* **Subdivision.**—*Ginglymus.*

The head of the metacarpal bone of the thumb differs considerably from the corresponding ends of the metacarpal bones of the fingers. It is less convex, wider from side to side, the volar edge of the articular surface is raised and irregular, and here on either side of the median line are the two facets for the sesamoid bones. The base of the first phalanx of the thumb, too, is more like the base of the second phalanx of one of the other fingers. The ligaments are:—

Collateral. Articular capsule. Dorsal.

The collateral ligaments are short, strong bands of fibers, which radiate from depressions on either side of the head of the metacarpal bone to the base of the first phalanx and sesamoid

As they descend they pass a little forward, so that the greater number are inserted in
f the center of motion.
dorsal ligament consists of scattered fibers which pass across the joint from one col-
ligament to the other, completing the **articular capsule** and protecting the synovial sac.
sesamoid bones are two in number, situated on either side of the middle line, and con-
together by strong transverse fibers which form the floor of the groove for the long
endon; they are connected with the base of the phalanx and head of the metacarpal bone
ng fibers. Anteriorly they give attachment to the short muscles of the thumb, and pos-
are smooth for the purpose of gliding over the facets. The collateral ligaments are
inserted into their sides.
arteries and **nerves** come from the digital branches of the thumb.
ations—Of the metacarpophalangeal joint of the thumb: In front and externally
or pollicis brevis and superficial head of flexor pollicis brevis. In front and medially
and transverse adductors and deep head of flexor pollicis brevis. Directly in front,
pollicis longus and terminal branches of first volar metacarpal artery. Behind, extensor
brevis and longus tendons. On either side, the dorsal digital vessels and the digital

movements (cf. p. 542) are chiefly flexion and extension, very little side-to-side move-
being permitted, and that only when the joint is slightly bent. Thus this joint more
approaches the simple hinge character than the corresponding articulations of the fingers.
umb gets its freedom of motion at the carpometacarpal joint; the fingers get theirs at
tacarpophalangeal, but they are not endowed with so much freedom as the thumb

scles which act upon the metacarpophalangeal joint of the thumb—*Flexors*.—Flexor
brevis, flexor pollicis longus. *Extensors*—Extensor pollicis brevis, extensor pollicis

11. THE INTERPHALANGEAL ARTICULATIONS

Class.—*Diarthrosis.* **Subdivision.**—*Ginglymus.*

ie ligaments which unite the phalanges of the thumb and of the fingers are
dition to the articular capsule):—

Accessory volar. Collateral.

accessory volar (or glenoid) **ligament** (fig. 338), sometimes called the sesamoid body,
firmly connected with the base of the distal bone, and loosely, by means of fibroareolar
with the head of the proximal one. It blends with the collateral ligaments at the sides,
er it pass the flexor tendons. Occasionally a sesamoid bone is developed in the cartilage
nterphalangeal joint of the thumb.
collateral ligaments (figs. 337, 338) are strong bands which are attached to the rough
ions on the sides of the upper phalanx, and to the projecting margins of the lower phalanx
joint. They are tense in every position, and entirely prevent any side to side motion;
e connected posteriorly with the expansion of the extensor tendon.
sually (fig. 338) the joint is covered in by the deep surface of the extensor tendon, and a
broareolar tissue extends from the tendon, and thickens the posterior portion of the
al sac, completing the **articular capsule**.
synovial membrane is loose and ample, and extends upward a little way along the shaft
proximal bone.
arteries and **nerves** come from their respective digital branches.
relations of the interphalangeal joints are the flexor and extensor tendons and the
vessels and nerves.
movements are limited to flexion and extension (see fig. 462). Flexion is more free,
be continued till one bone is at a right angle to the other, and is most free at the junction
first and second bones; the second phalanx can be flexed on the first through 110° to
hen the latter is not flexed. The greater freedom of flexion is due to the greater extent of
icular surface in front of the heads of the proximal bones, and to the direction of the
f the collateral ligaments, which pass a little forward to their insertion into the distal

muscles which act upon the interphalangeal joints are the extensors and flexors of
its and the lumbricales.

THE ARTICULATIONS OF THE LOWER LIMB

e articulations of the lower limb are the following:—

1. The **hip-joint.**
2. The **knee-joint.**
3. The **tibiofibular union.**
4. The **ankle-joint.**
5. The **tarsal joints.**
6. The **tarsometatarsal joints.**
7. The **intermetatarsal joints.**
8. The **metatarsophalangeal joints.**
9. The **interphalangeal joints.**

1. THE HIP-JOINT

Class.—*Diarthrosis.* **Subdivision.**—*Enarthrodia.*

The hip-joint [articulatio coxæ] is the most typical example of a ball-and-socket joint in the body, the round head of the femur being received into the cup-shaped cavity of the acetabulum (figs. 342, 1139). Both articular surfaces are coated with cartilage, that covering the head of the femur being thicker above where it has to bear the weight of the body, and thinning out to a mere edge below; the pit for the ligamentum teres is the only part uncoated, but the cartilage is somewhat heaped up around its margin. Covering the acetabulum, the cartilage is horseshoe-shaped, and thicker above than below, being deficient over the depression at the bottom of the acetabulum, where a mass of fatty tissue—the so-called synovial or Haversian gland—is lodged.

The ligaments of the joint are:—

Articular capsule.	Ligamentum teres.
Transverse.	Glenoid lip.

The **articular capsule** is one of the strongest ligaments in the body. It is large and somewhat loose, so that in every position of the body some portion of

FIG. 339.—ANTERIOR VIEW OF THE ARTICULAR CAPSULE OF THE HIP-JOINT.

Iliofemoral ligament
Pubocapsular ligament

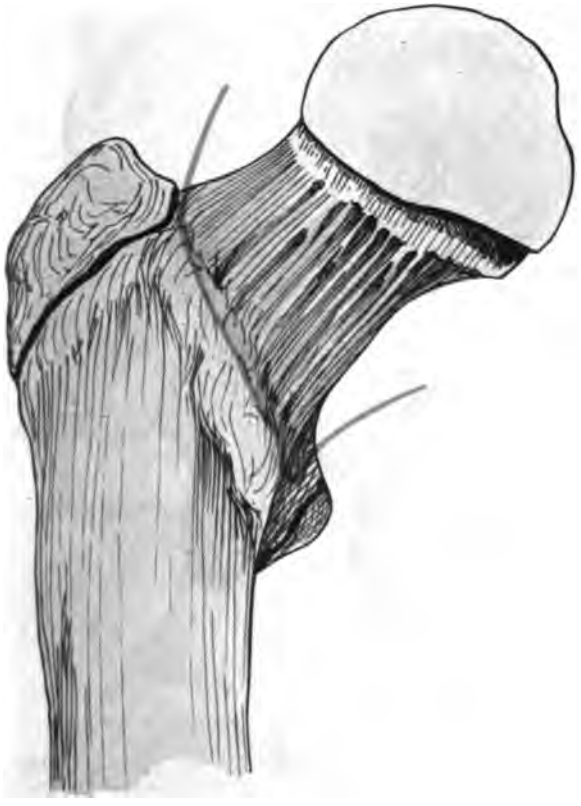
it is relaxed. At the pelvis it is attached, superiorly, to the base of the anterior inferior iliac spine; curving backward, it becomes blended with the deep surface of the reflected tendon of the rectus femoris; posteriorly, it is attached a few millimeters from the acetabular rim; and below, to the upper edge of the groove between the acetabulum and tuberosity of the ischium. Thus it reaches the transverse ligament, being firmly blended with its outer surface, and frequently sends fibers beyond the notch to blend with the obturator membrane. Anteriorly it is attached to the pubis near the obturator notch, to the iliopectineal eminence and thence backward to the base of the inferior iliac spine.

A thin strong stratum is given off from its superficial aspect behind; this extends beneath the gluteus minimus and small rotators, to be attached above to the dorsum of the ilium higher

than the reflected tendon of the rectus, and posteriorly to the ilium and ischium nearly as far as the sciatic notch. As this expansion passes over the long tendon of the rectus, the tendon may be described as being in part contained within the substance of the capsule.

At the femur, the capsule is fixed to the anterior portion of the upper border of the great trochanter and to the cervical tubercle. Thence it runs down the intertrochanteric line as far as the medial border of the femur, where it is on a level with the lower part of the lesser trochanter. It then runs upward and backward along an oblique line about 1.6 cm. in front of the lesser trochanter, and continues its ascent along the back of the neck nearly parallel to the intertrochanteric crest, and from 12 to 16 mm. above it; finally, it passes along the medial side of the trochanteric fossa to reach the anterior superior angle of the great trochanter.

FIG. 340.—UPPER EXTREMITY OF THE FEMUR (ANTERIOR VIEW), TO SHOW THE RELATION OF THE ARTICULAR CAPSULE OF THE HIP-JOINT (IN RED) TO THE EPIPHYSEAL LINES.



On laying open the capsule, some of the deeper fibers are seen reflected upward long the neck of the femur, to be attached much nearer the head: these are the retinacula. One corresponds to the upper, and another to the lower, part of the intertrochanteric line; a third is seen at the upper and back part of the neck. They form flat bands, which lie on the femoral neck.

Superadded to the capsule, and considerably strengthening it, are three auxiliary bands, whose fibers are intimately blended with, and in fact form part of, the capsule, viz., the iliofemoral, ischiocapsular, and pubocapsular ligaments.

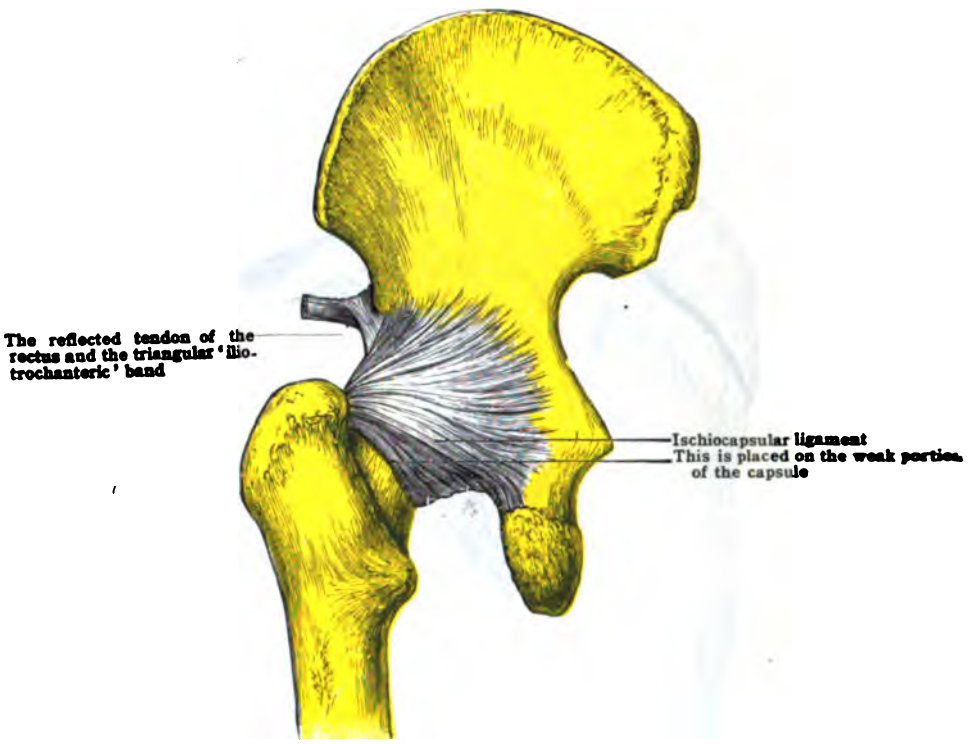
The iliofemoral ligament (fig. 339) is the longest, widest, and strongest of the bands. It is of triangular shape, with the apex attached above to a curved line on the ilium immediately below and behind the anterior inferior spine, and its base below to the anterior edge of the greater trochanter and to the spiral line as far as the medial border of the shaft. The highest or most lateral fibers are coarse, almost straight, and shorter than the rest; the most medial fibers are also thick and strong, but oblique. This varying obliquity of the fibers, and their accumulation at the borders, explain why this band has been described as the Y-shaped ligament; but it should be noted that the Y is inverted. About the center of its base, near the femoral attachment, is an aperture transmitting an articular twig from the ascending branch of the external circumflex artery.

The ischiocapsular ligament (fig. 341) is formed of very strong fibers attached all along the upper border of the groove for the external obturator, and to the ischial margin of the ace-

tabulum above the groove. The highest of these incline a little upward as they pass laterally to be fixed to the greater trochanter in front of the insertion of the piriformis tendon, while the other fibers curve more and more upward as they pass laterally to their insertion at the inner side of the trochanteric fossa, blending with the insertion of the external rotator tendons. When the joint is in flexion, these fibers pass in nearly straight lines to their femoral attachment, and spread out uniformly over the head of the femur; but in extension they wind over the back of the femur in a zonular manner [*zona orbicularis*], embracing the posterior aspect of the neck of the femur.

The **pubocapsular** (**pectineofemoral**) ligament (fig. 339) is a distinct but narrow set of fibers which are individually less marked than the fibers of the other two bands; they are fixed above to the obturator crest and to the anterior border of the iliopectineal eminence, reaching as far down as the pubic end of the acetabular notch. Below, they reach the neck of the femur, and are fixed above and behind the lowermost fibers of the iliofemoral band, with which they blend.

FIG. 341.—POSTERIOR VIEW OF THE ARTICULAR CAPSULE OF THE HIP-JOINT.



The reflected tendon of the rectus and the triangular 'ilio-trochanteric' band
Ischiocapsular ligament
This is placed on the weak portion of the capsule

In **thickness** and strength the capsule varies greatly; thus, if two lines be drawn, one from the anterior inferior spine to the medial border of the femur near the lesser trochanter, and the other from the anterior part of the groove for the external obturator to the trochanteric fossa, all the ligament between these lines on the lateral and upper aspects of the joint is very thick and strong, while that below and to the medial side, except at the narrow pubocapsular ligament, is thin and weak, so that the head of the bone can be seen through it. The capsule is thickest in the course of the iliofemoral ligament, toward the lateral part of which it measures over 6 mm. Between the iliofemoral and ischiocapsular ligaments the capsule is very strong, and with it here, near the acetabulum, is incorporated the reflected tendon of the rectus, and here also a triangular band of fibers runs downward and forward to be attached by a narrow insertion to the ridge on the front border of the great trochanter near the gluteus minimus (the **iliotrochanteric band**) (fig. 341).

The capsule is strengthened also at this point by a strong band from the under surface of the gluteus minimus, and by the **tendinotrochanteric band** which passes down from the reflected tendon of the rectus to the vastus lateralis (externus) (fig. 339). This is closely blended with the capsule near the lateral edge of the iliofemoral ligament.

The thinnest part of the capsule is between the pubocapsular and iliofemoral ligaments; this is sometimes perforated, allowing the bursa under the psoas to

communicate with the joint. The capsule is also very thin at its attachment to the back of the femoral neck, and again opposite the acetabular notch.

The ligamentum teres (figs. 342, 343) is an interarticular flat band which extends from the acetabular fossa to the head of the femur, and is usually about

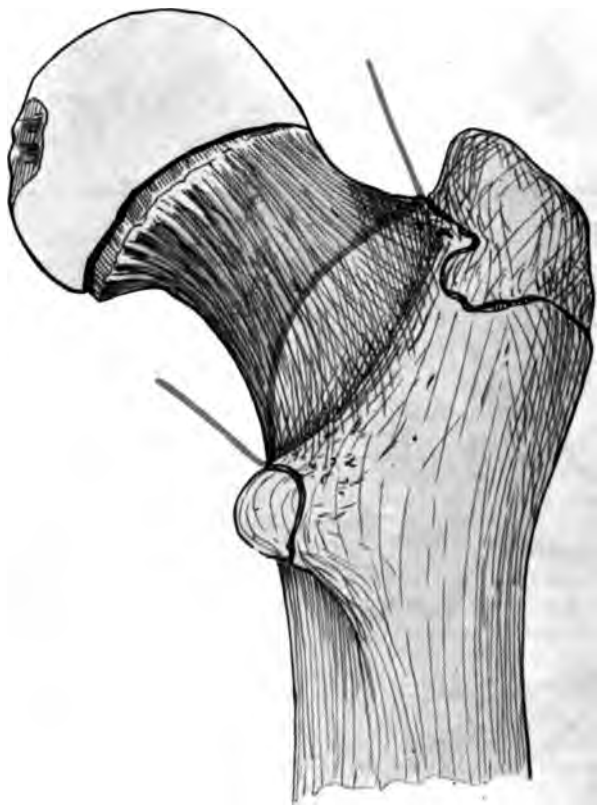
3.7 cm. long. It has two bony attachments, one on either side of the acetabular notch immediately below the articular cartilage, while intermediate fibers spring from the lower surface of the transverse ligament. The ischial portion is the stronger, and has several of its fibers arising outside the cavity, below and in

connection with the origin of the transverse ligament, where it is also continuous with the capsule and periosteum of the ischium. At the femur it is fixed to the front part of the depression on the head, and to the cartilage round the margin of the depression.

FIG. 344.—PORTIONS OF ISCHIUM AND PUBIS, SHOWING THE ACETABULAR NOTCH AND THE LIGAMENTUM TERES ATTACHED OUTSIDE THE ACETABULUM.

It is covered by a prolongation of synovial membrane, which also covers the cushion of fat in the recess of the acetabulum; the portion of the membrane reflected over the fatty tissue does not cling closely to the round ligament, but forms a triangular fold, the apex of which is at the femur.

FIG. 345.—THE UPPER EXTREMITY OF THE FEMUR (POSTERIOR VIEW), TO SHOW THE RELATION OF THE ARTICULAR CAPSULE OF THE HIP-JOINT (IN RED) TO THE EPIPHYSIAL LINES.



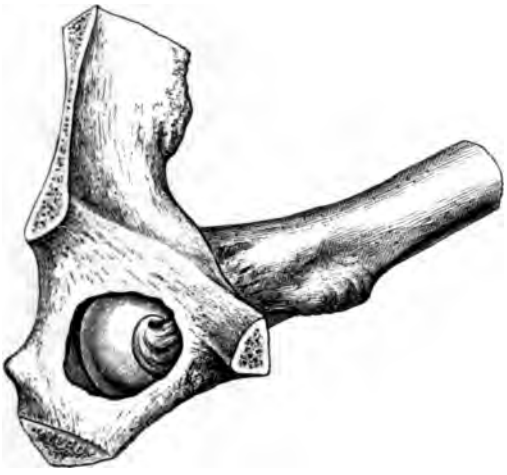
The **transverse ligament** [lig. transversum acetabuli] (fig. 344) passes across the acetabular notch and converts it into a foramen; it supports part of the glenoid lip, and is connected with the ligamentum teres and the capsule. It is composed of decussating fibers, which arise from the margin of the acetabulum on either side of the notch, those coming from the pubis being more superficial, and

o form the deep part of the ligament at the ischium, while those superfi-
ıe ischium are deep at the pubis. It thus completes the rim of the ace-

glenoid lip (cotyloid fibrocartilage) (figs. 342, 343) is a yellowish-white
ɜ, which deepens the acetabulum by surmounting its margin. It varies
;th and thickness, but is stronger at its iliac and ischial portions than
ɜ. Its base is broad and fixed to the bony rim as well as to the articular
of the acetabulum on the inner, and the periosteum on the outer, side of
ends inseparably with the transverse ligament which supports it over the
ar notch.

ɜe margin of the glenoid lip is thin; on section it is somewhat lunated, having its outer
ıvex and its articular face concave and very smooth in adaptation to the head of the
ich it tightly embraces a little beyond its greatest circumference. It somewhat
the aperture of the acetabulum, and retains the head of the femur within its grasp
ion of the muscles and capsular ligament. It is covered on both aspects by synovial
ɜ.

FIG. 346.—LIGAMENTUM TERES, LAX IN FLEXION.



synovial membrane lines the capsule and both surfaces of the glenoid
passes over the border of the acetabulum to reach and cover the fatty
it contains. The part covering the fatty cushion is unusually thick, and
ıed round the edges of the rough bony surface on which the cushion rests.
nbrane is loosely reflected off this on to the ligamentum teres, along
is prolonged to the head of the femur; thus the fibers of the round liga-
ɜ shut out from the joint cavity. From the capsule the synovial mem-
also reflected below on to the neck of the femur, whence it passes over
acula to the margin of the articular cartilage.

rterial supply comes from—(*a*) the transverse branches of the medial and lateral
: arteries; (*b*) the lateral branch of the obturator sends a branch through the acetabular
ıeath the transverse ligament, which ramifies in the fat at the bottom of the ace-
ınd travels down the round ligament to the head of the femur; (*c*) the inferior branch
p division of the superior gluteal; and (*d*) the inferior gluteal (sciatic) arteries. The
ɔm the obturator to the ligamentum teres is sometimes very large when the branch
ıedial circumflex does not also supply the ligament.
perior and inferior gluteal send several branches through the coxal attachment of the
:apsule: these anastomose freely beneath the capsule around the outer aspect of
ɔulum, and supply some branches to enter the bone, and others which enter the
of the glenoid lip. There is quite an arterial crescent upon the posterior and postero-
ortions of the acetabulum; but no vessels are to be seen on the inner aspect of the
ɔ. A fold of synovial membrane on the lower aspect of the neck often conveys to the
e femur a branch of an artery—generally a branch of the medial circumflex.
ıerve-supply comes from—(*a*) femoral (anterior crural), (*b*) anterior division of the
(*c*) the accessory obturator (where present), and (*d*) the sacral plexus, by a twig from
to the quadratus femoris, or from the upper part of the great sciatic, or from the lower
e sacral plexus.
ıas.—In *front* and in contact with the capsule are the psoas bursa, the tendinous
e psoas magnus, and the iliacus. Still more anteriorly and not in contact are the
tery, the femoral (anterior crural) nerve, the rectus femoris, the sartorius, and the
:iæ latæ muscles.

Above and in close relation with the capsule are the piriformis, the obturator internus the gemelli, and the reflected head of the rectus femoris, whilst more superficially lie the gluteus minimus and medius.

Behind and in close relation with the capsule are the obturator externus, the gemelli and obturator internus, and the piriformis. More superficially lie the quadratus femoris, the sciatic and posterior femoral cutaneous nerves, and the gluteus maximus.

Below the obturator externus, the pectineus, and the medial circumflex artery are in close relation with the capsule.

The movements (cf. p. 543).—The hip-joint, like the shoulder, is a ball-and-socket joint, but with a much more complete socket and a corresponding limitation of movement. Each variety of movement is permitted, viz., flexion, extension, abduction, adduction, circumduction, and rotation; and any two or more of these movements not being antagonistic can be combined, i. e., flexion or extension associated with abduction or adduction can be combined with rotation in or out.

FIG. 347.—LIGAMENTUM TERES, VERY LAX IN COMPLETE EXTENSION.

It results from the obliquity of the neck of the femur that the movements of the head in the acetabulum are always more or less of a rotatory character. This is more especially the case during flexion and extension, and two results follow from it. First, the bearing surfaces of the femur and acetabulum preserve their apposition to each other, so that the amount of articular surface of the head in the acetabulum does not sensibly diminish *pari passu* with the transit of the joint from the extended to the flexed position, as would necessarily be the case if the movement of the femoral head, like that of the thigh itself, was simply angular, instead of rotatory and angular. Secondly, as rotation of the head can continue until the ligaments are tight without being checked by contact of the neck of the thigh bone with the rim of the acetabulum, flexion of the thigh so far as the joint is concerned is practically unlimited. Flexion is the most important and most extensive movement, and in the dissected limb, before the ligaments are disturbed, can be carried to 160°, and is then checked by the lower fibers of the ischiocapsular ligament. In the living subject simple flexion can continue until checked by the contact of the soft parts at the groin, if the knee be bent; if the knee be straight, flexion of the hip is checked in most persons by the hamstring muscles at nearly a right angle. This is very evident on trying to touch the ground with the fingers without bending the knees, the chief strain being felt at the popliteal space. This is due to the shortness of the hamstrings. Extension is limited by the iliofemoral ligament.

Abduction and lateral rotation can be performed freely in every position of flexion and extension—abduction being limited by the pubocapsular ligament; lateral rotation by the iliofemoral ligament, especially its medial portion, during extension; but by the lateral portion, as well as by the ligamentum teres, during flexion.

Adduction is very limited in the extended thigh on account of the contact with the opposite limb. In the slightly flexed position adduction is more free than in extension, and is then limited by the lateral fibers of the iliofemoral band and the superior portion of the capsule. In flexion the range is still greater, and limited by the ischiocapsular ligament, the ligamentum teres being also rendered nearly tight. Medial rotation in the extended position is limited by the lower fibers of the iliofemoral ligament; and in flexion by the ischiocapsular ligament and the portion of the capsule between it and the iliofemoral band.

The iliofemoral band also prevents the tendency of the trunk to roll backward on the thigh bones in the erect posture, and so does away with the necessity for muscular power for this purpose; it is put on stretch in the stand-at-ease position.

The ligamentum teres is of little use in resisting violence or in imparting strength to the joint. It assists in checking lateral rotation, and adduction during flexion. A ligament can only be of use when it is tight, and it was found by trephining the bottom of the acetabulum, removing the fat, and threading a piece of whip cord round the ligament, that the ligament was slack in simple flexion, and very loose in complete extension, but that its most slack condition was in abduction. It is tightest in flexion combined with adduction and lateral rotation and almost as tight in flexion with lateral rotation alone, and in flexion with adduction alone (figs. 346–348).

Muscles which act upon the hip-joint (cf. p. 487ff.).—*Flexors.*—The psoas and iliacus, the rectus femoris, the pectineus, the adductors, the sartorius, the tensor fasciæ latæ, and the gluteus

FIG. 348.—LIGAMENTUM TERES, DRAWN TIGHT IN FLEXION COMBINED WITH LATERAL ROTATION AND ADDUCTION.

medius. *Extensors.*—The gluteus maximus, the posterior fibers of the glutei medius and minimus, the biceps, the semitendinosus, the semimembranosus, and the ischial fibers of the adductor magnus; also (slightly) the piriformis, obturator internus and gemelli. *Abductors.*—Gluteus maximus (upper fibers), tensor fasciæ latæ, gluteus medius, gluteus minimus, and, when the joint is flexed, the piriformis, obturator internus, the gemelli, and the sartorius also become abductors. *Adductors.*—Adductores magnus, longus, brevis, and minimus, semitendinosus, biceps, the gracilis, the pectineus, the quadratus femoris, and the lower fibers of the gluteus maximus. *Medial rotators.*—Psoas (slightly), adductor magnus, semimembranosus, the anterior fibers of the gluteus medius and minimus, and the tensor fasciæ latæ. *Lateral rotators.*—Gluteus maximus, posterior fibers of gluteus medius and minimus, the adductors, obturator externus, quadratus femoris, obturator internus, the gemelli, and the piriformis when the joint is extended.

2. THE KNEE-JOINT

Class.—*Diarthrosis.* **Subdivision.**—*Ginglymus.*

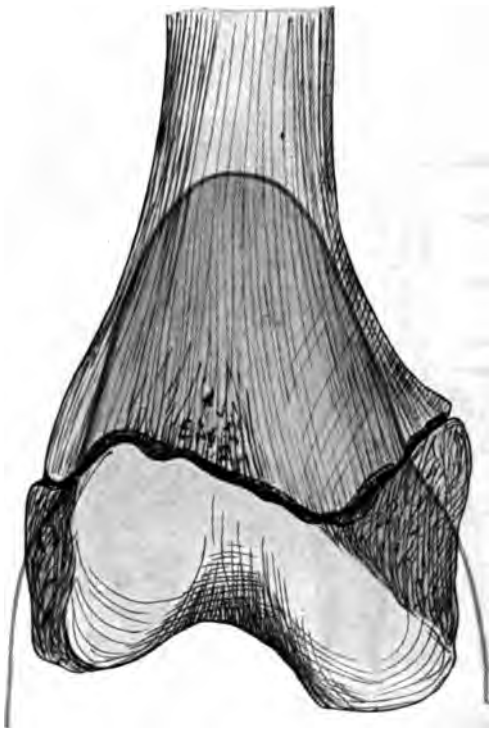
The knee is the largest joint in the body. It is rightly described as a ginglymoid joint, but there is also an arthrodial element; for, in addition to flexion and extension, there is a sliding backward and forward of the tibia upon the femoral condyles, as well as slight rotation round a vertical axis. It is one of the most superficial, and, as far as adaptation of the bony surfaces goes, one of the weakest joints, for in no position are the bones in more than partial contact. Its strength lies in the number, size, and arrangement of the ligaments, and the powerful muscles and fascial expansions which pass over the articulation and enable it to withstand the leverage of the two longest bones in the body. It may be said to consist of two articulations with a common synovial membrane—the patellofemoral and the tibiofemoral, the latter being double. It is composed of the condyles and trochlear surface of the femur, the condyles of the tibia, and the

pass between it and the bone. Superficially, a bursa separates it from the tendons of the gracilis and semitendinosus muscles and from the aponeurosis of the sartorius muscle.

The **fibular** (external) **collateral ligament** (fig. 350) consists of two portions: anterior and posterior. The **anterior,** which is the longer and better marked, is a strong, rounded cord, about 5 cm. long, attached above to the tubercle on the lateral side of the lateral epicondyle of the femur, just below and in front of the origin of the lateral head of the gastrocnemius, whilst the tendon of the popliteus arises from the groove below and in front of it. Below, it is fixed to the middle of the lateral surface of the head of the fibula, 1.2 cm. or more anterior to the apex.

Superficially is the tendon of the biceps, which splits to embrace its lower extremity; while beneath it pass the popliteus tendon in its sheath, and the inferior lateral articular vessels and nerve. Some fibers of the peroneus longus occasionally arise from the lower end of the ligament. The **posterior** portion is 8 mm. behind the anterior. It is broader and less defined; fixed below to the apex of the fibula, it inclines upward and somewhat backward, and ties down the popliteus against the lateral condyle of the tibia, blending beneath the lateral head of the gastrocnemius with the oblique popliteal ligament of the knee, of which it is really a portion.

FIG. 351.—THE LOWER EXTREMITY OF THE FEMUR (ANTERIOR VIEW) TO SHOW THE RELATION OF THE ARTICULAR CAPSULE OF THE KNEE-JOINT (IN RED) TO THE EPIPHYSIAL LINE.



The **oblique popliteal ligament** (ligament of Winslow) (fig. 350) is a broad dense structure of interlacing fibers, with large orifices for vessels and nerves. It is attached above to the femur close to the articular margins of the condyles, stretching across the upper margin of the intercondyloid fossa, to which it is connected by fibro-fatty tissue; it thus reaches across from the tibial to the fibular collateral ligaments. Below, it is fixed to the border of the lateral condyle of the tibia, to the bone just below the posterior intercondyloid notch and to the shaft of the tibia below the medial condyle, blending with the descending slip of the semimembranosus and tibial collateral ligament.

Superficially, an oblique fasciculus from the semimembranosus runs across the center, passing upward and laterally from near the back part of the medial condyle of the tibia to the lateral epicondyle of the femur, where it joins the lateral head of the gastrocnemius, a sesamoid plate being sometimes developed at the point of junction. This slip greatly strengthens the oblique popliteal ligament, of which, if not the chief constituent, it is at least a very important part.

Its deep surface is closely connected with the semilunar menisci (especially the medial) and coronary ligaments, and in the interval between the cartilages with the posterior crucial ligament is fibro-fatty tissue within the joint. Superficially it forms part of the floor of the popliteal ace. A special band, the *arcuate ligament*, is sometimes found extending from the lateral condyle passing under the oblique ligament and attaching to the head of the fibula by two ands [retinaculum ligamenti arcuati].

The articular capsule (fig. 352) is thin but strong, covering the synovial membrane, and forming a loose sac. It is attached to the femur near the articular margin on the medial side, but further away on the lateral; it passes beneath the fibular collateral ligament to join the sheath of the popliteus. Medially it joins the tibial collateral ligament. Below, it is fixed to the upper as well

s the medial and lateral borders of the patella and the anterior border of the ead of the tibia. It is strengthened superficially between the femur and patella y an expansion from the articularis genu (subcrureus) and is separated from he fibrous expansion of the extensor tendon by a layer of fatty tissue. The synoial membrane lines its deep surface, and holds it against the borders of the semiinar menisci; it is also attached to the coronary ligaments.

Internal Ligaments

The **anterior crucial ligament** (figs. 352, 353) is strong and cord-like. It is ttached to the medial half of the fossa in front of the intercondyloid eminence f the tibia, and to the lateral border of the medial articular facet as far back as he medial intercondyloid tubercle. It passes upward, backward, and laterally o the back part of the medial surface of the lateral condyle of the femur. To he tibia, it is fixed behind the anterior extremity of the medial semilunar menisus. Behind and to the lateral side it has the anterior extremity of the lateral ieniscus, a few fibers of which blend with the lateral edge of the ligament.

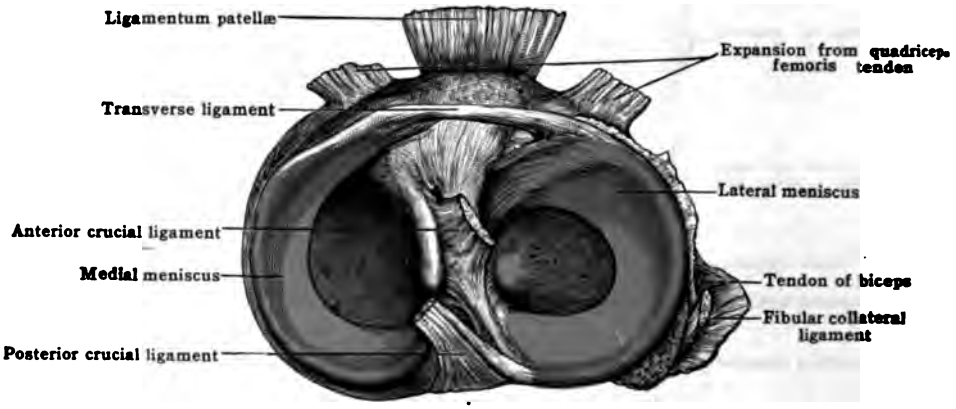
Its anterior fibers at the tibial end are strongest and longest, being fixed highest on the femur; while the posterior, springing from the intercondyloid eminence, are shorter and more oblique. Near the spine, a slip is sometimes given off to the posterior crucial ligament.

The **posterior crucial ligament** (figs. 352, 353, 355) is stronger and less oblique than the anterior. It is fixed below to the greater portion of the fossa behind the intercondyloid eminence of the tibia, especially the lateral and posterior portion, and then medially along the posterior intercondyloid fossa; being joined by fibers, which arise between the intercondyloid tubercles, it ascends to the anterior part of the lateral surface of the medial condyle of the femur, having a wide crescentic attachment 1.5 cm. in extent just above the articular surface.

Behind, it is connected at the tibia directly with the oblique ligament, and a little higher up by means of a quantity of interposed areolar tissue. In front it rests upon the posterior horn of the medial semilunar meniscus, and receives a large slip from the lateral meniscus, which ascends along it, either in front or behind, to the femur; higher up in front it is connected with the anterior crucial ligament.

Until they rise above the intercondyloid eminence of the tibia the two crucial ligaments are closely bound together, so that no interspace exists between their tibial attachments and the point of decussation; the only space between them is therefore a V-shaped one corresponding to the upper half of their X-shaped arrangement, and this is a mere chink in the undissected state, and can be seen from the front only, owing to the fatty tissue beneath the synovial membrane which surrounds their femoral attachment.

FIG. 353.—STRUCTURES LYING ON THE HEAD OF THE TIBIA. (Right knee.)



The interarticular **menisci** (semilunar fibrocartilages) (figs. 352, 353) are two crescentic disks resting upon the circumferential portions of the articular facets of the tibia, and moving with the tibia upon the femur. They somewhat deepen the tibial articular surfaces, and are dense and compact in structure, becoming looser and more fibrous near their extremities, where they are firmly fixed in front of and behind the intercondyloid eminence of the tibia. The circumferential border of each is convex, thick, and somewhat loosely attached to the borders of the condyles of the tibia by the coronary ligaments and the reflexion of the synovial membrane. The inner border is concave, thin, and free. About 1.3 cm. broad at the widest part, they taper somewhat toward their extremities, and cover rather less than two-thirds of the articular facets of the tibia. Their upper surfaces are slightly concave, and fit on to the femoral condyles, while the lower are flat and rest on the head of the tibia; both surfaces are smooth and covered by synovial membrane.

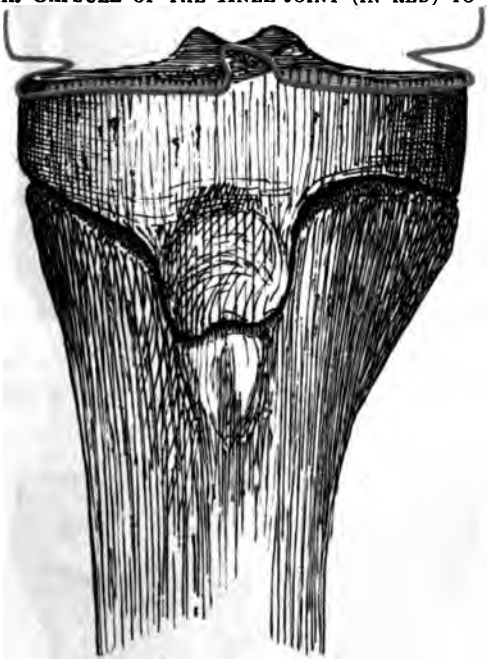
The **lateral meniscus** (fig. 353) is nearly circular in form and less firmly fixed than the medial, and consequently slides more freely upon the tibia. Its anterior cornu is attached to a narrow depression along the lateral articular facet, just in front of the lateral intercondyloid tubercle of the tibia, close to, and on the lateral side of, the anterior crucial ligament; a small slip from the cornu is often fixed to the tibia in front of the crucial ligament. The posterior cornu is firmly attached to the tibia behind the lateral intercondyloid tubercle, blending with the posterior crucial ligament, and giving off a well-marked fasciculus, which runs up along the anterior border of the ligament to be attached to the femur (ligament of Wrisberg, fig. 359). It also sends a narrow slip into the back part of the anterior crucial ligament. Its outer border is grooved toward its posterior part by the popliteus tendon, which is held to it by fibrous tissue and synovial membrane, and separates it from the fibular collateral ligament. From its anterior border is given off the transverse ligament.

The **medial meniscus** (fig. 353) is a segment of a larger circle than the lateral, and has an outline more oval than circular. Its anterior cornu is wide, and has a broad and oblique attachment to the anterior margin of the head of the tibia. It reaches from the margin of the condyle toward the middle of the fossa in front of the intercondyloid eminence, being altogether in front of the anterior crucial ligament. The posterior cornu is firmly fixed by a broad insertion in an anteroposterior line along the medial side of the posterior intercondyloid fossa, from the medial tubercle to the posterior margin of the head of the tibia. Its convex border is connected with the tibial collateral ligament and the semimembranosus tendon.

The **transverse ligament** (figs. 352, 353) is a rounded, slender, short cord, which extends from the convex border of the lateral meniscus to the concave border or anterior cornu of the medial, near which it is sometimes attached to the bone. It is an accessory band of the lateral meniscus, and is situated beneath the synovial membrane.

The **coronary ligaments** (fig. 352) connect the margins of the semilunar disks with the head of the tibia. The lateral is much more lax than the medial, permitting the lateral disk to change its position more freely than the medial. They are not in reality separate structures, but consist of fibers of the several surrounding ligaments of the knee-joint which become attached to the margins of the disk as they pass over them.

FIG. 354.—THE UPPER EXTREMITY OF THE TIBIA (ANTERIOR VIEW), TO SHOW THE RELATION OF THE ARTICULAR CAPSULE OF THE KNEE-JOINT (IN RED) TO THE EPIPHYSIAL LINE.



The **synovial membrane** (figs. 349, 351, 354–357, 1149) of the knee forms the largest synovial sac in the body. Bulging upward from the patella, it follows the capsule of the joint into a large *cul-de-sac* beneath the tendon of the extensor muscles on the front of the femur. It reaches some distance beyond the articular surface of the bone, and communicates very frequently with a large bursa interposed between the tendon and the femur above the line of attachment of the articular capsule. After investing the circumference of the lower end of the femur, it is reflected upon the fibrous envelope of the joint formed by the capsular, posterior, and collateral ligaments. The cavity may communicate with that of the superior tibiofibular joint.

The synovial membrane covers a great portion of the crucial ligaments, but leaves uncovered the back of the posterior crucial where the latter is connected with the posterior ligament, and the lower part of both crucial ligaments where they are united. Thus the ligaments are completely shut out of the synovial cavity. Along the fibrous envelope the synovial membrane is conducted down to the semilunar menisci, over both surfaces of which it passes, and is reflected off the under surface on to the coronary ligaments, and thence down to the head of the tibia, around the circumference of which it extends a short way. It dips down between the external

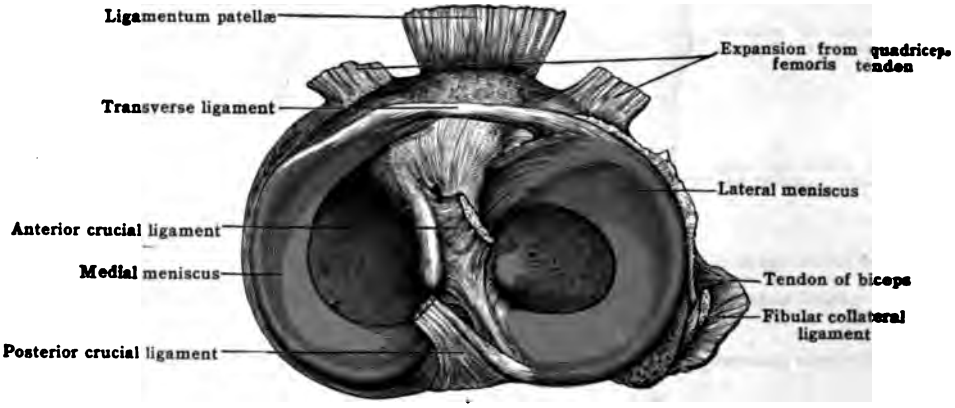
Its anterior fibers at the tibial end are strongest and longest, being fixed highest on the femur; while the posterior, springing from the intercondyloid eminence, are shorter and more oblique. Near the spine, a slip is sometimes given off to the posterior crucial ligament.

The **posterior crucial ligament** (figs. 352, 353, 355) is stronger and less oblique than the anterior. It is fixed below to the greater portion of the fossa behind the intercondyloid eminence of the tibia, especially the lateral and posterior portion, and then medially along the posterior intercondyloid fossa; being joined by fibers, which arise between the intercondyloid tubercles, it ascends to the anterior part of the lateral surface of the medial condyle of the femur, having a wide crescentic attachment 1.5 cm. in extent just above the articular surface.

Behind, it is connected at the tibia directly with the oblique ligament, and a little higher up by means of a quantity of interposed areolar tissue. In front it rests upon the posterior horn of the medial semilunar meniscus, and receives a large slip from the lateral meniscus, which ascends along it, either in front or behind, to the femur; higher up in front it is connected with the anterior crucial ligament.

Until they rise above the intercondyloid eminence of the tibia the two crucial ligaments are closely bound together, so that no interspace exists between their tibial attachments and the point of decussation; the only space between them is therefore a V-shaped one corresponding to the upper half of their X-shaped arrangement, and this is a mere chink in the undissected state, and can be seen from the front only, owing to the fatty tissue beneath the synovial membrane which surrounds their femoral attachment.

FIG. 353.—STRUCTURES LYING ON THE HEAD OF THE TIBIA. (Right knee.)



The interarticular **menisci** (semilunar fibrocartilages) (figs. 352, 353) are two crescentic disks resting upon the circumferential portions of the articular facets of the tibia, and moving with the tibia upon the femur. They somewhat deepen the tibial articular surfaces, and are dense and compact in structure, becoming looser and more fibrous near their extremities, where they are firmly fixed in front of and behind the intercondyloid eminence of the tibia. The circumferential border of each is convex, thick, and somewhat loosely attached to the borders of the condyles of the tibia by the coronary ligaments and the reflexion of the synovial membrane. The inner border is concave, thin, and free. About 1.3 cm. broad at the widest part, they taper somewhat toward their extremities, and cover rather less than two-thirds of the articular facets of the tibia. Their upper surfaces are slightly concave, and fit on to the femoral condyles, while the lower are flat and rest on the head of the tibia; both surfaces are smooth and covered by synovial membrane.

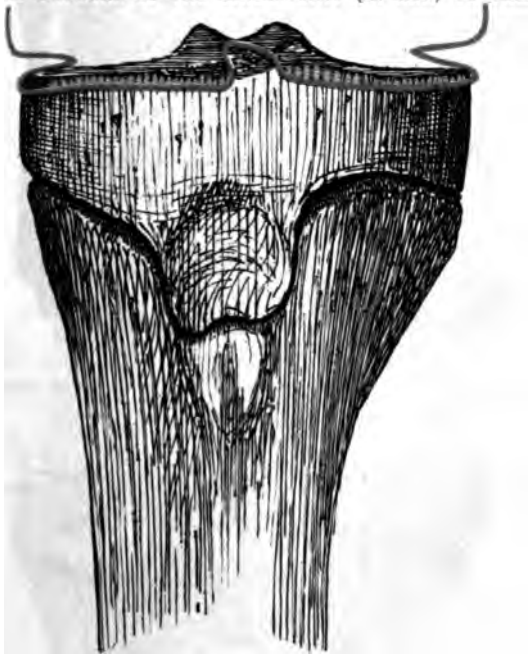
The **lateral meniscus** (fig. 353) is nearly circular in form and less firmly fixed than the medial, and consequently slides more freely upon the tibia. Its anterior cornu is attached to a narrow depression along the lateral articular facet, just in front of the lateral intercondyloid tubercle of the tibia, close to, and on the lateral side of, the anterior crucial ligament; a small slip from the cornu is often fixed to the tibia in front of the crucial ligament. The posterior cornu is firmly attached to the tibia behind the lateral intercondyloid tubercle, blending with the posterior crucial ligament, and giving off a well-marked fasciculus, which runs up along the anterior border of the ligament to be attached to the femur (ligament of Wrisberg, fig. 359). It also sends a narrow slip into the back part of the anterior crucial ligament. Its outer border is grooved toward its posterior part by the popliteus tendon, which is held to it by fibrous tissue and synovial membrane, and separates it from the fibular collateral ligament. From its anterior border is given off the transverse ligament.

The **medial meniscus** (fig. 353) is a segment of a larger circle than the lateral, and has an outline more oval than circular. Its anterior cornu is wide, and has a broad and oblique attachment to the anterior margin of the head of the tibia. It reaches from the margin of the condyle toward the middle of the fossa in front of the intercondyloid eminence, being altogether in front of the anterior crucial ligament. The posterior cornu is firmly fixed by a broad insertion in an anteroposterior line along the medial side of the posterior intercondyloid fossa, from the medial tubercle to the posterior margin of the head of the tibia. Its convex border is connected with the tibial collateral ligament and the semimembranosus tendon.

The **transverse ligament** (figs. 352, 353) is a rounded, slender, short cord, which extends from the convex border of the lateral meniscus to the concave border or anterior cornu of the medial, near which it is sometimes attached to the bone. It is an accessory band of the lateral meniscus, and is situated beneath the synovial membrane.

The **coronary ligaments** (fig. 352) connect the margins of the semilunar disks with the head of the tibia. The lateral is much more lax than the medial, permitting the lateral disk to change its position more freely than the medial. They are not in reality separate structures, but consist of fibers of the several surrounding ligaments of the knee-joint which become attached to the margins of the disk as they pass over them.

FIG. 354.—THE UPPER EXTREMITY OF THE TIBIA (ANTERIOR VIEW), TO SHOW THE RELATION OF THE ARTICULAR CAPSULE OF THE KNEE-JOINT (IN RED) TO THE EPIPHYSIAL LINE.



The **synovial membrane** (figs. 349, 351, 354–357, 1149) of the knee forms the largest synovial sac in the body. Bulging upward from the patella, it follows the capsule of the joint into a large *cul-de-sac* beneath the tendon of the extensor muscles on the front of the femur. It reaches some distance beyond the articular surface of the bone, and communicates very frequently with a large bursa interposed between the tendon and the femur above the line of attachment of the articular capsule. After investing the circumference of the lower end of the femur, it is reflected upon the fibrous envelope of the joint formed by the capsular, posterior, and collateral ligaments. The cavity may communicate with that of the superior tibiofibular joint.

The synovial membrane covers a great portion of the crucial ligaments, but leaves uncovered the back of the posterior crucial where the latter is connected with the posterior ligament, and the lower part of both crucial ligaments where they are united. Thus the ligaments are completely shut out of the synovial cavity. Along the fibrous envelope the synovial membrane is conducted down to the semilunar menisci, over both surfaces of which it passes, and is reflected off the under surface on to the coronary ligaments, and thence down to the head of the tibia, around the circumference of which it extends a short way. It dips down between the external

meniscus and the head of the tibia as low as the superior tibiofibular ligament, reaching in nearly as far as the intercondyloid notch, and forming a bursa for the play of the popl tendon.

FIG. 355.—ANTERIOR VIEW OF THE KNEE-JOINT, SHOWING THE SYNOVIAL LIGAMENT (Anterior portion of capsule with the extensor tendon thrown downward.)

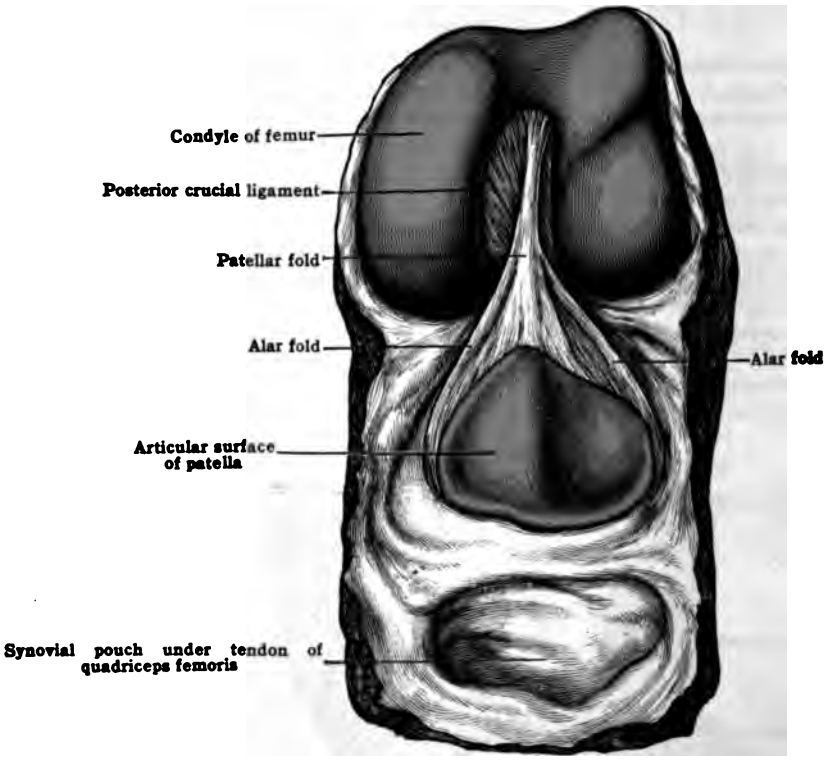


FIG. 356.—THE UPPER EXTREMITY OF THE TIBIA (POSTERIOR VIEW), TO SHOW THE RELA OF THE ARTICULAR CAPSULE OF THE KNEE-JOINT (IN RED) TO THE EPIPHYSIAL LIN

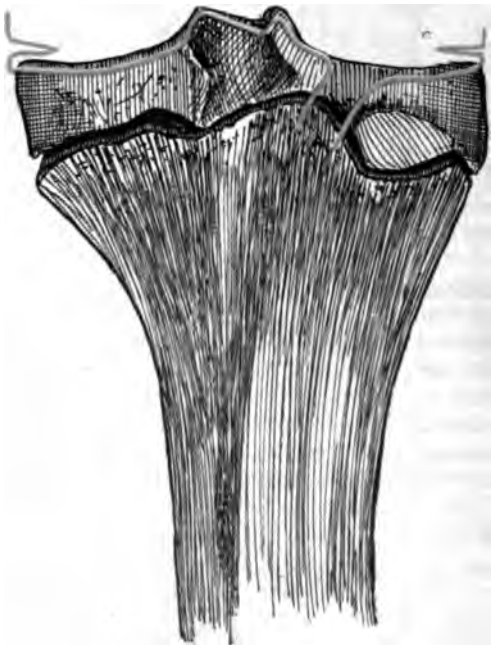
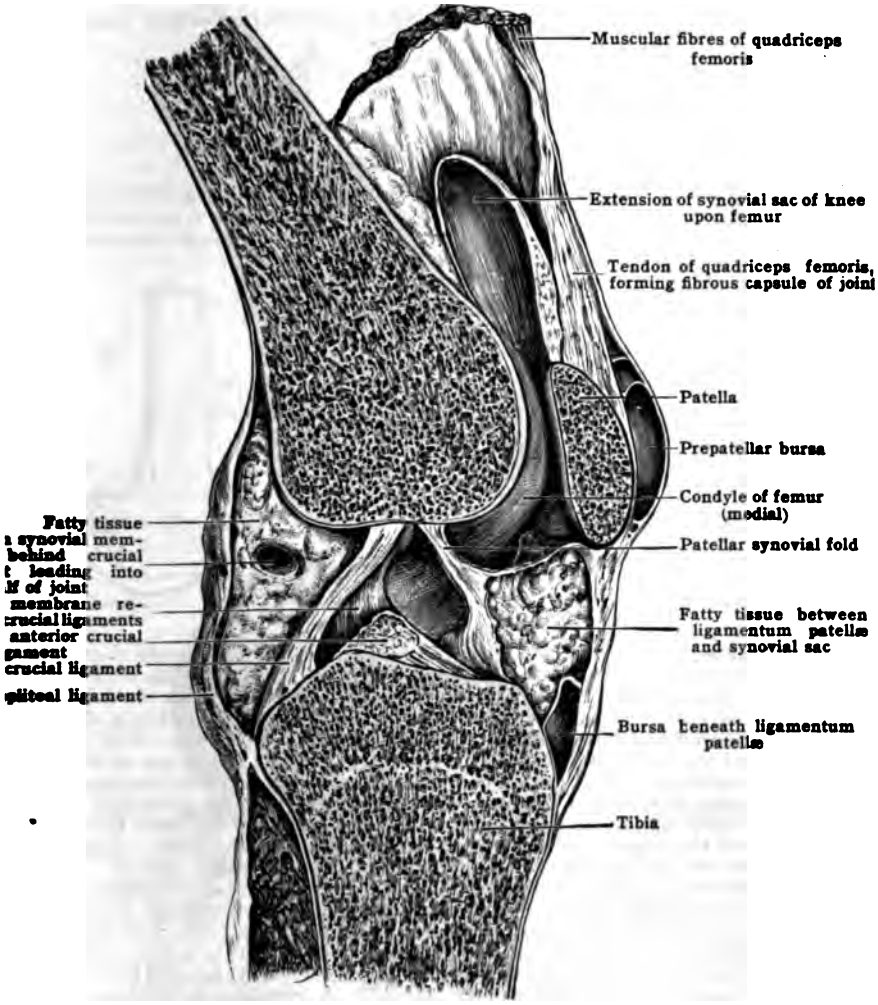


At the back of the joint two pouches are prolonged beneath the muscles, one on each between the condyle of the femur and the origin of the gastrocnemius. Large processes of s vial membrane also project into the joint, and being occupied by fat serve as padding to fi

The chief of these processes, the **patellar synovial fold** (ligamentum mucosum) (figs. 357), springs from the infrapatellar fatty mass. This so-called ligament is the central of the large process of synovial membrane, of which the alar folds form the free margins. ds from the fatty mass, below the patella, backward and upward to the intercondyloid the femur, where it is attached in front of the anterior crucial, and lateral to the poste- ial ligament. Near the femur it is thin and transparent, consisting of a double fold of membrane, but near the patella it contains some fatty tissue. Its anterior or upper ee, and fully 2.5 cm. long; the posterior or lower edge is half the length, and is attached ucial ligaments above, but is free below.

ng backward from the capsule on each side of the patella is a prominent crescentic ned by reduplications of the synovial membrane—these are the **alar folds** (fig. 355). e margins are concave and thin, and are lost below in the patellar fold. There is a sa above and another below each ligament.

FIG. 357.—SAGITTAL SECTION OF THE KNEE-JOINT.
(The bones are somewhat drawn apart.)



rterial supply of the knee-joint is derived from the art. genu suprema (anastomotica); rior and inferior medial and lateral articular; the medial articular; the descending f the lateral circumflex; the anterior recurrent branch from the anterior tibial; and the tibial recurrent.

nerve-supply comes from the great sciatic, femoral, and obturator sources. The atic gives off the tibial and common peroneal; the tibial sends two, sometimes three —one with the medial articular artery; one with the inferior medial, and sometimes the superior medial articular artery; the common peroneal gives a branch which accom- s superior, and another which accompanies the inferior articular artery, and a recurrent hich follows the course of the anterior recurrent branch of the anterior tibial artery. ral sends an articular branch from the nerve to the vastus lateralis; a second from the the vastus medialis; and sometimes a third from that to the vastus intermedius. Thus three articular twigs to the knee derived from the muscular branches of the femoral.

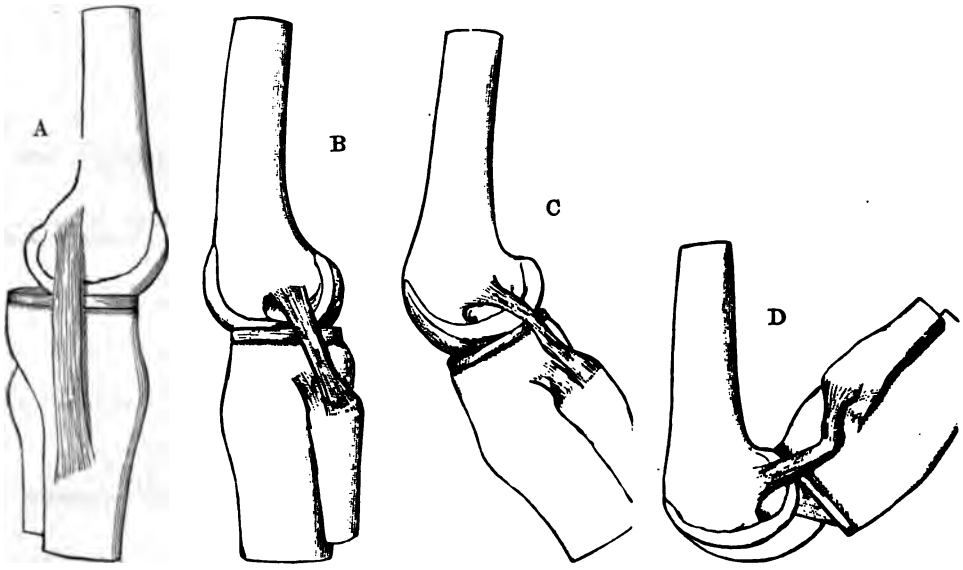
The obturator by its deep division sends a branch through the adductor magnus on to the popliteal artery, which enters the joint posteriorly.

Relations.—Anteriorly and at the sides the knee-joint is merely covered and protected by skin, fascia, and the tendinous expansions of the quadriceps extensor muscle. Laterally and posteriorly it is crossed by the biceps tendon. Medially and posteriorly lie the sartorius and the tendons of the gracilis and semitendinosus muscles. Posteriorly it is in relation with the popliteal vessels and nerves, the semimembranosus, the two heads of the gastrocnemius, and the plantaris. The tendon of the popliteus pierces the capsule behind and medial to the biceps tendon.

The movements which occur at the knee-joint are flexion and extension, with some slight amount of rotation in the bent position (cf. also p. 544). These movements are not so simple as the corresponding ones at the elbow, for the knee is not a simple hinge-joint. The movements of rotation instead of occurring between tibia and fibula, as between radius and ulna, are movements of the tibia with the fibula upon the condyles of the femur.

The knee differs from a true hinge-joint, like the elbow or ankle, in the following particulars:—

FIG. 358.—THE COLLATERAL LIGAMENTS OF THE KNEE IN FLEXION AND EXTENSION.



1. The points of contact of the femur with the tibia are constantly changing. Thus, in the flexed position, the posterior part of the articular surface of the tibia is in contact with the rounded back part of the femoral condyles; in the semiflexed position the middle parts of the tibial facets articulate with the anterior rounded part of the condyles; while in the fully extended position the anterior and middle parts of the tibial facets are in contact with the anterior flattened portion of the condyles. So with the patella: in extreme flexion the medial articular facet rests on the lateral part of the medial condyle of the femur; in flexion the upper pair of facets rests on the lower part of the trochlear surface of the femur; in midflexion the middle pair rests on the middle of the trochlear surface; while in extension the lower pair of facets on the patella rests on the upper portion of the trochlear surface of the femur. This difference may be described as the shifting of the points of contact of the articular surface.

2. It differs from a true hinge in that, in passing from a state of extension to one of flexion, the tibia does not revolve round a single transverse axis drawn through the lower end of the femur, as the ulna does round the lower end of the humerus. The articular surface of the tibia slides forward in extension and backward in flexion; thus the axis round which the tibia revolves upon the femur is a shifting one, as is seen by reference to fig. 358, B, C, D.

3. Another point of difference is that extension is accompanied by lateral rotation, and flexion by medial rotation. This rotation occurs round a vertical axis drawn through the middle of the lateral condyle of the femur and the lateral condyle of the tibia, and is most marked at the termination of extension and at the commencement of flexion. This rotation of the leg at the knee is a true rotation about a vertical axis, and thus differs from the obliquity of the flexion and extension movements at the elbow which is due to the oblique direction of the articular surfaces of the bones.

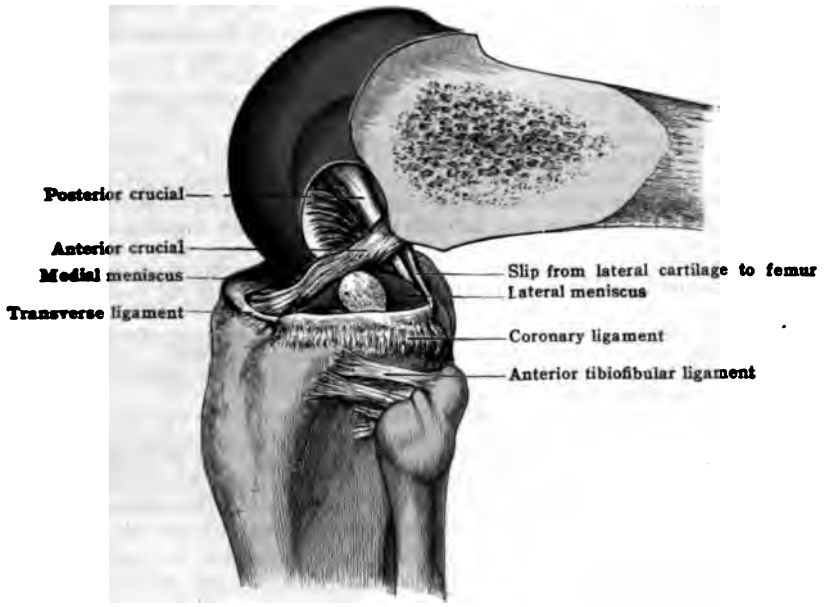
4. The anteroposterior spiral curve of the femoral condyles is such that the anterior part is an arc of a greater circle than the posterior; hence certain ligaments which are tightened during extension are relaxed during flexion, and thereby a considerable amount of rotatory movement is permitted in the flexed position. The axis of this rotation is longitudinal, and passes through the medial intercondyloid tubercle of the tibia, so that the lateral condyle moves in the arc of a larger circle than does the medial, and is therefore required to move more freely and easily; hence the shape of the lateral articular facet and the loose connection of the lateral meniscus which is adapted to it.

In extension of the knee-joint all the ligaments are on the stretch with the exception of the **ligamentum patellæ** and front of the capsule. Extension is checked by both the crucial ligaments and the collateral ligaments (figs. 358, A, B, and 359).

In flexion the ligamentum patellæ and anterior portion of the capsule are on the stretch; so also is the posterior crucial in extreme flexion, though it is not quite tight in the semiflexed state of the joint. All the other ligaments are relaxed (fig. 358, C, D), although the relaxation

FIG. 359.—SECTION OF KNEE, SHOWING CRUCIAL LIGAMENTS IN EXTENSION.

FIG. 360.—CRUCIAL LIGAMENTS IN FLEXION.



of the anterior crucial ligament is slight in extreme flexion (fig. 360). Flexion is only checked during life by the contact of the soft parts, i. e., the calf with the back of the thigh.

Rotation medially is checked by the anterior crucial ligament; the collateral ligaments being loose. Rotation laterally is checked by the collateral ligaments; the crucial ligaments have no controlling effect on it, as they are untwisted by it.

Sliding movements are checked by the crucial and collateral ligaments—sliding forward especially by the anterior, and sliding backward by the posterior crucial.

Muscles which act upon the knee-joint (cf. p. 497ff.).—*Flexors.*—Biceps, semimembranosus, semitendinosus, sartorius, gastrocnemius, plantaris, and popliteus. *Extensor.*—Quadriceps extensor. **Medial** *Rotators.*—Sartorius, gracilis, semitendinosus, semimembranosus, popliteus. **Lateral** *Rotator.*—Biceps.

3. THE TIBIOFIBULAR UNION

The fibula is connected with the tibia throughout its length by an interosseous membrane, and at the upper and lower extremities by means of two joints. Very little movement is permitted between the two bones. The union therefore includes: (*a*) The **superior tibiofibular joint**; (*b*) The **middle tibiofibular union**; (*c*) The **inferior tibiofibular joint.**

(*a*) The Superior Tibiofibular Joint

Class.—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

The superior tibiofibular joint is about 6 mm. below, and quite distinct from, the knee at its upper and anterior part; but at its posterior and superior aspect, where the border of the lateral condyle of the tibia is bevelled by the popliteus muscle, the joint is in the closest proximity to the bursa from the knee-joint beneath the tendon of that muscle. There is often a communication between the synovial cavities of the two joints, which are separated by a thin septum. The ligaments uniting the bones are:—

Articular capsule. Anterior tibiofibular (capitular).
Posterior tibiofibular (capitular).

The **articular capsule** is a well-marked fibroareolar structure; it is attached close round the articular margins of the tibia and fibula. In front it is shut off completely from the knee-joint by the capsule of the knee and the coronary ligament; but behind, it is often very thin, and may communicate with the knee-joint through the bursa under the popliteus tendon.

The **anterior tibiofibular (capitular) ligament** [lig. capituli fibulæ] (fig. 359) consists of a few fibers which pass upward and medially from the fibula to the tibia. It lies beneath the anterior portion of the tendon of the biceps.

The **posterior tibiofibular (capitular) ligament** [lig. capituli fibulæ] (fig. 350) consists of a few fibers which pass upward and medially between the adjacent bones, from the head of the fibula to the lateral condyle of the tibia.

The **superior interosseous ligament** consists of a mass of dense yellow fibroareolar tissue, binding the opposed surfaces of the bones together for 2 cm. (¾ in.) below the articular facets. It is continuous with the interosseous membrane along the tibia.

The **biceps tendon** is divided by the fibular collateral ligament of the knee; of the two divisions the anterior is by far the stronger, and is inserted into the lateral condyle of the tibia as well as to the front of the head of the fibula, and thus the muscle, acting on both bones, tends to brace them more tightly together; indeed, it holds the bones strongly together after all other connections have been severed.

The **arterial supply** is from the inferior lateral articular and recurrent tibial arteries.

The **nerve-supply** is from the inferior lateral articular, and also from the recurrent branch of the common peroneal.

Relations.—In front, the upper ends of the tibialis anterior, the extensor digitorum longus, and the peroneus longus. Behind, the tendon of the popliteus overlapped by the lateral head of the gastrocnemius. Laterally, the biceps tendon and the common peroneal nerve. Below and medially, the anterior tibial vessels.

The **movements** are but slight, and consist merely of a gliding of the two bones upon each other. The joint is so constructed that the fibula gives some support to the tibia in transmitting the weight to the foot. The articular facet of the tibia overhangs, and is received upon the articular facet of the head of the fibula in an oblique plane. This joint allows of slight yielding of the lateral malleolus during flexion and extension of the ankle-joint, the whole fibula gliding slightly upward in flexion, and downward in extension, of the ankle.

(*b*) The Middle Tibiofibular Union

Class.—*Synarthrosis.* **Subdivision.**—*Syndesmosis.*

The **interosseous membrane** [membrana interossea cruris] is attached along the lateral border of the tibia and the interosseous border of the fibula. It is deficient above for about 2.5 cm. or more. Its upper border is concave, and over it pass the anterior tibial vessels.

The membrane consists of a thin aponeurotic and translucent lamina, formed of oblique fine fibers, some of which run from the tibia to the fibula, and some from the fibula to the tibia, but all are inclined downward. They are best marked at their attachment to the bones, and gradually grow denser and thicker as they approach the inferior interosseous ligament. The chief use of the membrane is to afford a surface for the origin of muscles. It is continuous below with the inferior interosseous ligament.

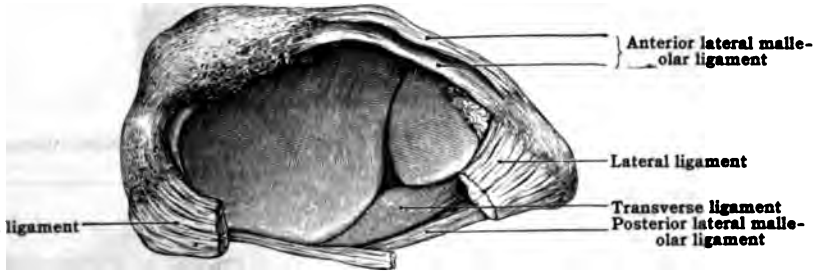
In front of the interosseous membrane lie the tibialis anterior, the extensor digitorum longus, the extensor hallucis longus, and the anterior tibial vessels and nerves. Behind it is in relation with the tibialis posterior, the flexor hallucis longus, and the peroneal artery.

(*c*) The Inferior Tibiofibular Articulation

Class.—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

This junction is formed by the lower ends of the tibia and fibula. The rough triangular surface on each of these bones formed by the bifurcation of their interosseous lines is closely and firmly united by the inferior interosseous ligament. The fibula is in actual contact with the tibia by an articular facet, which is small in size, crescentic in shape, and continuous with the articular facet of the malleolus.

Fig. 361.—Lower Ends of Left Tibia and Fibula, showing the Ligaments. The synovial fold between these bones has been removed to show the transverse ligament forming part of the capsule of the joint, and the deeper fibers of the anterior lateral malleolar ligament which come into contact with the talus.
(From a dissection by Mr. W. Pearson, of the Royal College of Surgeons Museum.)



The ligaments which unite the bones are:—

Anterior lateral malleolar ligament.	Transverse ligament.
Posterior lateral malleolar ligament.	Inferior interosseous ligament.

The anterior lateral malleolar ligament (anterior inferior tibiofibular ligament) (figs. 361 and 366) is a strong triangular band about 2 cm. wide, and is attached to the lower extremity of the tibia at its anterior and lateral angle, close to the margin of the facet for the talus and passes downward and laterally to the anterior border and contiguous surface of the lower end of the fibula, some fibers passing along the edge nearly as far as the origin of the anterior talofibular ligament.

The fibers increase in length from above downward. In front it is in relation with the peroneus tertius and deep fascia of the leg, and gives origin to fibers of the anterior ligament of the ankle-joint. Behind, it lies in contact with the interosseous ligament, and comes into contact with the articular surface of the talus (see figs. 361 and 362).

The posterior lateral malleolar ligament (figs. 361 and 366) is very similar to the anterior, extending from the posterior and lateral angle of the lower end of the tibia downward and laterally to the lowest 1.5 cm. (½ in.) of the border separating the medial from the posterior surface of the shaft of the fibula, and to the upper part of the posterior border of the lateral malleolus. It is in relation in front with the interosseous ligament; below, it touches the transverse ligament.

The inferior interosseous ligament is a dense mass of short, felt-like fibers, passing transversely between and firmly uniting the opposed rough triangular surfaces at the lower ends of the tibia and fibula, except for 1 cm. at the extremity, where there is a synovial cavity. It extends from the anterior to the posterior lateral malleolar ligaments, reaching upward 4 cm. in front, but only half this height behind.

The **transverse ligament** (fig. 361, 364) is a strong rounded band, attached to nearly the whole length of the inferior border of the posterior surface of the tibia, just above the articular facet for the talus. It then inclines a little forward and downward, to be attached to the medial surface of the lateral malleolus, just above the fossa, and into the upper part of the fossa itself.

The **synovial membrane** is continuous with that of the ankle-joint; it projects upward between the bones beyond their articular facets as high as the inferior interosseous ligament.

The **nerve-supply** is the same as that of the ankle-joint; the **arterial supply** is from the peroneal and the anterior peroneal, and sometimes from the anterior tibial, or its lateral malleolar branch.

Relations.—In front of the inferior tibiofibular joint are the anterior peroneal artery and the tendon of the peroneus tertius, and behind it are the posterior peroneal artery and the pad of fat which lies in front of the tendo Achillis.

The **movement** permitted at this joint is a slight gliding, chiefly in an upward and downward direction, of the fibula on the tibia. The bones are firmly braced together and yet form a slightly yielding arch, thus allowing a slight side to side expansion during extreme flexion, when the broad part of the talus is brought under the arch, by the upward gliding of the fibula on the tibia. To this end the direction of the fibers of the lateral malleolar ligaments is downward from tibia to fibula. This mechanical arrangement secures perfect contact of the articular surfaces of the ankle-joint in all positions of the foot.

FIG. 362.—RIGHT ANKLE-JOINT, SHOWING THE LIGAMENTS.

4. THE ANKLE-JOINT

Class.—*Diarthrosis.* **Subdivision.**—*Ginglymus.*

The ankle [articulatio talocruralis] is a perfect ginglymus or hinge-joint. The bones which enter into its formation are: the lower extremity and medial malleolus of the tibia, and the lateral malleolus of the fibula, above; and the upper and lateral articular surfaces of the talus (astragalus) below. The ligaments (supplementing the articular capsule) uniting the bones are:—

Anterior.	Deltoid.
Posterior.	Lateral ligament.

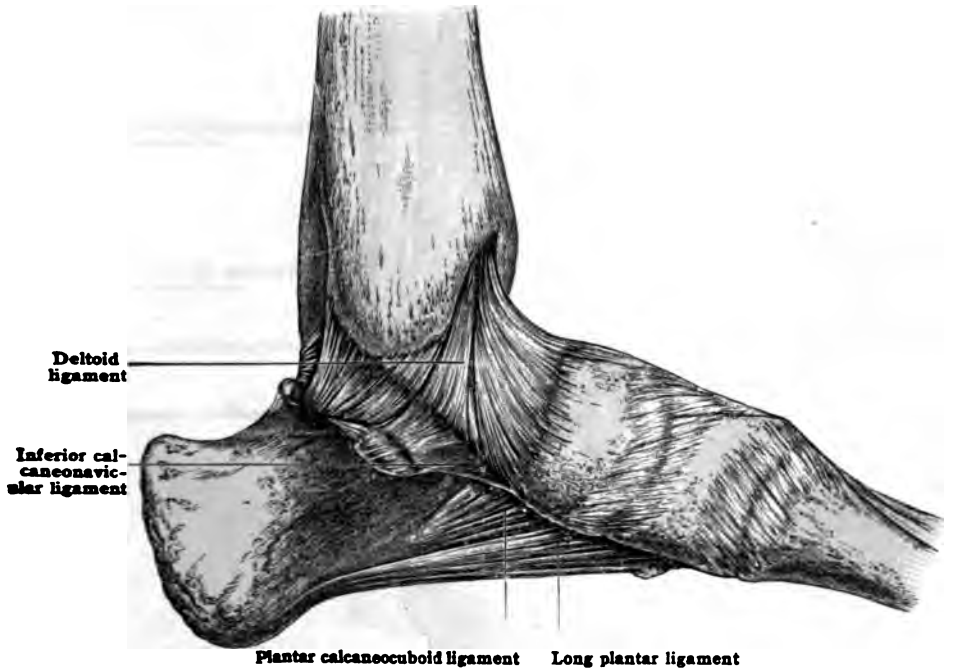
The **anterior ligament** (fig. 366) is a thin, membranous structure, which completes the capsule in front of the joint. It is attached above to the anterior border of the medial malleolus, to a crest of bone just above the transverse groove at the lower end of the tibia, to the anterior lateral malleolar ligament, and to the anterior border of the lateral malleolus. Below, it is attached to the rough upper surface of the neck of the talus (astragalus). Medially it is thicker, and is fixed to the talus close to the facet for the medial malleolus, being continuous with the deltoid ligament, and passing forward to blend with the talonavicular ligament. Laterally it is attached to the talus, just below and in front of the angle between the superior and lateral facets, close to their edges, and joins the anterior talofibular ligament.

It is in relation, in front with the tibialis anterior muscle, the anterior tibial vessels and nerve, the extensor tendons of the toes, and the peroneus tertius; and behind with a mass of fat and synovial membrane.

The posterior ligament (fig. 364) is a very thin and disconnected membranous structure, attached above to the lateral malleolus, medial to the peroneal groove; to the posterior margin of the lower end of the tibia lateral to the groove for the tibialis posterior; and to the posterior lateral malleolar ligament. Below, it is attached to the posterior surface of the talus from the deltoid to the lateral ligaments. The passage of the flexor hallucis longus tendon over the back of the joint materially strengthens the posterior ligament.

The deltoid ligament (fig. 363) is attached superiorly to the medial malleolus along its lower border, and to its anterior surface superficial to the anterior ligament; some very strong fibers are fixed to the notch in the lower border of the malleolus, and, getting attachment below to the rough depression on the medial side of the talus, form a deep portion to the ligament. The ligament radiates. The posterior fibers [lig. talotibiale posterius] are short, and incline a little back-

FIG. 363.—MEDIAL VIEW OF THE ANKLE AND THE TARSUS, SHOWING THE GROOVE FOR THE TENDON OF THE TIBIALIS POSTERIOR.



ward to be fixed to the rough medial surface of the talus, close to the superior articular facet, and into the tubercle to the medial side of the flexor hallucis longus groove. The fibers next in front are numerous and form a thick and strong mass, filling up the rough depression on the medial surface of the talus, whilst some [lig. calcaneotibiale] pass over the talocalcaneal joint to the upper and medial border of the sustentaculum tali. The fibers which are connected above with the anterior surface of the malleolus [lig. tibionaviculare] pass downward and somewhat forward to be attached to the navicular and to the margin of the calcaneonavicular ligament.

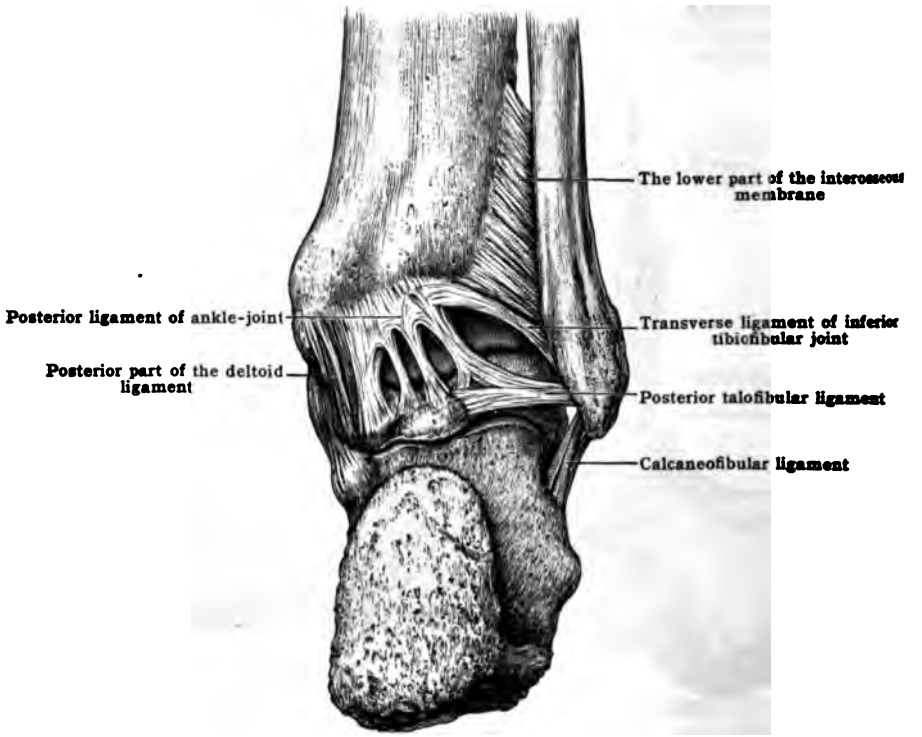
The lateral ligament (figs. 362, 364, 366) consists of three distinct slips. The **anterior talofibular ligament** (anterior fasciculus), is ribbon-like and passes from the anterior border of the lateral malleolus near the tip to the rough surface of the talus in front of the lateral facet, and overhanging the sinus tarsi. The **calcaneofibular ligament** (middle fasciculus), is a strong roundish bundle, which extends downward and somewhat backward from the anterior border of the lateral malleolus close to the attachment of the anterior fasciculus, and from the lateral surface of the malleolus, just in front of the apex, to a tubercle on the middle of the lateral surface of the calcaneum. The **posterior talofibular ligament** (posterior fasciculus), is almost horizontal; it is a strong, thick band attached at one end to the posterior border of the malleolus, and slightly to the fossa on the

medial surface; and at the other end to the talus, behind the articular facet for the fibula, as well as to a tubercle on the lateral side of the groove for the *flexor hallucis longus*.

The middle fasciculus is covered by the tendons of the *peronei longus* and *brevis;* and in extension, the posterior fasciculus is received into the pit on the medial surface of the lateral malleolus.

The **synovial membrane** is very extensive. Besides lining the ligaments of the ankle, it extends upward between the tibia and fibula, forming a short *cul-de-sac* as far as the interosseous ligament. Upon the anterior and posterior ligaments it is very loose, and extends beyond the limits of the articulation. It is said to contain more synovia than any other joint.

FIG. 364.—LIGAMENTS SEEN FROM THE BACK OF THE ANKLE-JOINT.



The lower part of the interosseous membrane
Posterior ligament of ankle-joint
Transverse ligament of inferior tibiofibular joint
Posterior part of the deltoid ligament
Posterior talofibular ligament
Calcaneofibular ligament

The **nerve-supply** is from the saphenous, posterior tibial, and the lateral division of the anterior tibial.

The **arterial supply** comes from the anterior tibial, the anterior peroneal, the lateral malleolar, the posterior tibial, and posterior peroneal.

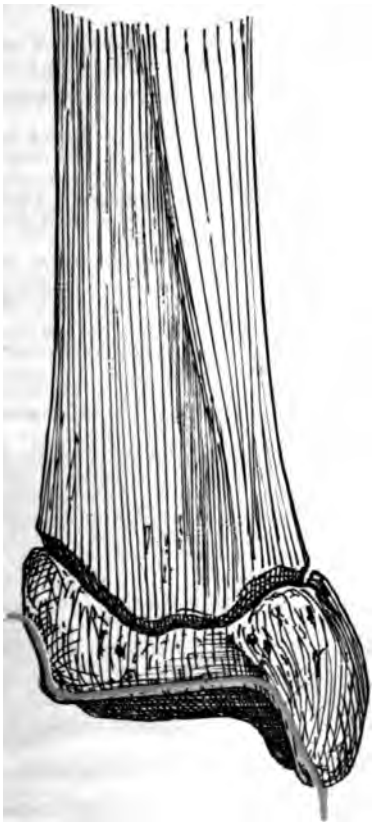
Relations.—In front and in contact with the anterior ligament, from medial to lateral aspects, are the tendon of the tibialis anterior, the tendon of the extensor hallucis longus, the anterior tibial vessels, the anterior tibial nerve, the tendons of the extensor digitorum longus, and the tendon of the peroneus tertius. To the medial side of the tibialis anterior and to the lateral side of the peroneus tertius the joint is subcutaneous anteriorly. Behind and laterally are the tendons of the peroneus longus and brevis. Behind and medially, from medial to lateral side, are the tendon of the tibialis posterior, the tendon of the flexor digitorum longus, the posterior tibial vessels, the posterior tibial nerve, and the tendon of the flexor hallucis longus. Directly behind is a pad of fat which intervenes between the tendo Achillis and the joint. Below and on the lateral side, crossing the middle fasciculus of the lateral ligament, are the tendons of the peroneus longus and brevis. Below and on the medial side, crossing the deltoid ligament, are the tendons of the tibialis posterior and the flexor digitorum longus.

Movements (cf. p. 545).—This being a true hinge-joint, flexion and extension are the only movements of which it is capable, there being no side to side motion, except in extreme extension, when the narrowest part of the talus is thrust forward into the widest part of the tibiofibular arch. In flexion the talus is tightly embraced by the malleoli, and side-to-side movement is impossible. Flexion of the ankle-joint is limited by:—(i) nearly the whole of the fibers of the deltoid ligament none but the most anterior being relaxed; (ii) the posterior and middle portions of the lateral ligament, especially the posterior; (iii) the posterior ligament of the ankle. It is also limited by the neck of the talus abutting on the edge of the tibia.

In most European ankle-joints the anterior edge of the lower end of the tibia is kept from actual contact with the neck of the talus in positions of extreme flexion by the intervention of a pad of fat situated beneath the anterior extension of the anterior ligament. In races which adopt a squatting posture, however, an actual articulation may be developed between these two bony surfaces, a facet being present both upon the anterior margin of the tibia and upon the neck of the talus. These facets are known as 'squatting facets' and are of common occurrence in ancient bones and in the bones of modern oriental people.

Extension of the ankle-joint is limited by:—(1) the anterior fibers of the deltoid ligament; (2) the anterior and middle portions of the lateral ligament; (3) the medial and stronger fibers of the anterior ligament. It is also limited by the posterior portion of the talus meeting with the tibia. Thus the middle portion of the lateral ligament is always on the stretch, owing to its

FIG. 365.—THE LOWER EXTREMITY OF THE TIBIA (ANTERIOR VIEW), TO SHOW THE RELATION OF THE ARTICULAR CAPSULE OF THE ANKLE-JOINT (IN RED) TO THE EPIPHYSIAL LINE.



obliquely backward direction, whereby it limits flexion; and its attachment to the fibula in front of the malleolar apex, whereby it prevents over-extension as soon as the foot begins to twist medialward. This medial twisting, or adduction of the foot, is partly due to the greater posterior length of the medial border of the superior articular surface of the talus, and to the less proportionate height posteriorly of the lateral border of that surface, but chiefly to the side to side movement in the talocalcaneal joints. Flexion and extension take place round a transverse axis drawn through the body of the talus. The movement is not in a direct anteroposterior plane, but on a plane inclined forward and laterally from the middle of the astragalus to the intermetatarsal joint of the second and third toes.

Muscles which act on the ankle-joint (cf. p. 508).—*Flexors.*—Tibialis anterior, extensor hallucis longus, extensor digitorum longus, peroneus tertius. *Extensors.*—Tibialis posterior, flexor digitorum longus, flexor hallucis longus, peroneus longus, peroneus brevis, soleus, gastrocnemius, plantaris.

5. THE TARSAL JOINTS

These may be divided into the following sub-groups:—(*a*) The **talocalcaneal union**; (*b*) The **articulations of the anterior portion of the tarsus**; (*c*) The **mediotarsal joint.** For skeletal relations see figs. 262 and 263. For an account of the longitudinal and transverse arches of the foot, which should be studied in connection with the joints, see pp. 251, 1464.

(*a*) The Talocalcaneal Union

There are two joints which enter into this union—viz., an anterior and a posterior; the former communicates with the mediotarsal; the posterior is separate and complete in itself. This joint is formed by the posterior articular facet of the calcaneus and the corresponding facet on the lower surface of the talus. The two bones are united by an articular capsule with the following ligaments:—

(1) *The Posterior Talocalcaneal Joint*

Class.—*Diarthrosis.*	**Subdivision.**—*Arthrodia.*
Interosseous.	Lateral talocalcaneal.
Posterior talocalcaneal.	Medial talocalcaneal.

The **interosseous ligament** (figs. 366 and 367) is a strong band connecting the apposed surfaces of the calcaneus and talus along their oblique grooves. It is composed of several vertical laminæ of fibers, with some fatty tissue in between.

It is better marked, deeper, and broader laterally. Strong laminæ extend from the rough inferior and lateral surfaces of the neck of the talus to the rough superior surface of the calcaneus anteriorly, forming the posterior boundary of the anterior talocalcaneal joint; these have been described as the **anterior (interosseous) ligament.** The posterior laminæ extend from the roof of the sinus tarsi to the calcaneus immediately in front of the lateral facet, thus forming the anterior part of the capsule of the posterior joint.

The **lateral talocalcaneal ligament** (fig. 366) extends from the groove just below and in front of the lateral articular facet of the talus, to the calcaneus some little distance from the articular margin. Its fibers are nearly parallel with those of the calcaneofibular ligament of the ankle, which passes over it and adds to its strength. It fills up the interval between the calcaneofibular and anterior talofibular ligaments, a considerable bundle of its fibers blending with the anterior border of the calcaneofibular.

The **posterior talocalcaneal ligament** passes from the lateral tubercle of the talus and lower edge of the groove for the flexor hallucis longus to the calcaneus, a variable distance from the articular margin.

The **medial talocalcaneal ligament** includes two portions. The first is a narrow band of well-marked fibers passing obliquely downward and forward from the medial tubercle of the talus, just behind the medial end of the sinus tarsi, to the calcaneus behind the sustentaculum tali, thus completing the floor of the groove for the flexor hallucis longus tendon. The second portion, which is often considered a separate ligament, is described below with the anterior talocalcaneal joint.

The **synovial sac** is distinct from any other.

The **nerve-supply** is from the posterior tibial or one of its plantar branches.

The **arteries** are, a branch from the posterior tibial, which enters at the medial end of the sinus tarsi; and twigs from the tarsal, lateral malleolar, and the peroneal, which enter at the lateral end of the sinus.

(2) *The Anterior Talocalcaneal Joint*

Class.—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

This joint is formed by the anterior facet on the upper surface of the calcaneus and the facets on the lower surface of the neck and head of the talus; it is bounded on the sides and behind by ligaments, and communicates anteriorly with the talonavicular joint. The ligaments are:—

Interosseous.	Medial talocalcaneal.
	Lateral calcaneonavicular.

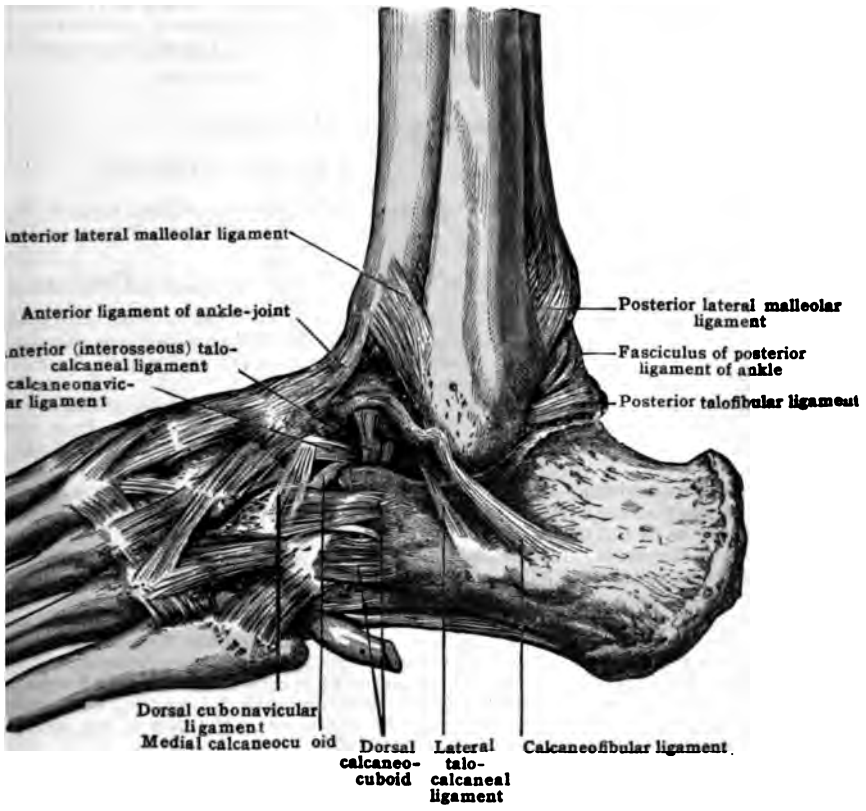
The **interosseous ligament** by its anterior laminæ limits this joint posteriorly. It has been already described with the posterior talocalcaneal joints.

The **medial talocalcaneal** ligament (second portion; see above) consists of short fibers attached above to the medial surface of the neck of the talus, and below to the upper edge of the free border of the sustentaculum tali, blending posteriorly with the medial extremity of the interosseous ligament, and anteriorly with the upper border of the plantar calcaneonavicular ligament. It is strengthened by the deltoid ligament, the anterior fibers of which are also attached to the plantar calcaneonavicular ligament.

The **lateral calcaneonavicular** (figs. 366 and 367) limits this, as well as the talonavicular joint, on the lateral side. It is a strong, well-marked band, extending from the rough upper surface of the calcaneus, lateral to the anterior facet, to a slight groove on the lateral surface of the navicular near the posterior margin. It blends below with the plantar calcaneonavicular, and above with the talonavicular ligament. Its fibers run obliquely forward and medially. The deltoid ligament and middle fasciculus of the lateral ligament of the ankle-joint also add to the security of these two joints, and assist in limiting movements between the bones by passing over the talus to the calcaneus.

synovial membrane is continuous with that of the talonavicular joint. The **arteries** **es are** derived from the same sources as those of the mediotarsal joints.
movements of which these two joints are capable (cf. p. 545) are adduction and abduc- **h some amount** of rotation. Adduction, or inclination of the sole medialward (inver- **combined** with some medial rotation of the toes, and some lateral rotation of the heel; **duction**, or inclination of the foot lateralward (eversion), is associated with turning of **laterally** and the heel medially. Thus the variety and the range of movements of the **the leg**, which at the ankle are almost limited to flexion and extension, are increased. **oid** moves with the calcaneus, while the navicular revolves on the head of the talus. **alking**, the heel is first placed on the ground; the foot is slightly adducted; but as the **ings forward**, first the lateral then the medial toes touch the ground, the talus presses **the navicular** and sinks upon the plantar calcaneonavicular ligament; the foot then **slightly abducted**. When the foot is firmly placed on the ground, the weight is trans- **o it obliquely** downward and medially, so that if the ligaments between the calcaneus **s did not check abduction**, medial displacement of the talus from the tibiofibular arch

FIG. 366.—LATERAL VIEW OF THE LIGAMENTS OF THE FOOT AND ANKLE.



nly be prevented by the tendons passing round the medial ankle (especially the tibialis **:)**. If the ligaments be too weak to limit abduction, the weight of the body increases it, **es the medial** malleolus and talus downward and medially, giving rise to flat foot.
advantages of the obliquity and peculiar arrangement of the posterior talocalcaneal **ion are seen** in walking:—(1) for the posterior facet of the calcaneus receives the whole **f the body** when the heel is first placed on the ground; (2) by the upward pressure of **t against the talus** it transfers the weight to the ball of the toes as the heel is raised, the **: edge of the sustentaculum tali** and the anterior and lateral part of the upper surface **lcaneus preventing** the talus from being displaced too far forward by the superincum- **ght; and** (3) the calcaneus serves to suspend the talus when, with the heel raised by **r action**, the other foot is being swung forward.

b) THE ARTICULATIONS OF THE ANTERIOR PART OF THE TARSUS

se include (1) the cubonavicular; (2) cuneonavicular; (3) intercuneiform; **) cuneocuboid** joints. The general relations and articular cavities are **in fig. 369.**

(1) *The Cubonavicular Union*

Class.—*Syndesmosis* (or *Diarthrosis*). **Subdivision.**—*Arthrodia* (occasional).

The joint cavity is only occasionally present, forming an arthrodial diarthrosis. This joint is often included in the transverse tarsal. The ligaments which unite the cuboid and navicular are:—

Dorsal. Plantar. Interosseous.

The **dorsal cubonavicular ligament** (fig. 366) runs forward and laterally from the lateral end of the dorsal surface of the navicular to the middle third of the medial border of the cuboid on its dorsal aspect, passing over the posterior lateral angle of the third cuneiform bone. It is wider laterally.

The **plantar cubonavicular ligament** is a well-marked strong band, which runs forward and laterally, from the plantar surface of the navicular to the depression on the medial surface of the cuboid, and slightly into the plantar surface just below it.

The **interosseous cubonavicular ligament** is a strong band which passes between the apposed surfaces of these bones from the dorsal to the plantar ligaments. Some of its posterior fibers reach the plantar surface of the foot behind the cubonavicular ligament, and radiate laterally and backward over the medial border of the cuboid to blend with the anterior extremity of the plantar calcaneocuboid ligament.

(2) *The Cuneonavicular Articulation*

Class.—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

The navicular articulates anteriorly with the three cuneiform bones (fig. 369). The ligaments uniting the bones are:—

Dorsal. Medial. Plantar.

The **dorsal cuneonavicular ligament** is very strong, and stretches as a continuous structure, on the dorsal surface of the navicular, between the tubercle of the navicular on the medial side, and the dorsal cubonavicular ligament laterally, passing forward and a little laterally to the dorsal surfaces of the three cuneiform bones.

The **medial cuneonavicular ligament** is a very strong thick band which connects the tubercle of the navicular with the medial surface of the first cuneiform bone. It is continuous with the dorsal and plantar ligaments. Its lower border touches the tendon of the tibialis posterior.

The **plantar cuneonavicular ligament** forms, like the dorsal, a continuous structure extending between the plantar surfaces of the bones. Its fibers pass forward and laterally. It is in relation below with the tendon of the tibialis posterior.

The *synovial membrane* is continuous with that of the cuneocuboid joint and also with those of the intercuneiform joints (fig. 369).

It must be noticed that the expanded tendon of insertion of the tibialis posterior, and the ligaments uniting the navicular with the cuboid and cuneiform bones, pass forward and laterally, while the peroneus longus tendon and the ligaments uniting the first and second rows of bones, except the medial half of the dorsal talonavicular ligaments, pass forward and medially. This arrangement is admirably adapted to preserve the arches of the foot, and especially the transverse arch. Had these tendons and ligaments run directly forward, all the strain on the transverse arch would have fallen on the interosseous ligaments, but as it is, the arch is braced up by the above-mentioned structures.

(3) *The Intercuneiform and* (4) *The Cuneocuboid Articulations*

Class.—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

The articular surfaces and cavities are indicated in fig. 369. The ligaments uniting these bones are divided into three sets:—

Dorsal. Interosseous. Plantar.

The **dorsal ligaments** are three in number, two, the **dorsal intercuneiform**, connecting the three cuneiform bones, and a third, the dorsal **cuneocuboid**, uniting the third cuneiform with the cuboid. They pass between the contiguous margins of the bones, and are blended behind with the dorsal ligaments of the cubonavicular and cuneonavicular joints.

The **plantar ligaments** are two in number: a very strong one, the **plantar intercuneiform**, passes laterally and forward from the lateral side of the base of the first cuneiform to the apex of the second cuneiform, winding somewhat to its lateral side. The second, the **plantar cuneocuboid**, connects the apex of the third cuneiform with the anterior half of the medial surface of the cuboid along its plantar border, joining with the plantar cubonavicular ligament behind.

The **interosseous ligaments** are three in number. They are strong and deep masses of ligamentous tissue which connect the second cuneiform with the first and third cuneiform bones, and the third cuneiform with the cuboid; occupying all the non-articular portions of the apposed surfaces of the bones. The ligaments extend the whole vertical depth between the second cunei-

m and the third, and the third cuneiform and the cuboid, and blend with the dorsal and ntar ligaments; they are situated in front of the articular facets, and completely shut off synovial cavity behind from that in front. The ligament between the first and second cuneirm bones occupies the inferior and anterior two-thirds of the apposed surfaces, and does not nerally extend high enough to separate the synovial cavity of the anterior tarsal joint from at of the second and third metatarsal and cuneiform bones. If it does extend to the dorsal rface, it divides the facets completely from one another, making a seventh synovial sac in the ot.

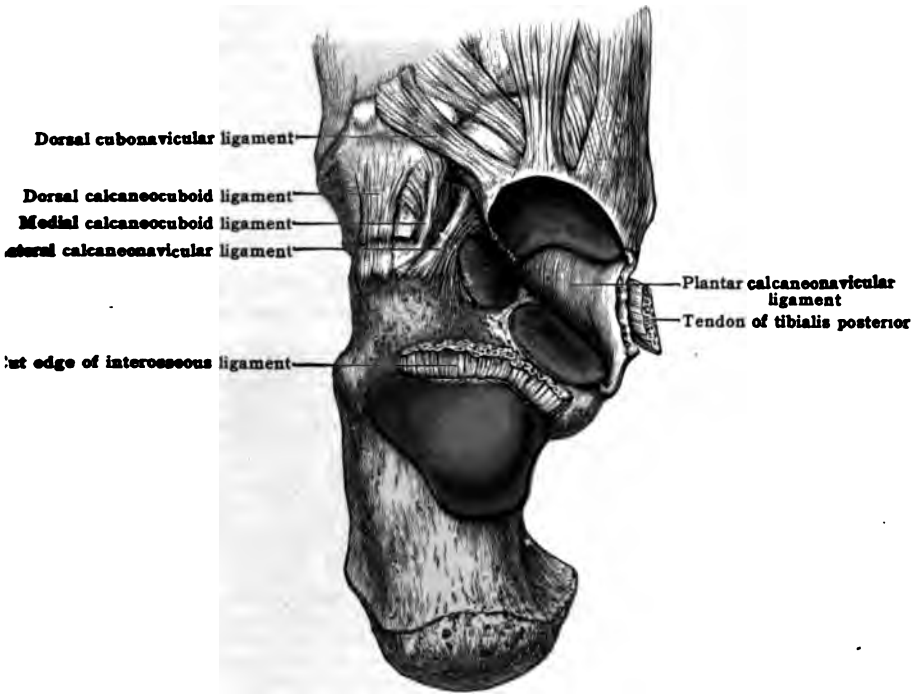
The **synovial cavity** is shown in fig. 369. It is continuous posteriorly with that of the cuneonavicular, and anteriorly (between the second and third cuneiforms) it communicates with the cond and third tarsometatarsal joints.

The **arterial supply** is from the metatarsal and plantar arteries.

The **nerves** are derived from the deep peroneal and medial and lateral plantar.

The **movement** permitted in these joints is very limited, but is of importance in adding to he general pliancy and elasticity of the tarsus without allowing any sensible alteration in the osition of the different parts of the foot, as do the mediotarsal and talocalcaneal joints. It s simply a gliding motion, and either deepens or widens the transverse arch. The third cuneiorm being wedged in between the others is less movable, and so forms a pivot upon which the est can move. The movement is produced more by the weight of the body than by direct nuscular action; and of the muscles attached to this part of the tarsus, all deepen the arch save he tibialis anterior, which pulls the first cuneiform up, and so tends to widen it.

IG. 367.—VIEW OF THE FOOT FROM ABOVE, WITH THE TALUS REMOVED TO SHOW THE PLANTAR AND LATERAL CALCANEONAVICULAR LIGAMENTS.



(*c*) THE TRANSVERSE TARSAL (CHOPART'S) JOINTS

The articulations of the anterior and posterior portions of the tarsus, although the same transverse line, consist of two separate joints, viz., (1) a medial, the onavicular, which communicates with the anterior talocalcaneal articulation; d (2) a lateral, the calcaneocuboid, which is complete in itself. The move-nts of the anterior upon the posterior portions of the foot take place at these nts simultaneously. It will be most convenient to deal with the joints sepa-ely as regards the ligaments; while the arteries, nerves, and movements will considered together.

(1) *The Talonavicular Articulation*

Class.—*Diarthrosis.* **Subdivision.**—*Arthrodia* (?).

Although it resembles a ball-and-socket joint, it is usually classified as arthro-l, on account of the limited extent of movement. It communicates with

the anterior talocalcaneal articulation, and two of the ligaments which close it in do not touch the talus, but pass from the calcaneus to the navicular. The uniting ligaments include, in addition to the articular capsule, the following:—

Lateral calcaneonavicular. Plantar calcaneonavicular.
Talonavicular.

The **lateral calcaneonavicular** has been already described (p. 342).

The **plantar calcaneonavicular ligament** (figs. 367 and 368) is an exceedingly dense, thick plate of fibroelastic tissue. It extends from the sustentaculum tali and the lower surface of the calcaneus in front of a ridge curving laterally to the anterior tubercle of that bone, to the whole width of the inferior surface of the navicular, and also to the medial surface of the navicular behind the tubercle. Medially it is blended with the anterior portion of the deltoid ligament of the ankle, and laterally with the lower border of the lateral calcaneonavicular ligament. It is thickest along the medial border. Its upper surface loses the well-marked fibrous appearance which the ligament has in the sole, and becomes smooth and faceted. In contact with the lower surface of the ligament the tendon of the tibialis posterior passes, giving considerable support to the head of the talus by augmenting the power and protecting the spring of the ligament. The fibers of the ligament run forward and medially. On account of its elasticity it is sometimes termed the **spring ligament.**

The **talonavicular ligament** is a broad, thin, but well-marked layer of fibers which passes from the dorsal and lateral surfaces of the neck of the talus to the whole length of the dorsal surface of the navicular. Many of the fibers converge to their insertion on the navicular. The fibers low down on the lateral side blend a little way from their origin with the upper edge of the lateral calcaneonavicular ligament, and then pass forward and medially to the navicular; those next above pass obliquely and with a distinct twist over the upper and lateral side of the head of the talus to the center of the dorsum of the navicular, overlapping fibers from the medial side of the talus as well as some from the anterior ligament of the ankle-joint.

Synovial membrane.—The talonavicular is lined by a continuation of the same synovial membrane as that lining the anterior talocalcaneal joint (fig. 369).

(2) *The Calcaneocuboid Articulation*

Class.—*Diarthrosis.* **Subdivision.**—*Saddle-shaped Arthrodia.*

The ligaments which are supplementary to the articular capsule and unite the bones forming the lateral part of the mediotarsal joint are:—

Medial calcaneocuboid. Dorsal cancaneocuboid.
Long plantar. Plantar calcaneocuboid.

The **medial calcaneocuboid ligament** (fig. 367) is a strong band of fibers attached to the calcaneus along the medial part of the non-articular ridge above the articular facet for the cuboid, and also to the upper part of the medial surface close to the articular margin, and passes forward to be attached to the depression on the medial surface of the cuboid, and also to the rough angle between the medial and inferior surfaces. At the calcaneus this ligament is closely connected with the lateral calcaneonavicular ligament. Toward the sole it is connected with the plantar calcaneocuboid ligament, and superiorly with the dorsal calcaneocuboid.

The **dorsal calcaneocuboid** (fig. 367) is attached to the dorsal surfaces of the two bones, extending low down laterally to blend with the lateral part of the plantar calcaneocuboid ligament. Over the medial half, or more, the ligament stretches some distance beyond the margins of the articular surfaces, reaching well forward upon the cuboid to be attached about midway between its anterior and posterior borders; but toward the lateral side, the ligament is much shorter, and is attached to the cuboid behind its tubercle.

The **long plantar ligament** (fig. 368) is a strong, dense band of fibers which is attached posteriorly to the whole of the inferior surface of the calcaneus between the posterior tubercles and the rounded eminence (the anterior tubercle) at the anterior end of the bone. Most of its fibers pass directly forward, and are fixed to the lateral two-thirds or more of the oblique ridge behind the peroneal groove on the cuboid, while some pass further forward and medially, expanding into a broad layer, and are inserted into the base of the second, third, fourth, and medial half of the fifth metatarsal bones. This anterior expanded portion completes the canal for the peroneus longus tendon, and from its lower surface arise the oblique adductor hallucis and the flexor digiti quinti brevis muscles.

The **plantar calcaneocuboid** (short plantar) (fig. 368) is attached to the rounded eminence (anterior tubercle) at the anterior end of the lower surface of the calcaneus, and to the bone in front of it, and then takes an oblique course forward and medially, and is attached to the whole of the depressed inferior surface of the cuboid behind the oblique ridge, except its lateral angle. It is strongest near its lateral edge, and is formed by dense strong fibers.

The **synovial membrane** is distinct from that of any other tarsal joint.

The **arterial supply** of the mediotarsal joints is from the anterior tibial, from the tarsal and metatarsal branches of the dorsalis pedis, and from the plantar arteries.

The **nerve-supply** of the mediotarsal joints is from the lateral division of the deep peroneal, and occasionally from the superficial peroneal or lateral plantar.

Relations.—On the *dorsal aspect* of the midtarsal joint lie the tendons of the tibialis anterior, extensor hallucis longus extensor digitorum longus, and peroneus tertius, the muscular part

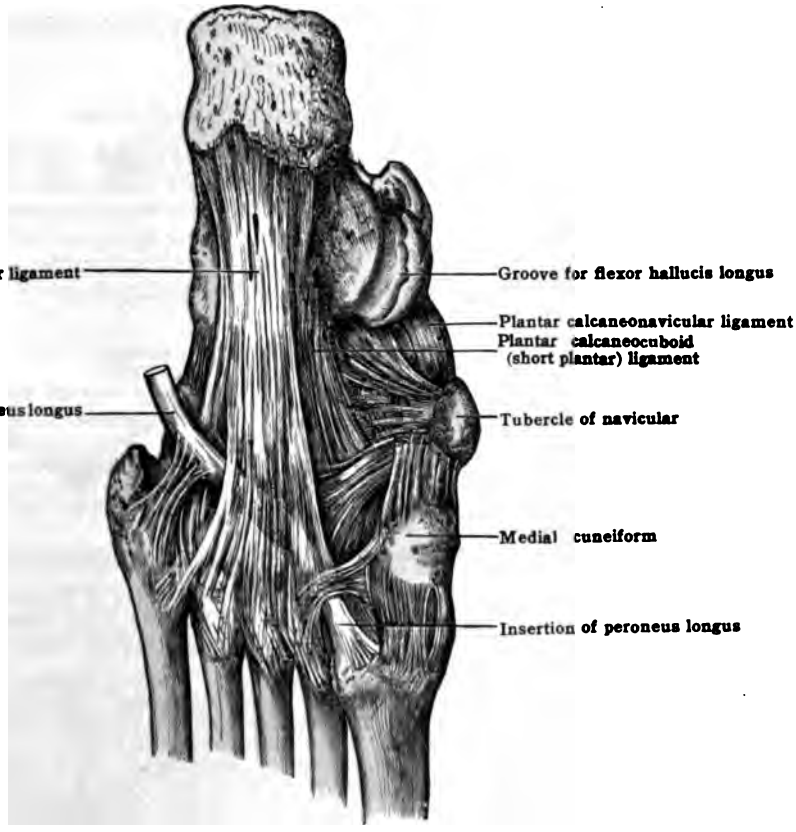
of the extensor digitorum brevis, the dorsalis pedis artery, and the deep peroneal (anterior tibial) nerve. On its *plantar aspect* are the tendons of the flexor digitorum longus and hallucis longus, quadratus plantæ (accessorius), and the medial and lateral plantar vessels and nerves. It is crossed laterally by the tendons of the peroneus longus and brevis and medially by the tendon of the tibialis posterior.

The **movements** (cf. p. 545) which take place at the mediotarsal joints are mainly flexion and extension, with superadded side-to-side and rotatory movements. Flexion at these joints is simultaneous with extension of the ankle, and *vice versa*. Flexion and extension do not take place upon a transverse, but round an oblique, axis which passes from the medial to the lateral side, and somewhat backward and downward through the talus and calcaneus.

Combined with flexion and extension is also some rotatory motion round an anteroposterior axis which turns the medial or lateral border of the foot upward. There is also a fair amount of side-to-side motion whereby the foot can be inclined medially (i. e., adducted) or laterally (i. e., abducted).

These movements of the mediotarsal joint occur in conjunction with those of the ankle and talocalaneal joints. Rotation at the talocalaneal joint is, however, round a vertical

FIG. 368.—LIGAMENTS OF THE SOLE OF THE LEFT FOOT.



axis in a horizontal plane, and so turns the toes medially or laterally; whereas at the mediotarsal union the axis is anteroposterior and the medial or lateral edge of the foot is turned upward. Gliding at the talocalcaneal joint elevates or depresses the edge of the foot, while at the mediotarsal it adducts or abducts the toes without altering the relative position of the calcaneus to the talus.

Thus flexion at the mediotarsal joint is associated with adduction and medial rotation of the foot, occurring simultaneously with extension of the ankle; and extension at the mediotarsal joint is associated with abduction and lateral rotation, occurring simultaneously with flexion of the ankle.

Flexion and medial rotation are far more free than extension and lateral rotation, which latter movements are arrested by the ligaments of the sole as soon as the foot is brought into the position in which it rests on the ground.

Although the talonavicular resembles a ball-and-socket joint, yet, owing to the union of the navicular with the cuboid, its movements are limited by the shape of the calcaneocuboid joint; this latter being concavoconvex from above downward, prevents rotation round a vertical axis, and also any side-to-side motion except in a direction obliquely downward and medially, and upward and laterally. This is also the direction of freest movement at the talonavicular joint. Movement is also limited by the ligamentous union of the calcaneus with the navicular. The twisting movement of the foot such as turning it upon its medial or lateral edge, and the increase

or diminution of the arch, take place at the tarsal joints, especially the mediotarsal and talocalcaneal articulations. Here too those changes occur which, owing to paralysis of some muscles or contraction of others, result in talipes equinovarus, or valgus.

Muscles which act on the midtarsal joint (cf. p. 545).—*Medial rotators* (inverters).—Tibialis anterior and posterior acting simultaneously; they are aided by the flexor digitorum longus and flexor hallucis longus. *Lateral rotators* (everters).—The peronei longus, brevis, and tertius, acting simultaneously. They are aided by the extensor digitorum longus.

6. THE TARSOMETATARSAL ARTICULATIONS

Class.—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

There may be said to be three articulations between the tarsus and metatarsus, as shown in figs. 262 and 369, viz.:—

(*a*) The medial, between the first cuneiform and first metatarsal bones.
(*b*) The intermediate, between the three cuneiform and second and third metatarsal bones.
(*c*) The lateral, or cubometatarsal, between the cuboid and fourth and fifth metatarsal bones.

(*a*) The Medial Tarsometatarsal Joint

A complete **articular capsule** unites the first metatarsal with the first cuneiform, the fibers of which are very thick on the inferior and medial aspects; those on the lateral side pass from behind forward in the interval between the interosseous ligaments which connect the two bones forming this joint with the second metatarsal. The ligament on the plantar aspect is by far the strongest, and blends at the cuneiform bone with the cuneonavicular ligament.

(*b*) The Intermediate Tarsometatarsal Joint

Into this union there enter the three cuneiform and second and third metatarsal bones, which are bound together by the following ligaments (supplementary to the articular capsule): dorsal, plantar, interosseous.

The dorsal ligaments [ligg. tarsometarsea dorsalia].—1. Some short fibers cross obliquely from the lateral edge of the first cuneiform bone to the medial border of the base of the second metatarsal bone; they take the place of a dorsal metatarsal ligament, which is wanting between the first and second metatarsal bones.

2. Between the second cuneiform and the base of the second metatarsal bone some fibers run directly forward.

3. The third cuneiform is connected with (1) the lateral corner of the second metatarsal bone by a narrow band passing obliquely medially; (2) with the third metatarsal by fibers passing directly forward; and (3) with the fourth metatarsal by a short band passing obliquely laterally to the medial edge of its base.

The plantar ligaments [ligg. tarsometarsea plantaria].—A strong ligament unites the first cuneiform and the bases of the second and third metatarsal bones. The tibialis posterior is inserted into these bones close beside it.. Other slender ligaments connect the second cuneiform with the second, and the third cuneiform with the third metatarsal bones.

The interosseous ligaments [ligg. cuneometatarsea interossea].—(1) A strong broad interosseous ligament extends between the lateral surface of the first cuneiform and the medial surface of the base of the second metatarsal bone. It is attached to both bones below and in front of the articular facets, and separates the intermediate from the medial tarsometatarsal joint. (2) A second band is attached behind to a fossa on the anterior and lateral edge of the third cuneiform and to the interosseous ligament between it and the cuboid, and passes horizontally forward to be attached to the whole depth of the fourth metatarsal bone behind its medial facet, and to the opposed surfaces of the third and fourth below the articular facets upon their sides. It separates the middle tarsometatarsal, and intermetatarsal between the third and fourth bones, from the cubometatarsal joint. It is more firmly connected with the third bone than with the fourth. (3) A slender ligament composed only of a few fibers often passes from a small tubercle on the medial and anterior edge of the third cuneiform to a groove on the lateral edge of the second metatarsal bone between the two facets upon their sides.

The **synovial membrane** (fig. 369) is prolonged forward from that of the cuneonavicular and intercuneiform articulations.

The **arteries for the tarsometatarsal joints** are derived:—(1) for the medial, from the dorsalis pedis and medial plantar; (2) for the rest, twigs from the arcuate and deep plantar arch.

The **nerve-supply** comes from the deep peroneal and plantar nerves.

The **movements** permitted at these joints are flexion and extension of the metatarsus on the tarsus; and at the medial and lateral divisions, slight adduction and abduction. In the lateral, the side-to-side motion is freer than in the medial joint, and freest between the fifth metatarsal bone and the cuboid. In the medial joint, flexion is combined with slight abduction and extension with adduction.

There is also a little gliding, which allows the transverse arch to be increased or diminished in depth; the medial and lateral two bones sliding downward, and the two middle a little upward, when the arch is increased; and *vice versa* when the arch is flattened.

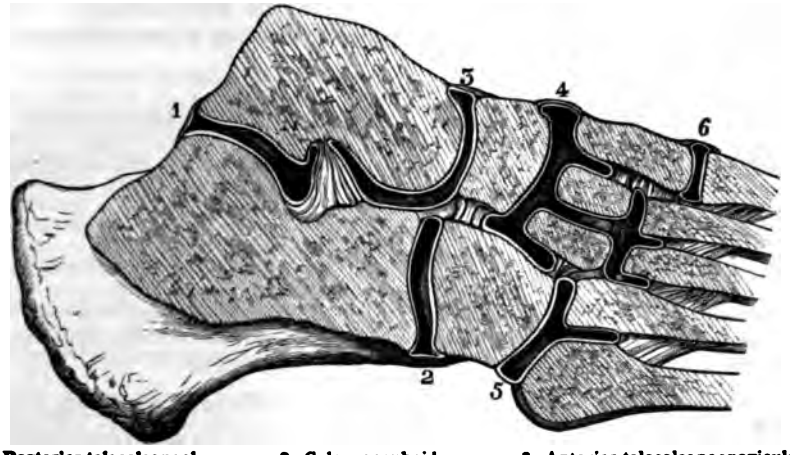
(*c*) The Lateral or Cubometatarsal Joint

The bones comprising this joint are the fourth and fifth metatarsal and the anterior surface of the cuboid, firmly connected on all sides by the articular capsule, and strengthened by the following ligaments:—

Dorsal. Plantar. Interosseous.

The **plantar cubometatarsal ligament** is a broad, well-marked ligament, which extends from the cuboid behind to the bases of the fourth and fifth metatarsal bones in front. It is continuous along the groove at the base of the fifth metatarsal bone with the dorsal ligament, and as it passes round the lateral border of the foot it is somewhat thickened, and may be described as the **lateral cubometatarsal ligament.** On its medial side it joins the interosseous

Fig. 369.—Section to show the Articular Cavities of the Foot.



1. Posterior talocalcaneal. 2. Calcaneocuboid. 3. Anterior talocalcaneonavicular.
4. Tarsal. 5. Cubometatarsal. 6. First metatarsocuneiform.

ligaments, thus completing the capsule below. It is not a thick structure, and to see it the long plantar ligament, the peroneus longus, and lateral slip of the tibialis posterior must be removed; the attachment of these structures to the fourth and fifth metatarsal bones considerably assists to unite them with the tarsus.

The **dorsal cubometatarsal ligament** is composed of fibers which pass obliquely outward and forward from the cuboid to the bases of the fourth and fifth metatarsal bones. They complete the capsule above, and are continuous laterally with the lateral cubometatarsal ligament.

The **interosseous ligament** shuts off the cubometatarsal from the middle tarsometatarsal joint. It is attached to the third cuneiform behind, and to the whole depth of the fourth metatarsal behind its medial facet, and to the apposed surfaces of the third and fourth bones below their articular facets. It is continuous below with the plantar ligament.

The **synovial membrane** is separate from the other synovial sacs of the tarsus, and is continued between the fourth and fifth metatarsal bones. (fig. 369).

Relations.—The line of the tarsometatarsal joints is crossed dorsally by the tendons of the long and short extensor muscles of the toes and the tendon of the peroneus tertius. On the plantar aspect it is in relation with the oblique adductor of the great toe, the short flexor of the great toe, the lateral plantar artery, and the tendon of the peroneus longus. Its medial end is subcutaneous except that it is crossed, near the plantar surface, by a slip of the tendon of the tibialis anterior, and its lateral end is crossed by the tendon of the peroneus brevis.

7. THE INTERMETATARSAL ARTICULATIONS

Class.—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

The bases of the metatarsal bones articulate with each other as shown in figs. 262 and 369. They are firmly held in position by dorsal, plantar, and interosseous ligaments, supplementing the articular capsules. The first only occasionally articulates by means of a distinct facet with the second metatarsal (figs. 279 and 280).

The **dorsal ligaments are broad,** membranous bands passing between the four lateral toes on their dorsal aspect; but in place of one between the first and second metatarsal bones, a ligament extends from the first cuneiform to the base of the second metatarsal bone.

The **plantar ligaments** are strong, thick, well-marked ligaments which connect the bones on their plantar aspect.

The three **interosseous ligaments** between the four lateral metatarsals are very strong, and are situated at the points of union of the shaft with the bases of the bones, and fill up the spaces on their sides. They limit the synovial cavities in front of the synovial facets.

The common **synovial membrane** (fig. 369) of the tarsus extends between the second and third, and third and fourth bones; that of the cubometatarsal joint extending between the fourth and fifth.

The **arterial** and **nerve-supply** is the same as for the tarsometatarsal joints.

The **movements** consist merely of gliding, so as to allow the raising or widening of the transverse arch. Considerable flexibility and elasticity are thus given to the anterior part of the foot, enabling it to become moulded to the irregularities of the ground.

The Union of the Heads of the Metatarsal Bones

The **heads of the metatarsal bones** are connected on their plantar aspect by the **transverse ligament** [ligg. capitulorum transversa], consisting of four bands of fibers passing transversely from bone to bone, blending with the fibrocartilaginous or sesamoid plates of the metatarsophalangeal joints, and the sheaths of the flexor tendons where they are connected with the fibrocartilages. It differs from the corresponding ligament in the hand by having a band from the first to the second metatarsal bone.

8. THE METATARSOPHALANGEAL ARTICULATIONS

The skeletal relations at these joints are shown in figures 262 and 263.

(*a*) The Metatarsophalangeal Joints of the Four Lateral Toes

Class.—*Diarthrosis.* **Subdivision.**—*Condylarthrosis.*

These joints are formed by the concave proximal ends of the first phalanges articulating with the rounded heads of the metatarsal bones, and united by articular capsules strengthened by the following ligaments:—

Collateral. Dorsal. Plantar accessory.

The two **collateral ligaments** are strong bands passing from a ridge on each side of the head of the metatarsal bone to the sides of the proximal end of the first phalanx, and also to the sides of the sesamoid plate which unites the two bones on their plantar surfaces. On the dorsal aspect they are united by the dorsal ligament.

The **dorsal ligament** consists of loose fine fibers, extending between the collateral ligaments, thus completing a capsule. It is connected by fine fibers to the lower surface of the extensor tendons, which pass over and considerably strengthen this portion of the capsule.

The **plantar accessory ligament** (or sesamoid plate) helps to deepen the shallow facet of the phalanx for the head of the metatarsal bone, and corresponds to the accessory volar ligament of the fingers. It is firmly connected to the collateral ligaments and the transverse ligament, and is grooved inferiorly where the flexor tendons pass over it. It serves to prevent dorsal dislocation of the phalanx.

The second metatarsophalangeal joint is about 6 mm. in front of both the first and third metatarsophalangeal joints. The third metatarsophalangeal joint is about 6 mm. in front of the fourth, and the fourth about 9 mm. in front of the fifth. The head of the fifth metatarsal is in line with the neck of the fourth. Thus the lateral side of the longitudinal arch of the foot is shorter than the medial; it is also distinctly shallower.

(*b*) The Metatarsophalangeal Joint of the Great Toe

Class.—*Diarthrosis.* **Subdivision.**—*Ginglymus.*

The metatarsophalangeal joint of the great toe differs from the rest in the following particulars:—

(1) The bones are on a larger scale, and the articular surfaces are more extensive.

(2) There are two grooves on the plantar surface of the metatarsal bone, one on each side of the median line, for the sesamoid bones.

(3) The sesamoid bones replace the accessory plantar ligament (sesamoid plate). They are two small hemispherical bones developed in the tendons of the flexor hallucis brevis, convex below, but flat above where they play in grooves on the head of the metatarsal bone; they are united by a strong transverse ligamentous band, which is smooth below and forms part of the channel along which the long flexor tendon plays. They are firmly united to the base of the phalanx by strong short fibers, but to the metatarsal bone they are joined by somewhat looser fibers. At the sides they are connected with the collateral ligaments and the sheath of the flexor tendon. They provide shifting leverage for the flexor hallucis brevis as well as for the flexor hallucis longus.

arteries come from the digital and metatarsal branches; and the **nerves** from the cutaneous, or from small twigs of the nerves to the interossei muscles.

movements of the metatarsophalangeal joints (cf. p. 546) are: flexion, extension, and abduction or adduction.

ion is more free than extension, and is limited by the extensor tendons and dorsal liga- extension is limited by the flexor tendons, the plantar fibers of the collateral ligaments, sesamoid plates. The side-to-side motion is possible from the shape of the bony sur- ut is very limited, being most marked in the great toe (although the joint is ginglymoid). The movement is limited by the collateral ligaments and sesamoid plates.

9. THE INTERPHALANGEAL JOINTS

Class.—*Diarthrosis.* **Subdivision.**—*Ginglymus.*

articulations between the first and second and second and third phalanges toes are similar to those of the fingers, with this important difference, that nes are smaller and the joints, especially between the second and third ges, are often ankylosed. The ligaments which unite them include, in n to the articular capsule:—

Collateral. Dorsal. Accessory plantar.

two collateral ligaments are well marked, and pass on each side of the joints from a ugh depression on the head of the proximal, to a rough border on the side of the base of al phalanx of the joint.

dorsal ligament is thin and membranous, and extends across the joint from one col- ligament to the other beneath the extensor tendon, with the deep surface of which it is ed and by which it is strengthened.

accessory plantar ligament covers in the joint on the plantar surface. It is a fibro- inous plate, connected at the sides with the collateral ligaments, and with the bones by gamentous fibers; the plantar surface is smooth, and grooved for the flexor tendons.

arteries and **nerves** are derived from the corresponding digital branches.

only movements permitted at these joints are flexion and extension.

he interphalangeal joint of the great toe there is very frequently a small sesamoid bone lays on the plantar surface of the first phalanx, in the same way as the sesamoid bones netatarsophalangeal joint play upon the plantar surface of the head of the metatarsal

tions of the muscles acting on the metatarsophalangeal and interphalangeal joints foot.—For these the student may refer to the accounts given of the relations of the onding joints in the hand and of the actions of the muscles upon those joints. See . 546, 547.

erences.—Extensive bibliographies for the joints are given in the larger works on human y by Quain, Poirier-Charpy and in the special treatise, 'Handbuch der Anatomie und nk der Gelenke,' by Professor Rudolf Fick (in von Bardeleben's Handbuch der Ana-

SECTION V

THE MUSCULATURE

REVISED FOR THE SIXTH EDITION

BY C. R. BARDEEN, A.B., M.D.

PROFESSOR OF ANATOMY IN THE UNIVERSITY OF WISCONSIN

ICLES, the movements of which are under the control of the will, almost
mpletely envelope the skeletal framework of the body; close in the oral,
bdominal, and pelvic cavities; separate the thoracic from the abdominal
rround the pharynx and the upper portion of the esophagus; and are
nected with the eye, ear, larynx, and other organs. They constitute
-fifths to three-sevenths of the weight of the body.

s section an account is given of the gross anatomy of the musculature
to the skeleton and the skin, with the exception of certain of the muscles
more conveniently treated in connection with the organs to which they
ded. Thus, the muscles of the eye, the ear, the pharynx, the larynx,
ntrinsic muscles of the tongue are described in the sections devoted to
ctures.

ons to the skin.—Beneath the skin is a sheet of connective tissue, the
itanea. In this, in some regions of the body (the head, neck, and palm),
subcutaneous muscles are embedded. Superficial muscles of this kind
a panniculus carnosus, much more extensive in the lower mammals
an. The tela subcutanea is separated from the more deeply seated mus-
y areolar tissue, which, in most places, is loose in texture over the mus-
some regions, as over the upper part of the back, the tela subcutanea is
ited to the underlying musculature and is less freely movable. In
ubcutanea more or less fat is usually embedded. This constitutes the
s adiposus, which varies greatly in thickness in different parts of the
s a rule, it is much more developed over muscles than over those regions
e and joints lie beneath the skin. From the tela subcutanea of the eye-
, and scrotum fat is absent. The deeper layer of the tela subcutanea is
ss free from fat, and in it run the main trunks of the cutaneous nerves
ls. In some regions, as over the lower part of the abdomen, one or more
embranes are differentiated in this deeper layer.

tela subcutanea the term **superficial fascia** has been commonly applied, but since
o a confusion with the superficial fasciæ which immediately invest the muscles, it
er to restrict the term fascia to the membranes connected with the muscular system,
the term **tela subcutanea,** or subcutaneous tissue, for the layer of connective tissue
rlies the skin and is continuous over the whole surface of the body.

veral places where the skin overlies bony prominences well-marked
bursæ, or sacs (**bursæ mucosæ**), are developed in the tela subcutanea.
the skin and the subcutaneous tissue must be removed in order to study
es of various regions, the tela subcutanea and subcutaneous bursæ may
iently described in connection with the muscles, and brief references will,
be made to them in connection with the musculature of various regons.

le-fasciæ.—The musculature of the body, with the exception of some of
itaneous muscles, is ensheathed by fibrous tissue, which, in certain re-
ns distinct membranes, while in other regions it is delicate and not
be distinguished from the superficial connective tissue of the muscles,
ysium externum. The membranes, or **muscle-fasciæ,** are united to

various parts of the skeleton, either directly or by means of intermuscular septa, and, where strong, keep the underlying musculature in place. In some regions they are united to the muscles; in others they are separated from the underlying musculature by loose areolar tissue, which allows free movement between the surface of the muscles and the overlying fascia. The best example of a strong fascia of this nature is that which envelopes the extensor muscles of the thigh. Where the fasciæ are well developed, the main bundles of constituent fibers take a course directly or obliquely transverse to the direction of the underlying muscles. They may be composed of several successive layers of fibrous tissue, the fibers of one layer taking a different direction from those of the next layer.

The **function** of the fasciæ is the mechanical one of restraining or modifying muscle action. The direction of the main component fiber-bundles indicates the direction of the greatest stress to which the fasciæ are subjected. Indirectly the fasciæ promote the circulation of the blood and lymph in places where the vessels lie between the contracting muscles and the overlying fascia.

Intermuscular septa.—Muscle-fasciæ enclose not only the external layer of the musculature of the body, but also the various groups of more deeply seated muscles. In addition, between the individual muscles, and between the different layers and groups of muscles, there intervenes a greater or less amount of connective tissue, sometimes loose in texture, sometimes dense in structure. In these intermuscular septa run the chief nerves and blood-vessels of the region in which the musculature lies.

Gross structure of the muscles.—The muscles are composed of bundles of reddish fibers surrounded by a greater or less extent of white and glistening connective tissue. They are attached by prolongations of this tissue in the form of **tendons** or **aponeuroses** usually to the bony skeleton, but also in places to cartilages, as in the thorax and larynx; to the skin, as in the face; to mucous membranes, as in the tongue and cheeks; to the tendons of other muscles, as in the case of the lumbrical muscles; to muscle fasciæ, as in the case of the oblique and transverse muscles of the abdomen; and to other structures, as, for instance, to the eyeball.

The fleshy portion of the muscle is called the **belly**. The belly is usually attached at one extremity to a portion of the skeleton or to some other structure which serves as a support for its action on the structures to which its other extremity is attached. The attachment to the more fixed part is called the **origin** of the muscle; the attachment to the structure chiefly acted on is called the **insertion**. Thus the origin of the biceps muscle, the chief flexor of the forearm at the elbow, is from the scapula; the insertion is into the radius and into the fascia of the forearm. The part of the muscle attached to the origin is called the **head** of the muscle. The part attached to the insertion is sometimes called the **tail**, but this term is much less frequently used than the former.

The muscles vary greatly in **size** and **form**. Thus the stapedius muscle of the middle ear is a slender little structure, only a few mm. long, while the gluteus maximus muscle of the hip is a large, rhomboid structure often several cm. thick and with a surface area of over 500 square cm. The length of a muscle from origin to insertion may be much less than the width of the muscle, as in the intercostal muscles; or much greater than the width, as in most of the long muscles of the limbs. The thickness of a muscle is usually less than the width—so much so in some instances that the muscle is described as flat, sheet-like, or ribbon-like; while in other instances the belly is cylindrical. In flat muscles the general outline is usually quadrilateral or triangular. In triangular muscles in most instances one angle of the triangle marks the insertion of the muscle, while the opposite side marks the origin. In cylindrical muscles the belly usually has a somewhat fusiform shape, and grows smaller both toward the origin and the insertion of the muscle.

Some muscles are divided by tendons transverse to the long axis of the muscle. When one such tendon exists, the muscle is called **digastric** (fig. 379); when several, **polygastric**, e. g., rectus abdominis (fig. 419).

Two muscle-masses with separate origins may have a common insertion. Such muscles are usually designated **bicipital** muscles (biceps muscles of the arm and thigh). Other muscles have three heads (the triceps muscle of the arm) or four (the quadriceps muscle of the thigh). In the latter case special names are given to the four parts or muscles which constitute the quadriceps as a whole. In

bdivisions of the musculature on each side of the body into individual s, but also in describing muscles placed near the median line either as single s with bilateral halves or as paired muscles. In addition some muscles are nstantly present, and there are differences of opinion as to which of these less nt muscles should be classed with the normal musculature. The BNA izes 347 paired and two unpaired skeletal muscles, and 47 paired and two ed muscles belonging to the visceral system and organs of special sense. ıe skeletal muscles the head has 25 paired and one unpaired; the neck 16 the back 112 paired; the thorax 52 paired, one unpaired; the abdomen and 3 paired; the upper extremity, 52 paired; the lower extremity, 62 paired).

r **structure of muscles.**—While no attempt can be made here to describe in detail the croscopic features of muscle structure, some of the more general features of muscle ture may be briefly mentioned.

contractile cells of voluntary muscle are long, slender, multinucleated **'fibers'**, the pro- of which exhibits both cross and longitudinal striation. The longitudinal striation ı the presence of fibrils situated in the sarcoplasma. The cross striation is due to alter- ments of singly and doubly refracting substance in these fibrils. The length of these the human body varies from a few millimeters to sixteen centimeters or more, and the ıs from ten to eighty microns. Each muscle-fiber is surrounded by an especially differ- sheath, the **sarcolemma.** Outside of this is a layer of delicate connective tissue, the ium internum or **endomysium,** the fibers of which are in part inserted into the sarco- This connective tissue, which is especially developed at the ends of the fibers, serves to hem either directly to the structures on which the muscle acts or to the skeletal frame- the muscle.

ıe simplest mammalian muscles the muscle-fibers take a parallel course from tendon to and are not definitely bound into secondary groups. An example may be seen in fig. which represents two segments of the rectus abdominis muscle of a mouse. More often , the individual fibers do not run the entire distance from tendon to tendon, but instead erdigitate, and the interdigitating fibers are bound up into secondary and tertiary ıosing fiber-bundles by connective tissue, in which there is usually a considerable of elastic tissue. Fig. 370,b, represents diagrammatically this interdigitation of fiber- as seen in the abdominal musculature of one of the larger mammals.

ıost of the flat muscles of the body the fiber-bundles either take a nearly parallel course ıdon to tendon or they converge from the tendon of origin toward the tendon of insertion 370, c–e). The greater the distance from tendon to tendon, the more marked is the itation of the constituent fiber bundles.

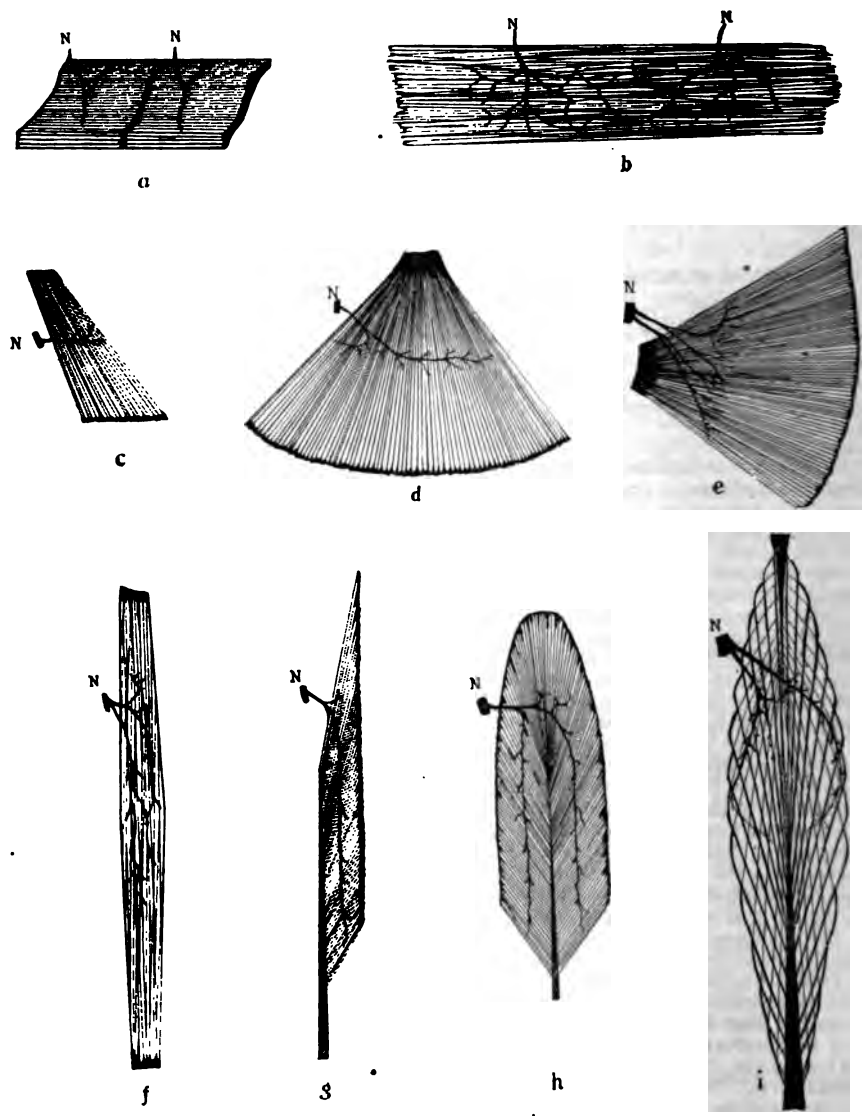
ongated muscles the tendons of origin and insertion may either arise near the extremities ıuscle or may extend for a considerable distance on the surface or within the substance of cle. In the former case the belly of the muscle is composed of bundles of interdigitating hich take a course parallel with the long axis of the muscle. This is shown diagrammatic- fig. 370, f. An example may be seen in the sartorius muscle of the thigh (fig. 442). he tendons extend far on the surface or within the substance of the muscle, the con- fiber-bundles take a course oblique to the long axis of the muscle. When they take a rom a tendon of origin on one side toward a tendon of insertion on the other, the muscle **unipenniform** (see fig. 370, g, and the extensor digitorum longus, fig. 446). In other s the fiber bundles converge from two sides toward a central tendon. Such a muscle **bipenniform** (see fig. 370, h, and the flexor hallucis longus, fig. 447). When there are endons in the muscle between which the fiber-bundles run obliquely, the muscle is called niform. In **fusiform** muscles the tendons usually either embrace the extremity of the ike a hollow cone, or they extend far on the surface or within the substance of the muscle. muscles the fiber-bundles take a curved course from one tendon to the other. The bundles ise highest on one tendon are inserted highest on one other, and the fiber-bundles of lowest ave the lowest insertion. This structure is diagrammatically shown in fig. 370, i. example may be found in the rectus femoris muscle (fig. 442).

y other arrangements of the fiber-bundles are found, and the arrangements here shown variously combined. In most muscles the architecture is decidedly complex. In the mplex muscles dense connective-tissue septa, or intramuscular fasciæ, serve to separate regions of the muscle from one another. In general there are groups of muscle fiber-

bundles surrounded by a greater amount of connective tissue, or perimysium internum, than that surrounding the individual fiber-bundles, and the latter are surrounded by a denser connective tissue than that surrounding the component muscle-fibers. The muscles are surrounded externally by a more or less dense sheet of connective tissue called the perimysium externum, or epimysium, which is continuous with the connective tissue within the muscle,

FIG. 370.—DIAGRAMMATIC OUTLINES TO ILLUSTRATE VARIOUS TYPES OF MUSCLE ARCHITECTURE AND THE RELATIONS OF THE MAIN NERVE BRANCHES TO THE FIBER-BUNDLES OF THE MUSCLE.

a. Two segments of the rectus abdominis muscle of a small mammal. b. Portion of sheet-like muscle with two nerve-branches and intramuscular nerve plexus. c. Typical quadrilateral muscle with nerve passing across the muscle about midway between the tendons. d and e. Two triangular muscles with different types of innervation. f. Long ribbon-like muscle with interdigitating fiber-bundles. g. Unipenniform muscle. h. Bipenniform muscle. i. Typical fusiform muscle. The main intramuscular nerve-branches are distributed to the fiber-bundles about midway between their origins and insertions. N. nerve.



the perimysium internum. In the following pages 'muscle fiber-bundle' is used to denote small groups of muscle-fibers, 'fasciculus' to denote large, more or less isolated, groups of fiber-bundles.

Embryonic development of muscles.—The voluntary muscles are of mesodermal origin. The muscles of the trunk arise chiefly from the myotomes (see p. 13), those of the head and limbs chiefly from the mesenchyme in these regions. New muscle-fibers are formed mainly before birth. After birth, growth of muscles depends on growth of individual muscle-fibers.

. Well-marked instances may be seen in the transverse muscle of the abdo- fig. 421), and the trapezius and latissimus dorsi muscles of the back (fig. 386). extent of development of these aponeuroses is generally inversely pro- ɔnal to the development of the muscle—the more extensively developed ıuscle is in a given individual, the less extensive the aponeurotic sheet.

ɜ terms facia and aponeurosis are often loosely and interchangeably used. It seems ɔ make a distinction by restricting the term fascia to membranous sheets of investment, oneurosis to broad tendons. The latter may, however, be inserted into and form a part former.

ost muscles are continued at one or both extremities into dense, tendinous ı which may be comparatively short and thick, like the tendon of Achilles 44), or very long and narrow, like the tendon of the palmaris longus (fig. 401). this latter case the tendon represents in part the remnants of musculature highly developed in the lower vertebrates. In most instances, however, ndons are structures specifically differentiated for definite functions and are ɔsed of bundles of parallel connectve-tissue fibrils held together by an inter- ; fibrous-tissue framework. The tendons usually contain a relatively small nt of elastic tissue.

ıe tendons are attached to the skeleton early in embryonic development. e bones enlarge the tendons become in part incorporated in the substance of ɔne and ossified.

ı some tendons **sesamoid bones** are developed in the neighborhood of joints ₩hich the tendons pass. Examples of these are the patella at the knee-joint 43) and the sesamoid bones of the thumb and great toe.

here muscles or tendons closely envelope a joint, there is usually formed a ınion between the connective tissue of the capsule of the joint and that of the le or the tendon. Special bands may develop in the direction of the pull ı muscle (lig. popliteum obliquum).

here tendons run for some distance across or beneath a fascia, they are ly either bound to the fascia by a special investment, as near the wrist and (figs. 397 and 445), or are fused with the fascia, as in the case of the ilio- band. Fibrous tracts in the fascia may indicate stress under muscle con- on (the lactertus fibrosus of the fascia of the forearm).

ften in broad aponeurotic attachments of muscles there is formed in the ten- ıear the attachment a fibrous archway [arcus tendineus] for the passage of -vessels, nerves, muscles, or tendons. The tendinous arch is either fastened ch ends to the bone, or at one end it is connected with a joint capsule or other

annulus fibrosus, may hold a tendon in place, as, for intance, the trochlea of the tendon of the superior oblique muscle of the eye.

Synovial bursæ [bursæ mucosæ].—Where there is freedom of action between muscles and tendons and the surrounding parts, there intervenes a loose connective tissue. In regions where the pressure is great or considerable friction would result were these conditions retained, there are developed special cavities with smooth surfaces and containing fluid. Most of these bursæ are developed from the intervening connective tissue at a period in embryonic life preceding muscular activity, but special bursæ may later be developed as the result of unusual pressure or muscular activity after birth. An instance of a bursa lying in a region of friction may be seen in the bursa intervening between the tendinous posterior surface of the iliopsoas muscle and the iliofemoral ligament. As an instance of a bursæ lying in a region of intermittent pressure may be cited that between the tendon of Achilles and the calcaneus.

Most synovial bursæ intervene between a tendon and a bone, a tendon and a ligament, or between two tendons (**subtendinous bursæ mucosæ**). Others lie between two muscles, a muscle and some skeletal part, or between a muscle and a tendon (**submuscular bursæ mucosæ**); or below a fascia (**subfascial bursæ mucosæ**). Subcutaneous bursæ have been referred to in connection with the tela subcutanea (see p. 353). Most bursæ are developed near joints. The bursæ may so expand during active life that they come to communicate with other bursæ or with a neighboring joint cavity.

Synovial sheaths [vaginæ mucosæ tendinum].—Synovial sheaths are developed about tendons where the latter are confined in osteofibrous canals, as in the fingers. The wall of the canal and the enclosed tendon, or tendons, are each covered by a smooth membrane which at the extremities of the canal is reflected from the wall to the tendon. Between the membrane covering the tendon and that lining the canal is a synovial cavity. An interesting feature of these tendon-sheaths is the presence of **mesotendons,** delicate bands of vascular connecive tissue which run in places from the osseous groove to the tendon and carry blood-vessels and nerves.

Trochleæ.—Where a tendon passes at an angle about a bone, the tissue in the groove in which the tendon runs frequently is composed of hyaline cartilage instead of bone. An example may be seen in the trochlear process of the calcaneus.

Nerves.—To each muscle of the body a nerve containing motor and sensory fibers is distributed. A few muscles receive two or more nerves. Sherrington has estimated that in the muscle-nerves of the cat two-fifths of the fibers are sensory and three-fifths motor. The muscles of the head and in part those of the neck are supplied by branches of the cranial nerves. The intrinsic muscles of the neck, back, thorax, and abdomen are supplied by branches which arise fairly directly from the spinal nerves. The muscles of the limbs are supplied by branches from nerve-trunks which arise from plexuses formed by the spinal nerves in the regions near which the limbs are attached.

The main nerve-trunks lie beneath the superficial muscles. They usually run in the intermuscular septa which separate the deeper groups of muscles from one another and from the superficial muscles. The nerve-branches which enter a given muscle usually pass in where the larger intramuscular septa approach the surface of the muscle, and then ramify through the perimysium internum, the smaller branches being distributed in the finer layers of connective tissue which surround and separate the primary muscle fiber-bundles, to the constituent muscle-fibers of which terminal branches are given. Special sensory end organs are distributed chiefly in the large intramuscular septa, in the tendons and in the muscles near the tendons. Simple sensory endings are found on the muscle-fibers.

The size of a nerve supplying a muscle is not proportional to the size of the latter, but rather to the complexity of movements in which the muscle plays a part.

Muscles receive their nerve supply early in development. During later development the muscle may wander a considerable distance from its place of origin and carry its nerve with it. The diaphragm, innervated by cervical nerves, is a good example.

The distribution of the motor nerves varies according to the architecture of the muscle, but in general it appears that the nerves are so distributed as to carry the main branches of distribution most directly to the middle of the constituent fiber-bundles. This is seen most clearly in muscles with comparatively short fiber-bundles, where the individual muscle-fibers run nearly or quite the entire distance from tendon to tendon (fig. 370 a, c, d, e, g, h, and i). When the distance is long, a marked plexiform arrangement is found (fig. 370, b and f). To each muscle fiber there is distributed a terminal nerve-fiber which passes through the sarcolemma and ends in a motor end organ (muscle plate). Occasionally there are two such nerve-fibers to one muscle-fiber.

ssels.—The muscles are richly supplied with blood. In many instances the
: blood-vessels accompany the larger nerve-trunks as they enter the muscle,
heir primary branches are distributed in the larger intramuscular septa.
ı, however, the main blood-vessels approach a muscle from a direction dif-
t from that taken by the nerves. Each muscle has, however, its own blood-
y. There is little anastomosis between the blood-vessels of a muscle and
of a neighboring structure, but the anastomosis between the vessels within
ıuscle is exceedingly rich. Veins, as a rule, accompany all but the smallest
es within the muscle. The veins are richly supplied with valves, so that
e contraction promotes the flow of blood through the muscle. Rich cap-
plexuses surround the muscle-fibers. The capillaries are of unusually
diameter.
ıring contraction, the blood is forced from the muscles; during expansion
hes in through dilated arteries which furnish five or six times as much
to muscles during exercise as that supplied to them during rest.
ıe connective-tissue sheaths, the larger intramuscular septa, and the tendons
scles are richly supplied with lymphatics. There are no lymphatics within
uscle-bundles or in small muscles.
menclature.—The names of the various muscles and their classification are
ıtisfactory than is desirable. The muscular system was first carefully
d in the human body, and names based sometimes upon the shape, structure,
r position, at other times upon the supposed function or other associated
were applied to the muscles found in various regions. Sometimes two or
ıames were applied to a muscle to indicate several of these factors. Thus
us and *triangularis* indicate the shape of the correponding muscles; *biceps*
ps indicates the origin by two or three heads; *rectus*, *obliquus*, and *trans-*
represent the direction taken by a muscle or its constituent fiber-bundles;
s and *minimus* indicate size; *sublimis* (superficial) and *profundus* (deep)
ent the relative positions occupied; *sterno-cleido-mastoid* indicates structures
ch the muscle is attached; *flexor* and *extensor* indicate function; and *sar-*
ndicates that the corresponding muscle was supposed to be of use to tailors.

e careful study has been devoted to the comparative anatomy of the muscles in various
ates, it has become apparent that a simple and more consistent nomenclature applicable
sponding muscles found in various animals would be of great value. A satisfactory
lature of this sort has not, however, as yet been devised and adopted in comparative
y, and the established usage of the terms now familiarly applied to the muscles of the
body makes it seem improbable that even if such a system were devised for compara-
ıtomy it could be brought into extensive use in human anatomy. For many of the
in the human body various synonyms have been in use in different countries. The
ical Congress assembled at Basil in 1895, to simplify the nomenclature of human ana-
dopted in large part the terms in familiar use in England and America. In the fol-
pages the terms approved by the Congress will be employed, but where they differ
lly from those previously in use, the synonym will be given in parentheses.
sification.—The muscles are usually treated strictly according to the region of the body
ı they are found. This method of consideration is still of value in a dissector's guide
ext-books of topographical anatomy. But in studying the muscles scientifically it is of
nce also to consider them in their more fundamental genetic relationships to one
and to the nervous system. Embryology and comparative anatomy have proved of the
value in revealing these relationships. Studies of this nature have revealed well-
relationships in the adult human musculature which are of practical as well as scientific
nce. The voluntary musculature may be broadly divided into that of the skeletal
e limbs, and the visceral orifices. The musculature of each of these divisions has a
t and in general simpler form in the lower than in the higher vertebrates, and in the
s of the higher vertebrates than in the adult. The musculature of the spinal region of
ly-axis of fishes, the tailed amphibia, and all vertebrate embryos is metamerically
ed; that is, it is divided along the axis of the body into a series of components corre-
g with the segmentation of the vertebral column. Although marked alterations take
the subsequent ontogenetic differentiation in higher vertebrates, traces of this primitive
ation are still to be found in the adult; in man, for instance, in the intercostal muscles
segments of the rectus abdominis. In the region of the head conditions are complex,
ı the concurrent presence of muscles which primitively correspond in nature with the
al spinal musculature, and muscles non-segmental in character, which surround the
orifices. This also is true of the anus and external genitalia, where, however, the con-
are simpler. Embryology and comparative anatomy have done much to clear up
features in both regions.
muscles of the limbs are metamerically arranged in no adult vertebrate. In some of the
rms a series of axial muscle-segments, myotomes, furnishes material from which the
ture of the limbs is differentiated. In the mammals this appears not to be the case, and
cles are differentiated from the non-segmental tissue of the limb-buds.

Where mammalian musculature is primitively segmental, each segment becomes associated with a corresponding spinal nerve or, in the head, with a nerve which corresponds in series with a spinal nerve. Even when subsequent differentiation brings about marked alterations in the axial musculature, the nerves maintain to a considerable degree a segmental distribution.

Into each of the limbs, where the intrinsic musculature is at no time segmental, there extends during embryonic development a series of segmental spinal nerves, so that in them, as in the region of the body axis, a certain segmentation in the nerve-supply can be made out in the adult. That part of the limb nearest the head in early embryonic development has its muscles supplied by the most cranial, that part nearest the caudal extremity of the body by the most caudal, of the nerves which supply the limb-musculature. There is here, however, considerable overlapping of the segmental areas.

Variation.—In man some variation in the arrangement of the muscles is met with in every individual, and often marked deviations from the normal conditions are found. The muscles vary in their mode of origin or insertion, and in the extent to which muscles of a given group are fused with one another or to which the chief parts of a complex muscle are isolated from one another. Some muscles, like the palmaris longus and the plantaris, are frequently entirely absent, and other muscles generally absent are frequently present.

In addition to these frequent variations there are others so rare that many authors prefer to speak of them as anomalies rather than variations. Sometimes muscles may be found doubled by longitudinal division, or two or more muscles normally present may be fused into a single indivisible muscle. Occasionally there occur muscles constantly present in some of the lower animals, but normally not met with in the human body (anomalies of reversion or of convergence). In such instances the muscle may be normally represented by a tendon or fascia. At times the anomalies are supposed to be not a reversion to an ancestral condition, but a distinct step in advance. This, however, is difficult to prove. At other times no phylogenetic relation is apparent, and the anomaly is looked upon as a monstrous sport or as the result of some pathological condition.

The nerve-supply of the muscles is of value in the study of muscle-variations. There is, however, not infrequent variation in the nerves with relation to the supply of the muscles.

Physiology.—From the standpoint of morphology the muscles are grouped according to their intimate relations to one another and to the peripheral nerves; relations, as noted above, that are made more clear by a study of comparative anatomy and embryology. From the physiological aspect a different grouping of the muscles is required, because muscles belonging morphologically in one group may have different physiological functions in the animal body. The chief features of the mechanical action of muscles may be briefly considered here.

Most muscles act on the bones as levers. In physics three types of levers are recognized. In levers of the first type (fig. 371, I) the fulcrum (F) lies between the place where power (P) is exerted on the lever and the point of resistance or load (L). Levers of this kind are frequently met with in the body. A good example is seen in the attachment of the skull to the vertebral column. The fulcrum lies at the region of attachment; the weight of the skull tends to bend the head forward, while the force exerted by the dorsal muscles of the neck serves to keep the head upright or to bend it back.

In levers of the second class (fig. 371, II) the point on which power is exerted moves through a greater distance than the point of resistance. Speed of movement is thus sacrificed to power. Levers of this type are exceedingly rare in the animal body. An example in the human body is the foot when the body is raised on the toes, if the contact of foot with ground be considered the fulcrum.

In levers of the third class (fig. 371, III) the point on which force is exerted moves a less distance than the point of resistance. Power is thus sacrificed to speed. This is the common form of leverage found in the body. A good example is found in the action of the muscles which flex the foream on the arm. The region in which the biceps and brachialis are attached is but a short distance from the elbow-joint or fulcrum, while the hand may be looked upon as the region of resistance to the force exerted. A movement of the point P through a short distance will cause L to move through a great distance.

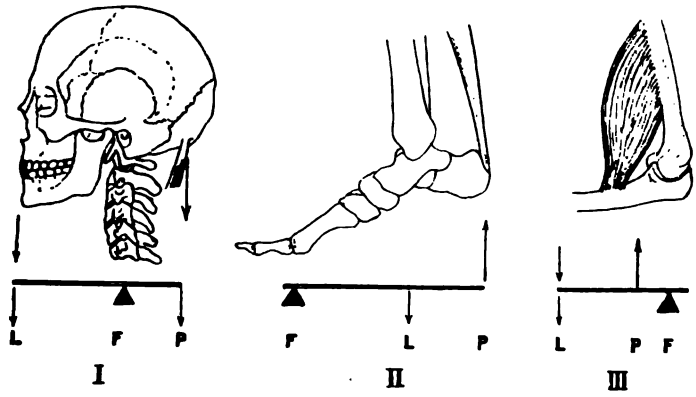
The more the angle between a muscle or its tendon and the bone on which it acts approaches a right angle, the greater is the power of movement exerted by the muscle. The arm in fig. 371, III, is in the position of greatest advantage for the action of the brachialis on the forearm. All boys know that it is easier to 'chin' oneself after the arm is partly bent than when hanging straight from a bar. Many of the muscles run nearly parallel with the parts on which they act, but the tendons before their attachment are usually either carried over a bony prominence or

some fascia or ligament acts as a pulley so that the tendon is inserted at an oblique angle. At other times a process for the attachment of the tendon projects from the bone and causes the force of the contracting muscle to be more advantageously exerted on the bone. It may, of course, readily be seen that the greater the distance of the attachment of a muscle from the joint on which it acts, the greater will be the power exerted by the muscle.

In considering the movements of the body, it is convenient to recognize two groups, simple and complex. To the former, which alone can be considered in a text-book of anatomy, belong such movements as flexion, extension, adduction, rotation, etc., while to the latter belong those associated movements which give rise to changes in the positions of the body as a whole or of extensive regions of the body.

In **flexion** the extremities of the trunk or limbs or special portions of these regions are bent near to one another; in **extension** the reverse movement is brought about. The parts are straightened or even bent beyond the straight position (over-extension).

FIG. 371.—THREE DIAGRAMS (AFTER TESTUT) TO ILLUSTRATE DIFFERENT TYPES OF LEVERS IN THEIR RELATIONS TO THE MECHANICAL ACTION OF THE MUSCLES.



In **abduction** transverse movements are made, a part being bent away from the median line of the body or limb; in adduction the reverse movement is brought about.

In **rotation** a part is turned on its longitudinal axis. The rotation of the femur at the hip-joint is called medial rotation when the toes are turned medialward, lateral rotation when the toes are turned lateralward. Rotation at the shoulder-joint is called medial when the thumb is turned forward and medialward toward the body, lateral when the reverse movement takes place. These movements are also carried out at the elbow-joint, but here medial rotation is called **pronation**, lateral rotation, **supination**. Fick prefers these terms also for the rotation at other joints as at the shoulder, hip and knee.

At the shoulder-joint the swinging of the arm toward the back is called extension; toward the front, flexion; and from the side, abduction. Moving the arm toward the mid-dorsal or mid-ventral line is called adduction.

Taking the body as a whole the musculature may be divided into two main divisions, an *expander division* and a *contractor division*. In general the extensors, abductors and lateral rotators expand, the flexors, adductors and medial rotators contract.

In the most expanded condition the head and spine are extended or even slightly hyperextended (flexed dorsally), and the limbs project laterally from the body with the backs of the hands and feet facing dorsalward, the palms and soles ventralward, and the digits spread out. In the fully formed human body it is not possible to put the lower extremity in the completely expanded position, although it is in this position early in embryonic development. As development proceeds the lower extremity is adducted and rotated medialward and the girdle is so fixed that full abduction becomes no longer possible. In many of the lower vertebrates full abduction is possible throughout life in the lower extremities just as it is throughout life in the upper extremities in man. Full extension of the spinal column in man is also hindered in the thoracic region by the thorax, and in the sacrococcygeal region by the osseous union of vertebræ with one another as well as by the attachment of the hip-girdles. The lumbar region in man is in a condition of permanent hyperextension.

In the fully contracted condition the head and spinal column are strongly flexed, and the digits are adducted, the various segments of the limbs are flexed and the limbs are adducted, flexed and rotated medialward toward the middle of the trunk. The body approaches a ball in form. It is the position taken by a gymnast when turning a somerset in the air, and is in marked contrast to the fully expanded condition which would be assumed could man fly like a bat or glide like a flying squirrel.

In general, the muscles which put the body or a part of the body into the expanded position form a distinct group as contrasted with those which put the body into the contracted position. The chief musculature which extends the head and trunk lies dorsolateral to the spinal column and is supplied by the dorsal divisions of the spinal nerves. The chief musculature which flexes the head and trunk lies ventrolateral to the spinal column and is supplied by ventrolateral divisions of the spinal nerves. The chief muscles which abduct, extend and rotate the limbs lateralward arise during embryonic development on the dorsal sides of the limb buds and are innervated by branches from the dorsal sides of the brachial and lumbosacral nerve plexus. The chief muscles which flex, adduct and rotate the limbs medialward arise on the ventral sides of the limb-buds and are supplied by nerves which arise from the ventral sides of the limb plexuses. To these general rules there are some exceptions, the most marked of which is at the hip-joint where rotation of the girdle has brought about a condition in which the primitive action of the flexor and extensor groups is partly reversed. The chief flexors (the iliopsoas and rectus femoris) belong to the dorsal division and some of the chief extensors (the hamstring muscles) belong to the ventral division. At the ankle-joint the exception is more apparent than real. What is usually called flexion at the ankle-joint is really hyperextension and the reverse movement is the nearest we can come to real flexion. In the extremely contracted positon of the body as a whole the feet are extended (flexed plantarward at the ankle joint.)

Muscles which produce a movement in a common direction are called **synergists**, while those whose contraction produces opposite movements are called **antagonists**; e. g., the flexors and extensors are antagonists. In the actual working of the muscular system, however, when a set of muscles is contracting to produce a movement, the antagonists are simultaneously relaxed. A more extended treatment of this subject is given on p. 533.

The relation of the internal architecture of a muscle to the movements to which its contraction gives rise is a complex subject, the details of which cannot be entered into here. In general it may be said that when the fiber-bundles run directly from one attachment to the other, as in fig. 370, a and f, the force exerted by the contraction of the individual muscle-fibers is most efficiently utilised and the extent of the movement varies directly as the length of the fibers, while the force exerted varies directly with the number of the fibers. In muscles with tendons of insertion relatively small in cross-section compared with the belly of the muscle, the power of the muscle is concentrated on a small area. Long tendons frequently take a course which improves the leverage.

In muscles of the types indicated in fig. 370, g, h, i, a certain amount of the extent of movement and of the force exerted by the contraction of the individual fibers is not effectively exerted on the parts moved by the muscles, as may be seen by applying to this action the laws of the parallelogram of forces. In such muscles, however, the great number of short muscle-fibers composing them makes possible the exertion of great power with some loss of speed of contraction in the muscle as a whole.

The direction of the movements which result from muscular contraction is in large part determined by the shape of the articular surfaces, none of which are to be looked upon as simple fulcra, but instead, during a given movement, the fulcrum shifts from one region to another of the joint.

In different muscles the extent of contraction of the constituent fiber-bundles during activity varies considerably. While usually the length of the contracted fiber-bundles is half that of those in the extended state, the amount of shortening in some muscles is only 25 to 35 per cent.

Functional activity is necessary for the full development or for the maintenance of development in muscles. Muscles atrophy if their nerve supply is injured or if they are passively prevented from contracting.

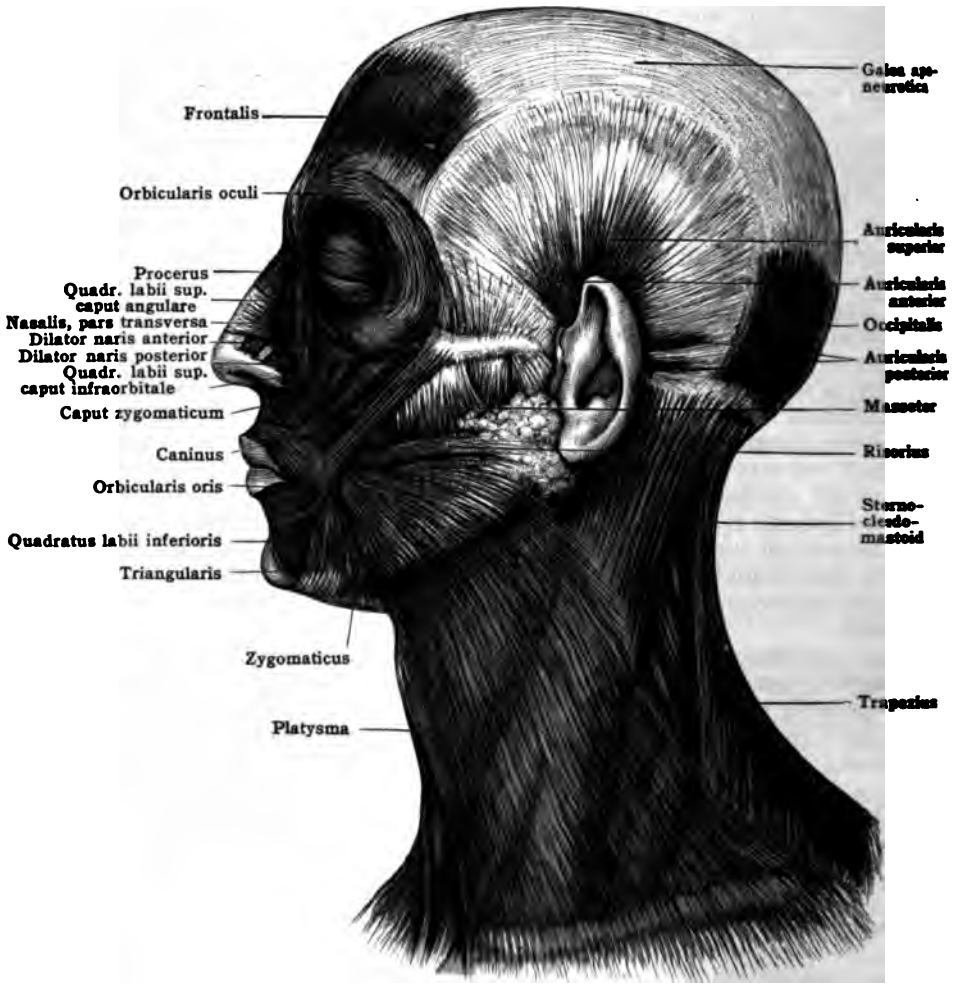
Order of treatment.—The muscles and fasciæ are here treated in the following order:—(1) those of the head and neck and shoulder-girdle (p. 363); (2) those of the upper extremity (p. 394); (3) those of the spine (p. 444); (4) those of the thorax and abdomen (p. 455); (5) those of the pelvic outlet (p. 472); (6) those of the lower extremity (p. 485). The reason for taking up the musculature in the order named is, that during embryonic development musculature belonging primitively to the head comes to overlap that of the neck; that of the neck spreads over the region of the back and thorax, and becomes attached to the shoulder-girdle; that of the arm extends over the region of the thorax, abdomen, and back; that of the back partially over the region of the thorax; while that of the abdomen enters into intimate relation with the pelvic girdle. So far as practicable the musculature of these various regions will be taken up according to fundamental morphological relationships.

Since a morphological grouping of the muscles does not accord perfectly with a physiological grouping, there is given at the end of this section a table showing what muscles are concerned in performing the simpler voluntary movements.

1. The facial group, p. 364.
2. The craniomandibular group, p. 373.
3. The suprahyoid musculature, p. 377.
4. The muscles of the tongue, p. 380.
5. The superficial shoulder-girdle musculature, p. 382.
6. The infrahyoid musculature, p. 384.
7. The scalene musculature, p. 388.
8. The prevertebral musculature, p. 389.
9. Anterior and lateral intertransverse muscles, p. 390.
10. Deep musculature of the shoulder girdle, p. 391.

The pectoral muscles and the latissimus dorsi, which extend from the skeleton of the limb to the front and side of the thorax and the lower part of the back, arise from the limb-bud during embryonic development, are innervated through the brachial plexus, and will, therefore, be taken up in considering the intrinsic musculature of the upper limb, p. 394.

FIG. 372.—THE SUPERFICIAL MUSCLES OF THE HEAD AND NECK.



THE FACIALIS MUSCULATURE

(Figs. 372, 375)

The muscles of this group are intimately connected with the scalp, with the skin of the face and neck, and with the mucous membrane lining the lips and the cheeks. Most of the muscles have an osseous origin and a cutaneous insertion, but there are exceptions. Both origin and insertion may be cutaneous, or the

ıent may be to an aponeurosis instead of directly to the skin. The nusculature about the mouth is attached to the mucous membrane.
muscles are composed of interdigitating muscle-fibers which are grouped lles that take a nearly parallel or slightly converging course and give rise muscle-sheets. The extent of development of the various muscles of the ınd their independence varies greatly in different individuals.

region from which the facial musculature originates in the embryo is, in the main at at of the hyoid arch immediately below the ear. From here the musculature spreads development of the facial nerve, dorsally to the occipital region behind the ear, caudal- er the neck, ventrally over the face, and upward toward the eye, forehead, and the side of l The course of the developn ent is indicated by the branches of the facial nerve. A ıt similar phylogenetic development is indicated by conditions found in the inferior ls and lower vertebrates. According to Ruge and Gegenbaur, the facial musculature looked upon as derived from two muscle-sheets, of which in man the deeper has dis- d in the region of the neck while it is differentiated into the deeper facial muscles in the f the head. The deeper layer of transverse fibers in the neck, the *sphincter colli*, is found al of the mammals. The complex development of the facial muscles in man is char- c of the human species, and is associated with the use of these muscles as a means of ɔn of the emotions, a physiological function superadded to the primitive function of and closing visceral orifices. (See Darwin: Expression of the Emotions in Man and .)

ıæ.—The skin of the head and neck is, in most regions, firmly fused with the **tela** ıea. This is composed of a dense fibrous tissue united by a looser areolar tissue to the ng structures. But a slight amount of fat is embedded in the subcutaneous tissue of ɔ, forehead, and nose Considerable fat may be embedded in the region of the cheeks, : of the neck, and the under surface of the chin (double chin). The constantly repeated f various muscles of the facialis group usually results by middle life in the production ınent wrinkles due to alterations in the structure of the tela subcutanea and the skin. subcutaneous muscles of the cranial vault and the neck are invested with fascial mem- That covering the cranial musculature externally is firmly fused to the subcutaneous f the scalp. That covering the subcutaneous muscle of the neck is less firmly fused ɜ subcutaneous tissue. In the facial region the more superficial muscles are so closely ɔd in the subcutaneous tissue that no distinct fasciæ intervening between the muscles skin can, as a rule, be distinguished. Of the deeper muscles of the facialis group, the ɔr alone possesses a distinct fascia. This muscle lies upon the mucous membrane of ral wall of the mouth, and is covered externally by a fascia continued into the fascia g the superior constrictor of the pharynx.
ɜ.—**Bursa subcutanea prementalis.** Between the periosteum at the tip of the chin overlying tissue. **Bursa subcutanea prominentiæ laryngeæ.** In front of the junction ght and left laminæ of the thyroid cartilage.

MUSCLES

ɜ muscles of the facialis group may be conveniently subdivided as follows:— **Cervical:** the platysma. (*b*) **Oral:** the orbicularis oris and the incisivus ıperioris and inferioris; the quadratus labii superioris and inferioris; the s, zygomaticus, risorius, and triangularis; and the buccinator. (*c*) **Mental sal:** the nasalis, depressor septi, and the dilatores naris. (*e*) **Periorbital:** ɔicularis oculi, corrugator, and procerus. (*f*) **Epicranial:** the frontalis and alis, with the galea aponeurotica. (*g*) **Auricular:** anterior, superior, and ior. With these the temporalis superficialis is also described.

(*a*) CERVICAL MUSCLE

ɜ **platysma** is a large, thin, quadrangular muscle which extends obliquely ıe chin, the corner of the mouth, and the lower part of the cheek across the ɔle and the neck to the upper part of the thorax and shoulder. The muscles ı side interdigitate across the chin. A short distance below the chin, in ɔk, the ventral margins diverge (fig. 372).

ɜn.—From the tela subcutanea by somewhat scattered bundles—(1) along a line extending e cartilage of the second rib to the acromion, and (2) along the dorsal margin of the

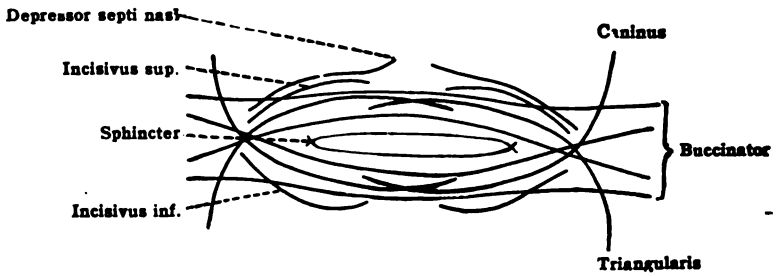
rtion.—Into—(1) the mental protuberance of the mandible and the inferior margin ıandible; and (2) into the skin of the lower part of the cheek and at the corner of the where it fuses more or less with the quadratus labii inferioris and the orbicularis oris.
e-supply.—The cervical branch (ramus colli) of the seventh cranial nerve forms beneath scle a plexus to which the cutaneus colli nerve contributes sensory branches.
tions.—The muscle is situated beneath the panniculus adiposus, to which in the neck it ery firmly attached. For the most part it is separated from the external layer of the

cervical fascia by loose areolar tissue. The main cutaneous rami of the cervical plexus and the external jugular vein lie beneath the muscle.

Action.—It wrinkles up the skin of the neck, depresses the corner of the mouth, and thus plays a part in expression of sadness, fright, and suffering. It aids the circulation by relieving pressure on the underlying veins.

Variations.—Either the facial or the thoracic development of the muscle may be more extensive than that described above. On the other hand, it may be less developed than usual, and rarely it is absent. Accessory slips have been seen going to the zygoma, the auricle, or the mastoid process, and to the clavicle and sternum. Rarely a deep transverse layer is found in man.

FIG. 373.—DIAGRAM TO ILLUSTRATE THE ARCHITECTURE OF THE ORBICULARIS ORIS. (After T. D. Thane.)



(*b*) ORAL MUSCLES
(Figs. 372–376)

The muscles of the mouth belonging to the facialis system include several *intralabial* muscles:—a sphincter, the **orbicularis oris**; a transverse, the **compressor labii**; and four deep submucous muscles which pass from the sides of the lips to the alveolar juga of the upper canine and lower lateral incisor teeth, the **incisivi labii superioris** and **inferioris.** From each corner of the mouth there radiate out several muscles; the **caninus** and **zygomaticus** upward to the maxilla and zygomatic bone; the **risorius** lateralward over the cheek; the **platysma** and the **triangularis** downward over the side of the jaw; and the **buccinator,** lateralward over the side of the oral cavity. From each of these, fiber-bundles are continued into the more peripheral and superficial portions of the orbicularis. In addition to these muscles there are two retractors or quadrate muscles, one of which, the **quadratus labii superioris,** extends to the bridge of the nose, the lower margin of the orbit, and the zygomatic bone from the upper lip medial to the angle; while the other, the **quadratus labii inferioris,** extends from a corresponding position in the lower lip to the side of the chin. The orbicularis oris, compressor labii, and incisive muscles close the lips; the other muscles open them and pull them in various directions. The buccinator, however, plays a part in the closing of the mouth by offering support for the orbicularis.

INTRALABIAL MUSCLES

The **orbicularis oris** (figs. 372–374) is a complex muscle which surrounds the oral orifice and forms the chief intrinsic musculature of the lips. Immediately about the orifice and on the deep surface of the muscle, is a fairly well-defined sphincter, although at the corners of the mouth the fiber-bundles of one lip cross those of the other and are inserted into the mucosa, and to a less extent into the skin. In the midline the fiber-bundles end partly in the perimysium, partly in the skin. About this sphincter area and between its outer margin and the skin is a complex musculature comprised partly of fiber-bundles prolonged from the muscles which radiate from the corners of the mouth. The more superficial portion of the muscle in the upper lip is composed of fiber-bundles from the triangularis (depressor anguli oris), the more superficial portion of that in the lower lip by fiber-bundles from the caninus (levator anguli oris). These fiber-bundles form commissures at the angles of the mouth and extend toward the median line, where many of them interdigitate with those of the opposite side, and are attached to the skin of the lips. The deeper portions are partly formed by fiber-bundles prolonged from the buccinator, the mandibular fiber-bundles of the latter muscle going mainly to the upper lip, the maxillary fiber-bundles mainly to the lower lip. These fiber-bundles are attached chiefly to the mucosa, near the corners of the mouth.

The **compressor labii,** or muscle of Klein, is composed of bundles of fibers which take a course transverse to those of the orbicularis, and pass obliquely from the skin surrounding the oral orifice toward the mucosa which bounds its inner margin. It is said to be best marked in infants.

The **incisivus labii superioris** is a small muscle-bundle which passes from the alveolar jugum of the upper canine tooth to the back of the orbicularis near the corner of the mouth.

The **incisivus labii inferioris** passes similarly from the alveolar jugum of the lower lateral or tooth to the back of the orbicularis in the lower lip.

-supply.—These muscles are supplied by the buccal branches of the facial nerve which
e orbicularis on the lateral border.
ions.—The main mass of intrinsic musculature of the lips is placed slightly nearer the
than the skin. On its deep surface lie the labial arteries.
n.—The orbicularis draws the upper lip downward, the lower lip upward. The
muscles draw the corners of the lips medialward, and the compressor flattens the lips.
r they serve to close the mouth. Acting separately they may draw different parts of
directions indicated by their structure. The circumferential portion of the orbicularis
ih the incisive muscles makes the lips protrude. The central portion of the orbicularis
ıe lips together, and when the buccinator also acts, draws them against the teeth. It
ɔortion of the muscle that has chiefly to do with nutritive functions. The more peri-
arts of the muscle are chiefly utilised in the expression of the emotions.

Retractors of the Lips or Quadrate Muscles.
(Fig. 372)

quadratus labii superioris is a thin, quadrangular muscle with three heads, all of which
rted into the skin and musculature of the upper lip. It includes the following:
The **caput zygomaticum** (zygomaticus minor) is long and slender and arises from the
rt of the external surface of the zygomatic bone beneath the lower border of the palpe-
tion of the orbicularis oculi. It passes obliquely forward over the caninus and orbicularis
cles, and extends to a cutaneous and muscular insertion in the upper lip medial to the
f the mouth. It lies medial to the zygomaticus.
The **caput infraorbitale** (levator labii superioris), a broad, flat muscle, arises from the
ital margin of the maxilla, where it is concealed by the orbicularis oculi. It extends
r forward over the caninus and beneath the caput angulare to the skin and musculature
teral half of the upper lip.
The **caput angulare** (levator labii superioris alæque nasi) arises from the root of the nose,
is fused with the frontalis. As it descends it divides into two fasciculi, one of which is
l to the skin and the alar cartilage of the nose; the other passes obliquely downward
caput infraorbitale to the skin and musculature of the lateral half of the upper lip.
-supply.—The zygomatic ramus of the facial nerve sends branches to enter the deep
of each of the divisions of the muscle.
ns.—It raises the lateral half of the upper lip and the wing of the nose. It is of value
ation, serves to express the emotion of discontent, and comes into play in violent weep-

ations.—The caput zygomaticum is often absent. It may be fused with the zygoma-
ajor). It may be doubled. Its origin may extend to neighboring structures. The
ads, though more stable, vary considerably, especially in the extent of their fusion with
ing muscles.
quadratus labii inferioris (depressor labii inferioris) is a thin, rhomboid muscle which
low the canine and bicuspid teeth from the base of the mandible, between the mental
ance and the mental foramen, and extends obliquely upward in a medial direction to the
ris oris, through which its fiber-bundles pass. Its more medial fibers cross at their
with those of the muscle of the other side. It is attached to the skin and mucosa of
r lip. It is essentially a part of the platysma, and is superficially united to the skin
here covered by the triangularis (depressor anguli oris). It crosses the mental vessels
res and a part of the mentalis (levator menti).
-supply.—The mandibular branch of the facial sends twigs into its deep surface near
al border.
n.—It draws down and everts the lower lip. It is an antagonist of the mentalis
menti). It plays a part in the expression of terror, irony, great anger, and similar
s.

Muscles of the Angle of the Mouth
(Figs. 372, 373, 374, 375, 376)

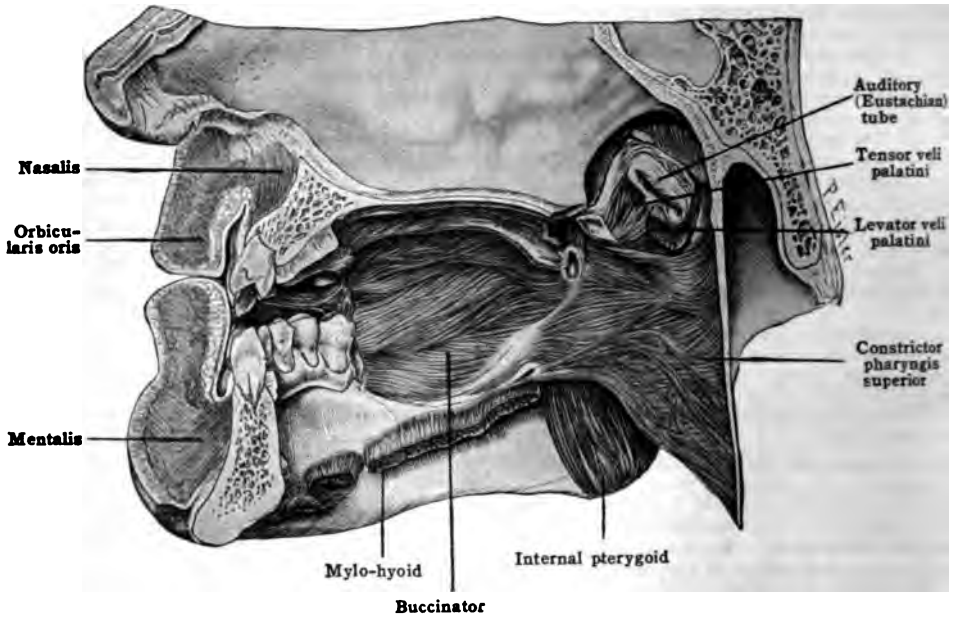
caninus (levator anguli oris) is a flat, quadrilateral muscle which arises from the canine
the maxilla and runs beneath the quadratus (levator) labii superioris to the corner of
th, where it becomes attached to the skin and sends some fasciculi into the orbicularis of
r lip. Between the caninus and the quadratus labii superioris there is a certain amount
areolar tissue through which the infraorbital vessels and nerves run. Its deep surface
over the canine fossa, the buccinator muscle, and the mucosa of the lip. The external
y (facial) artery passes over its inferior extremity.
zygomaticus (z. major) is a long, ribbon-shaped muscle which arises by short tendinous
s from the zygomatic bone near the temporal suture under cover of the orbicularis oculi.
s obliquely to the corner of the mouth, where it is attached to the skin and mucosa.
ly of the muscle is subcutaneous and is usually surrounded by fat. It crosses the
r and buccinator muscles and the anterior facial vein.
risorius is a thin, triangular, subcutaneous muscle which extends across the middle of
k and lies in a more superficial plane than the platysma, with which it is often fused. It
ɔm the tela subcutanea above the parotid fascia. Its fibers converge across the masseter
oward the angle of the mouth and are attached to the skin and mucosa in this vicinity.
bove the anterior facial vein and external maxillary artery.
platysma has been described above.
triangularis (depressor anguli oris) is a broad, flat, well-developed, subcutaneous muscle
rises from the base and external surface of the body of the mandible below the canine,
and first molar teeth. From here its fibers converge toward the corner of the mouth,
ıey are in part inserted into the skin and in part are continued into the orbicularis or

of the upper lip. It overlies the buccinator and the quadratus (depressor) labii inferioris muscles. Not infrequently (58 out of 92 bodies—LeDouble) some fasciculi are continued into the neck as the **transversus menti**, a fibromuscular band formed by the interdigitation of the slips prolonged from each side below the chin and superficial to the platysma. Santorini described the transversus menti as an independent though inconstant muscle. According to Eisler the true transversus menti muscle is to be distinguished from aberrant slips of the triangularis or of the platysma in this region. In one instance Eisler found a slender nerve emerging through the platysma and passing to this muscle.

Nerve-supply.—The zygomatic branch of the facial nerve supplies the canine (levator anguli oris) and zygomatic (major) muscles. Branches enter the middle of the deep surface of the latter muscle and the superficial surface of the former near its lateral border. The risorius is supplied by branches from the buccal rami of the facial nerve, which enter its deep surface. The triangularis (depressor anguli oris) is supplied by the buccal branch through branches which enter its deep surface near the posterior margin.

FIG. 374.—BUCCINATOR MUSCLE AND PTERYGOMANDIBULAR RAPHÉ, AS SEEN FROM THE BUCCAL SIDE. (AFTER EISLER.)

The alveolar processes of both jaws have been removed in the region of the molar teeth. The soft palate and its muscles have been removed.



Action.—The caninus (levator anguli oris) and zygomatic (z. major) muscles raise the corner of the mouth, the former at the same time drawing it medially, the latter, laterally. The caninus gives rise to expression of bitterness or menace. The zygomaticus is active in smiling or laughing. When contracted greatly it elevates the cheek and the lower eyelid and produces crow's-foot wrinkles at the corner of the eye. The risorius draws the angle of the mouth laterally. In spite of its name it is not used to express pleasure, but instead gives rise to an expression of pain. The triangularis (depressor anguli oris) depresses the corner of the mouth and draws it laterally, giving rise to the expression of grief.

Variations.—The risorius is very inconstant in its development, and in its relations to neighboring muscles, and is not infrequently quite small. The zygomaticus is rarely absent. Its origin may extend to the temporal or masseteric fasciæ. It may be doubled throughout its length or at one extremity. Frequently the triangularis is divided into three fasciculi.

The **buccinator** (figs. 373, 374) arises from—(1) the molar portion of the alveolar process of the maxilla; (2) the buccinator crest of the mandible, and (3) the pterygomandibular raphe of the buccopharyngeal fascia. This narrow fibrous band, which separates the buccinator from the superior constrictor of the pharynx, extends from the pterygoid hamulus to the buccinator crest of the mandible. The fiber-bundles of the muscle are divisible into four sets. The most cranial extend directly into the orbicularis of the upper lip. The next pass through the commissure at the corner of the lips into the orbicularis of the lower lip; the third through the commissure into the orbicularis of the upper lip, and the fourth directly into the orbicularis of the lower lip. The muscle is attached chiefly to the mucosa of the lips near the angle of the mouth. Some fiber-bundles extend to the more medial portion of the mucosa and some through the the orbicularis to the skin.

Nerve-supply.—By the buccal branch of the facial nerve through filaments which enter the posterior half of its outer surface.

Relations.—The muscle is covered externally by the thin buccopharyngeal fascia; internally by the mucosa of the mouth. Above its outer surface lie the zygomatic (z. major), risorius, and

masseter muscles. Between the last and the buccinator lies a large pad of fat (the buccal fat pad). The parotid duct passes forward over the muscle, and slightly in front of its center pierces it and passes into the mouth. It is crossed by the external maxillary (facial) artery and anterior facial vein and by the buccal artery and nerve.

Actions.—It draws the corner of the mouth laterally, pulls the lips against the teeth, and flattens the cheek. It is of use in mastication, swallowing, whistling, and blowing wind-instruments.

Variations.—Occasionally it consists of two laminæ, a condition found in many mammals. It may be continuous in part with the superior constrictor of the pharynx, as in the cat.

(*c*) MENTAL MUSCLE

The **mentalis** (levator menti) (fig. 374) is a short, thick muscle which arises from the alveolar jugum of the lower lateral incisor tooth and the neighboring region of the mandible under cover of the quadratus (depressor) labii inferioris and beneath the oral mucosa, where this is reflected from the lips to the gums. It extends to the chin, where it is fused with the muscle of the opposite side and is inserted into the skin of the chin.

Nerve-supply.—The mandibular branch of the facial nerve sends terminal twigs into this muscle.

Actions.—It draws up the skin of the chin and thus indirectly causes the lower lip to protrude. It is of use in articulation, in forcing bits of food from between the gums, and in the expression of various emotions (muscle of pride).

Variations.—It varies greatly in size and generally is fused with the platysma.

(*d*) NASAL MUSCLES
(Figs. 372 and 375)

Toward the nasal apertures several muscles converge. Those extending from above elevate and dilate, those from below depress and contract, the nostrils. To the former belongs the **pars transversa** of the **nasalis** (compressor naris), a triangular muscle extending from the bridge of the nose to the nasolabial sulcus; the **caput angulare** of the **quadratus labii superioris** (levator labii superioris alæque nasi), which arises from the root of the nose and sends a fasciculus to the wing of the nose; and the **dilatores naris,** described below; to the latter, the **pars alaris** of the **nasalis** (depressor alæ nasi), which extends from the alveolar juga of the upper lateral incisor and canine teeth to the dorsal margin of the nostril; and the small **depressor septi nasi.**

The **nasalis** consists of two parts, the pars transversa and the pars alaris. The **pars transversa** (compressor naris) is triangular. It lies on the side of the nose above the wing. Its fiber-bundles arise from an aponeurosis which overlies the bridge of the nose, is adherent to the skin, and is not closely attached to the underlying cartilage. From this aponeurosis the fiber-bundles converge toward the back of the wing, where they are attached to the skin along the line which separates the wing from the cheek (nasolabial sulcus). Its insertion is covered by the nasal process of the caput angulare (levator labii superioris alæque nasi) of the quadratus labii superioris (p. 367), with which its fibers interdigitate. An attachment (origin) is also described by many as taking place in the lower part of the canine fossa of the maxilla.

The **pars alaris** (depressor alæ nasi) (figs. 374, 375), is a small quadrangular muscle situated below the aperture of the nose, between this and the alveolar portion of the maxilla. It is covered by the mucosa of the gum, by the orbicularis oris and the quadratus (levator) labii superioris, and laterally is fused with the pars transversa (compressor naris). It arises from the alveolar juga of the lateral incisor and the canine teeth. Its fiber-bundles extend vertically to the skin of the dorsal margin of the nostril, from the dorsal part of the cartilage of the wing to the septum.

The **dilator naris posterior** is a thin, triangular muscle which lies on the side of the wing of the nose. It arises from the skin of the nasolabial groove and is attached to the inferior border of the wing of the nose.

The **dilator naris anterior** is a very small, thin muscle which runs from the lower margin of the cartilage at the front of the wing of the nose to the skin. It is not usually clearly marked.

Nerve-supply.—The muscles of this group are supplied by the infraorbital and buccal branches of the facial nerve.

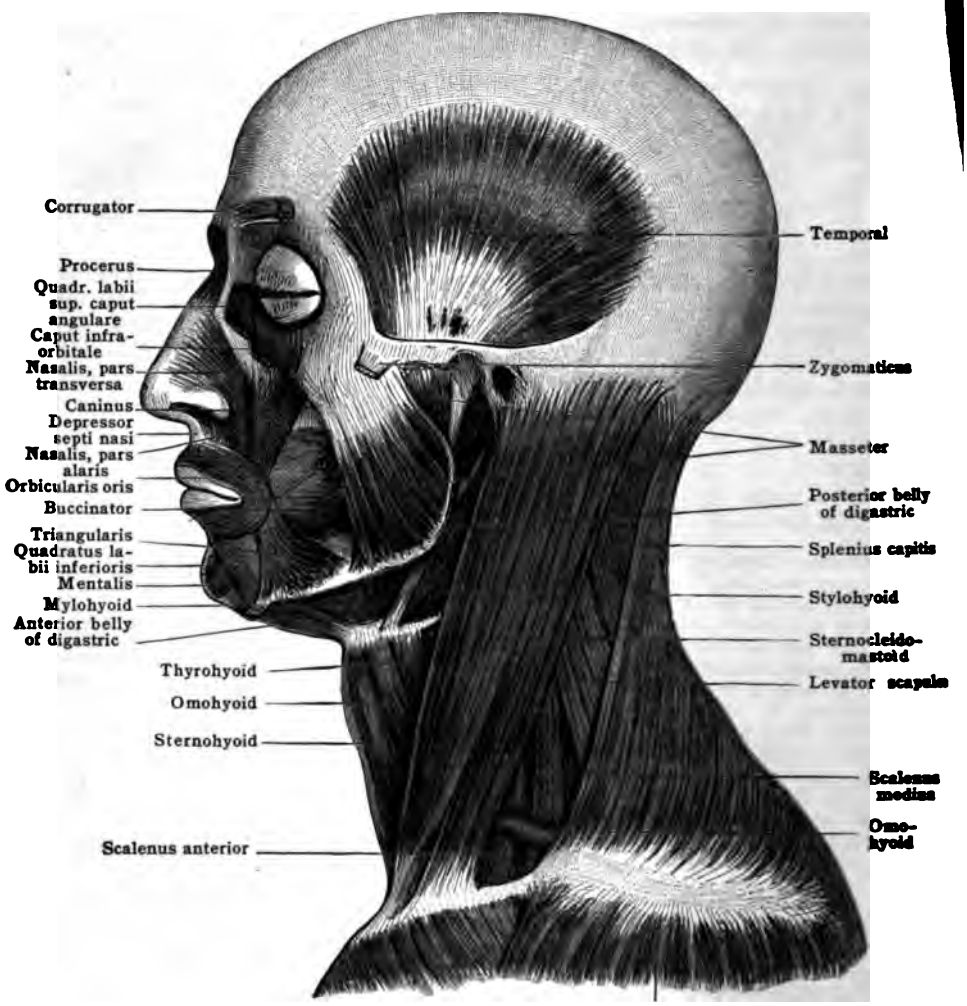
Actions.—The transverse portion of the nasalis (compressor naris) acts with the angular head (levator labii superioris alæque nasi) of the quadratus labii superioris in drawing the lateral margin of the wings of the nose laterally and upward, and gives rise to the expression of sensuality. (Poirier.) This accords with the electrical experiments of Duchenne. However, acting in conjunction with the alar portion, the transverse portion of the nasalis may constrict the nostrils. The alar portion (depressor alæ nasi) of the nasalis and the depressor septi nasi draw down the nostril. The former tends to contract it from side to side, the latter from front to back, and at the same time to depress the tip of the nose. They play a part in the expression of anger and of pain. The functions of the other muscles are indicated by their names.

Variations.—The muscles of the nose vary considerably in extent of development, and one or more may be absent. Authors differ considerably in their description of several of the muscles. The **anomalus** is a longitudinal muscle strip occasionally found running from the frontal process to the body of the maxilla near the lateral margin of the nasal aperture.

(e) PERIORBITAL MUSCLES
(Figs. 372 and 375)

The muscles which encircle the orbit constrict the entrance of the orbit so as to shut out light and protect the eye against foreign bodies. To these belong the orbicularis oculi, the corrugator, and the procerus. The **orbicularis oculi** is a large, flat, elliptical mucle which lies in the eyelids and over the bone surrounding the orbit. **Three parts** are recognized: a **palpebral,** an **orbital** and a **lacrimal.** The quadrangular **corrugator** extends from the nasal portion of the frontal bone to the skin of the middle half of the eyebrow; the narrow **procerus** (pyramidalis nasi) from the bridge of the nose to the skin at the root. The muscles which

FIG. 375.—THE DEEPER MUSCLES OF THE FACE AND NECK.



have an antagonistic action are the levator palpebræ superioris and the epicranius. The levator palpebræ is described in the chapter on the EYE (see Section IX), the epicranius in the following subsection.

The **orbicularis oculi.**—The **palpebral portion** arises from the anterior surface and margins of the lateral portion of the medial palpebral ligament (tendo oculi), and from the covering of the lacrimal sac. The fiber-bundles spread out as they pass into the eyelids and again are concentrated toward their insertion into the outer surface of the lateral palpebral ligament. Many of the fiber-bundles interdigitate here without being inserted into the ligament. The muscle in each eyelid lies between the tarsal plate and the skin, separated from both by loose tissue. The superficial muscle-fibers nearest the margin of the lids constitute the ciliary muscle, or muscle of Riolan. They are very small fibers and probably act on the eyelashes and Meibomian glands.

orbital portion arises by a superior origin from the medial palpebral ligament (tendo
ne nasal portion of the frontal bone, and the anterior lacrimal crest of the maxilla and
ferior origin from the medial palpebral ligament and the medial portion of the inferior
ne orbit. The fiber-bundles form a flat ring which surrounds the orbit for a consider-
ance, especially inferiorly. The muscle is adherent to the overlying skin. It lies over
s surrounding the margin of the orbit and over the attachments of several of the facial
attached to these bones. With these muscles some of the fiber-bundles are usually
ous.

lacrimal portion (tensor tarsi or Horner's muscle) arises from the posterior lacrimal
the lacrimal bone and passes down on the dorsal surface of the lacrimal sac and the
palpebral ligament (tendo oculi). It bifurcates and furnishes a fasciculus attached to
sal plate. Some of the fiber-bundles surround the lacrimal canaliculi and some surround
s of the tarsal glands and the roots of the eyelashes.

corrugator arises from the frontal bone near the frontonasal suture. It extends ob-
upward and lateralward to be inserted into the skin of the medial half of the eyebrow.
r-bundles of insertion interdigitate with those of the frontalis. The muscle lies rela-
ep. It is covered by the procerus (pyramidalis nasi), the frontalis, and the orbicularis.
lie the supraorbital vessels and nerves.

procercus (pyramidalis nasi) overlies the nasal bone. It arises from the lateral cartilage
se through a fibrous membrane and also directly from the nasal bone, and is attached
in over the root of the nose, where its fibers interdigitate with those of the frontalis.

-supply.—The muscles of this group are supplied by temporal and infraorbital branches
cial nerve which enter the deep surfaces near the lateral margins.

n.—The palpebral portion of the orbicularis closes the eyelids, of which the upper
nore freely than the lower. It also serves to dilate the lacrimal sac and allow the
flow away readily. The tensor tarsi probably contracts the sac and forces the tears
nose. The upper half of the orbital portion of the orbicularis contracts and depresses
ie overhanging the orbit, and stretches the skin of the forehead. The corrugator draws
of the brow downward and medially, thus aiding the preceding muscle. It causes the
cular furrows characteristic of frowning. The procerus (pyramidalis nasi) draws
skin of the forehead and wrinkles the skin across the root of the nose. The lower half
bital portion of the orbicularis raises the skin of the cheek, causing the wrinkles seen to
rom the corner of the eye. The whole set of muscles comes into play in the forcible
of the eyes. In case of violent expiratory efforts, as in shouting, sneezing, coughing,
eye is thus usually forcibly closed. The pressure thus exerted on the eyeball prevents
lent flow of blood to the vessels of the eye. Pressure is thought at the same time to
ed on the lacrimal gland so as to cause the excessive flow of tears often experienced at
es.

ations.—The muscles of this group vary in extent and differentiation, and may be more
used with one another or with neighboring muscles. The orbital portion of the or-
, the corrugator, and the procerus have been found absent.

(*f*) THE EPICRANIAL MUSCULATURE
(Fig. 372)

epicranius (occipitofrontalis) is formed of the two **frontal** muscles, which
ach side of the forehead, the two **occipital** muscles, which occupy corre-
ig positions on the occipital bone, and of the epicranial aponeurosis, the
poneurotica, which extends between these. The occipital muscles arise
ne supreme nuchal line and are inserted into the galea aponeurotica. The
muscles arise from the latter and are inserted into the skin near the eye-
The chief function of these muscles is to elevate the brows. The
and the intervening aponeurosis lie between two layers of fascia, the ex-
of which is fused to the skin, while the internal moves freely over the peri-
, to which it is loosely attached. Hemorrhages and abscesses spread freely
n the deep layer of fascia and the periosteum.

frontalis is a large, thin muscle with convex upper and concave lower border. It arises
epicranial aponeurosis midway between the coronal suture and the orbital arch, and is
into the skin of the eyebrow and of the root of the nose. The medial fiber-bundles take
l direction; the lateral converge obliquely toward the brow. The medial margins of
les of each side are approximated near the attachment. The more medial fiber-bundles
inuous with those of the procerus (pyramidalis nasi) and the angular portion (levator
erioris alæque nasi) of the quadratus labii superioris; the more lateral interlace with
the corrugator and orbicularis muscles. The branches of the vessels and nerves of the
egion pierce the muscle and are distributed between it and the skin.

occipitalis, flat and quadrangular, lies on the occipital bone above the supreme nuchal
rises by tendinous fibers from the lateral two- thirds of this line and from the posterior
he mastoid process of the temporal bone, and is inserted into the epicranial aponeurosis.
lial fiber-bundles run sagitally, while the lateral run obliquely forward. The occipital
id nerve lie between the muscle and the skin. The lateral border of the muscle comes
t with the posterior auricular muscle. The muscles of each side are usually separated
p of aponeurosis.

galea aponeurotica (epicranial aponeurosis) is a fibrous membrane which extends be-
e occipital muscles and from them anteriorly to the frontal muscles. In the area be-

tween these two sets of muscles it is composed largely of sagitally running fibers into which coronal fibers radiate from the region of the muscles of the ear. Between the two occipital muscles the aponeurosis is attached to the supreme nuchal line and external occipital protuberance. Laterally the fascia covering it is continued as a special investment of the auricular muscles, beyond which it is attached to the mastoid process, the zygoma, and to the external cervical and the masseteric fasciæ.

Nerve-supply.—The frontalis is supplied by the temporal branches of the facial nerve, the occipitalis by the posterior auricular branch. The branches enter the deep surface of each of these muscles near its lateral border.

Action.—The occipitalis serves to draw back and to fix and make tense the epicranial aponeurosis. The frontalis, with its aponeurotic extremity fixed, elevates the brows and throws the skin of the forehead inso transverse wrinkles as in the expression of attention, surprise, or horror. When both muscles contract forcibly there is, in addition, a tendency to make the hair stand on end because the hair-bulbs of the occipital region slant forward, those of the frontal region backward. The frontalis when fixed below pulls the scalp forward.

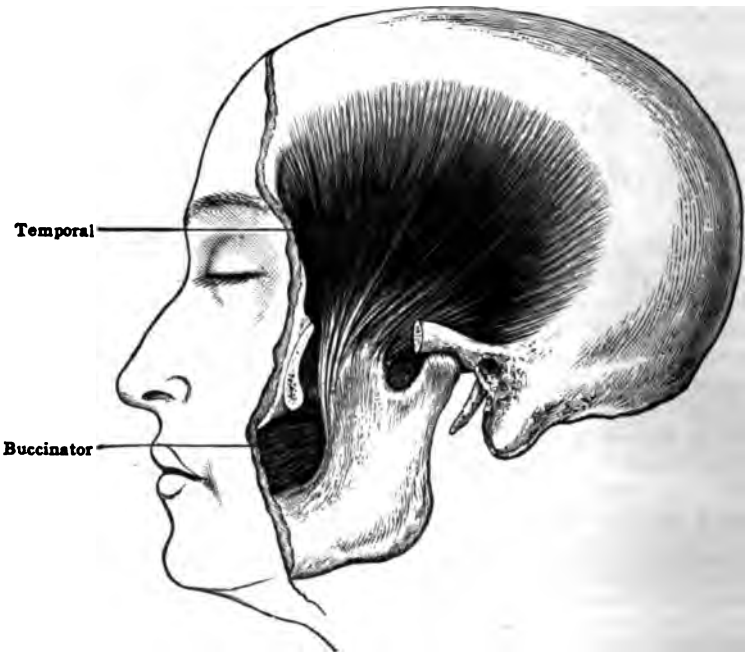
Variations.—The occipitalis is occasionally absent, a condition normal in ruminants. The muscles of the two sides may be fused in the median line (normal in dogs). It may be fused with the posterior auricular. The frontalis is rarely missing. The frontalis may send slips to the medial or lateral angles or the orbital arch of the frontal bone, to the nasal process of the maxilla or to the nasal bone. The fiber-bundles of the frontalis may interdigitate across the median line.

The **transversus nuchæ**, or occipitalis minor, is a small muscle, frequently present (27 per cent., Le Double), which runs from the occipital protuberance toward the posterior auricular muscle, with which it may be fused. It may lie over or under the trapezius.

(*g*) AURICULAR MUSCLES
(Fig. 372)

The intrinsic muscles of the auricle are described in Section IX. There are three 'extrinsic' auricular muscles which converge from regions anterior, superior, and posterior to the auricle and are inserted into it.

FIG. 376.—THE TEMPORAL MUSCLE.



The **auricularis anterior** (attrahens aurem) is a small, flat, triangular muscle which arises between the two layers of the fascia of the galea aponeurotica, extends over the zygomatic arch, and is inserted into the front part of the helix. The fiber-bundles converge from the origin toward a tendon of insertion. The area of origin of this muscle is often marked by a fibrous band tangential to its component fibers. From this band muscle fiber-bundles radiate but toward the frontal region of the skull. To the muscle formed of these radiating fibers the names **epicraniotemporalis** (Henle), **temporalis superficialis** (Sappey) and **auriculofrontalis** (Gegenbaur) have been given.

The **auricularis superior** (attollens aurem) is a large, thin, triangular muscle which, from its tendinous insertion on the eminence of the triangular fossa of the ear, radiates upward into the fascia of the galea aponeurotica, between the layers of which it takes origin near the temporal ridge. It lies over the temporal fascia and the periosteum of the parietal bone.

he auricularis posterior (retrahens aurem) is a thin, band-like muscle which extends over nsertion of the sternocleidomastoid from the base of the mastoid process and the apo- is of the sternocleidomastoid muscle to the convexity of the concha, where it has a ten- n insertion. It is usually composed of two fasciculi, and is contained between two layers scia derived from the galea aponeurotica.

erve-supply.—The auricularis anterior and superior are supplied by the temporal branch e facial, the auricularis superior and posterior by the posterior auricular branch. The of supply run to the deep surface of the muscles.

elations.—The superficial ascending branch of the auriculotemporal nerve usually runs rficial to the anterior and superior auricular muscles. The superficial temporal vessels run st beneath these muscles and the lateral expansion of the galea aponeurotica, then between wo fascial layers which enclose the muscles. Their branches of distribution finally come between the muscles and aponeurosis and the skin. The posterior auricular artery and usually run under cover of the auricularis posterior.

ction.—The anterior muscle is a protractor, the superior an elevator, and the posterior a ctor of the ear, but usually in man they are inactive.

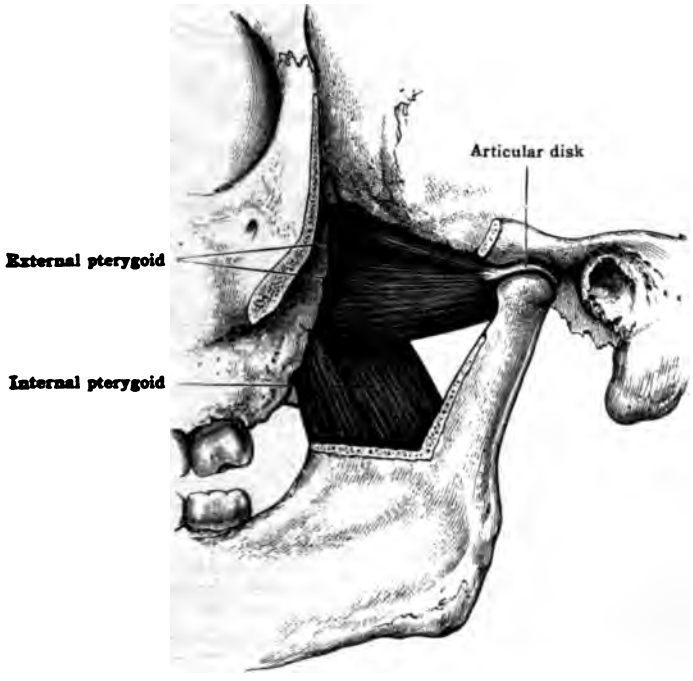
ariations.—These muscles vary much in development. The most constant of them is perior. The posterior frequently is increased in size and may be fused with the occipitalis, originally was probably an ear muscle From the anterior muscle a special deep fascicu- occasionally isolated. Each of the muscles is occasionally, though rarely, absent, the ior most frequently. An inferior auricular muscle is very rarely found in man, though nt in many of the lower mammals. A slip of the posterior auricular may run beneath the the parotid fascia.

2. CRANIOMANDIBULAR MUSCULATURE

(Figs. 375–378C)

The craniomandibular muscles, or muscles of mastication, pass from the base e skull to the lower jaw. They are represented in the selachians by a single le mass, the adductor mandibulæ (Gegenbaur), but in the higher vertebrates

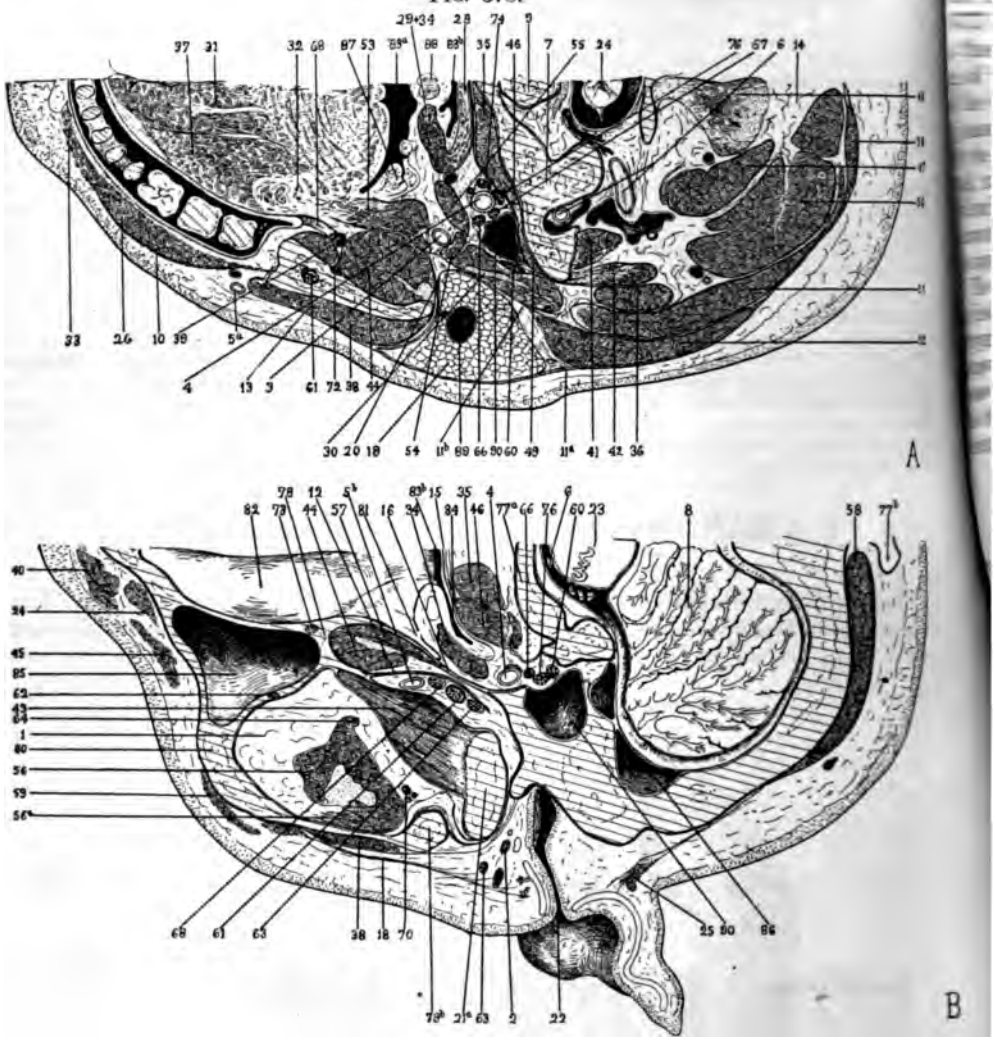
FIG. 377.—THE PTERYGOID MUSCLES.

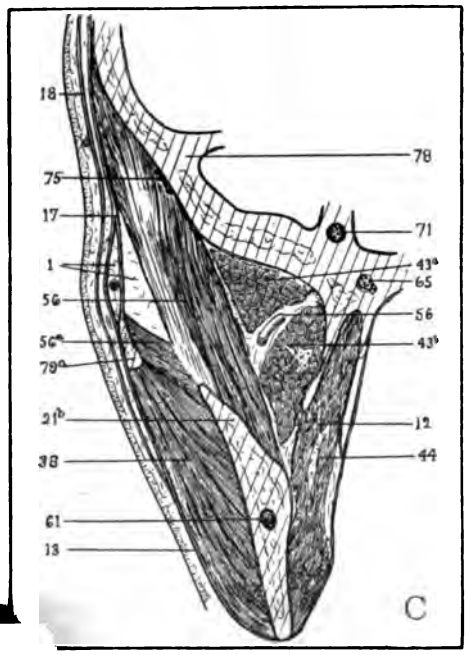


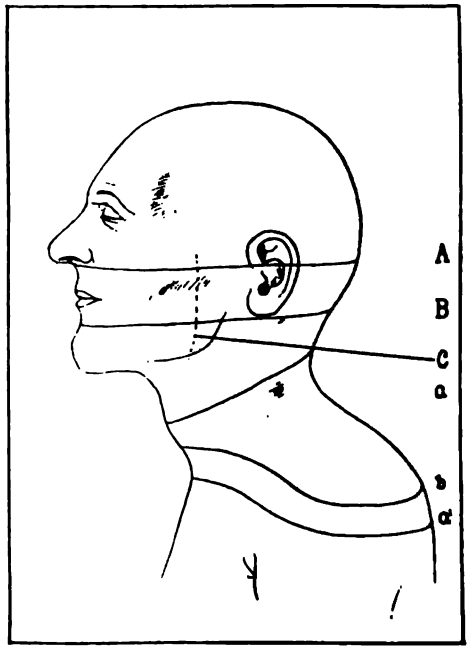
muscle mass becomes variously subdivided during embryonic development. muscles are innervated by the masticator nerve (motor root of the tri- inal cranial nerve, the nerve of the mandibular arch). In man four muscles ecognized, the temporal, masseter, and internal and external pterygoids.

The **temporal** and **masseter** muscles are situated on the lateral surface of the , partly under cover of muscles of the facialis group. The **temporal** muscle 376), which resembles the quadrant of a circle, arises from the temporal and is inserted into the coronoid process of the mandible; the thick, quad- eral **masseter** (fig. 375) muscle arises from the zygomatic arch and is inserted

FIG. 378.







ıto the lateral surface of the ramus and angle of the mandible. The **pterygoids** ig. 377) are more deeply seated. The cone-shaped **external pterygoid** arises om the lateral side of the pterygoid process and lower surface of the great ing of the sphenoid and is inserted into the condyloid process of the mandible nd the capsule of the joint. The thick, quadrilateral **internal pterygoid** parallels he masseter. It arises from the pterygoid fossa of the sphenoid and is inserted nto the inner side of the angle of the mandible. It will be noted that the temporal, masseter, and internal pterygoid muscles have an approximately vertical pull and adduct the lower jaw, while the external pterygoid has an approximately horizontal pull and draws the jaw forward and, when acting on one side, toward the opposite side.

The first three muscles act in the main on the joint between the condyle and the disk, about an axis passing transversely through the condyle. The external pterygoid, on the other hand, acts chiefly on the joint between the disk and the temporal bone. When both of the latter muscles act, the axis of movement passes transversely from the base of the articular tubercle on one side to that of the other. When only one muscle contracts, the approximate axis is vertical, through the condyle of the opposite side of the mandible (fig. 454).

FASCIÆ

The temporal fascia arises from the temporal line of the frontal bone and from the superior emporal line of the parietal and the periosteum immediately below this. It extends to the ygomatic arch. In its inferior quarter the fascia divides into two lamellæ, one of which passes o the outer, the other to the inner, surface of the arch, but at the superior margin of the arch hese two lamellæ are united by dense fibrous tissue. Between the two lamellæ above the rch lies a fatty areolar tissue in which the middle temporal artery often runs. The outer surıce of the fascia is covered by the superficial temporal and anterior and superior auricular uscles, and by a thin layer of fascia from the galea aponeurotica, with which, toward the zygoıatic arch, it becomes merged The superficial temporal artery and auriculotemporal nerve ross it.

Vena facialis posterior (temporomaxillary). 90. V. jugularis interna.

*This and the following series of cross-sections are taken from a thin, not very muscular, lult male. The fasciæ are represented in most instances disproportionately thick.

The **masseteric fascia** represents essentially a continuation of the temporal fascia from the inferior margin of the zygomatic arch over the masseter muscle which it covers. It is less thick than the temporal fascia, but is firm and strong. It is attached posteriorly to the posterior margin of the mandible, inferiorly to the inferior margin, and anteriorly to the body and to the anterior margin of the ramus and the coronoid process of the mandible. In part it extends over the fat pad of the cheek to the buccinator fascia. The parotid gland, covered by the parotid extension of the external cervical fascia, extends over the posterior portion of this fascia. The **parotid fascia** becomes fused to its external surface at the anterior margin of the gland. Over it lie the parotid duct, the transverse facial artery, branches of the facial nerve, the zygomatici (major), risorius, and platysma muscles.

The pterygoid muscles are each surrounded by a delicate membrane. In addition an **interpterygoid fascia** separates the two muscles. This arises from the sphenoidal spine and follows the internal surface of the external pterygoid to the mandible. Medially it is attached to the lateral lamella of the pterygoid process; posteriorly and laterally it presents a free margin which forms with the neck of the mandibular condyle, an orifice for the passage of the internal maxillary artery, the auriculotemporal nerve, and several veins. Its posterior margin is strengthened into the sphenomandibular ligament, which runs from the spine of the sphenoid to the lingula of the mandible.

The pharyngeal region is separated from the pterygoid by a dense membrane, the **lateral pharyngeal fascia.** This extends from the depth of the pterygoid fossa to the prevertebral fascia, and separates the tensor veli palatini from the internal pterygoid muscle. It is attached above along a line extending from the external margin of the carotid canal to the internal margin of the oval foramen.

The **sigmoidal septum** is a thin membrane which occupies the incisura mandibulæ and separates the masseter from the external pterygoid muscle.

MUSCLES

The **temporalis** (figs. 376 and 378C).—**Origin.**—(1) From the whole of the temporal fossa with the exception of that part formed by the body and temporal process of the zygomatic (malar) bone; and (2) from the fascia covering the fossa. **Insertion** is into the tip, posterior and anterior borders, and the whole internal surface of the coronoid process of the mandible and the anterior portion of the medial surface of the ramus.

In *structure*, the muscle is thin near its superior margin, but becomes thick as its insertion is approached. The fiber-bundles arising from the medial surface of the fossa and from the fascia converge upon the medial and lateral surfaces and the margins of a thick, broad tendon which begins very high in the muscle, becomes visible laterally some distance above the zygomatic arch, and is inserted into the tip, edges, and internal surface of the coronoid process. On the anterior and posterior margins of the tendon the insertion of fiber-bundles continues to the coronoid process, while medially the insertion of the fiber-bundles is continued on the medial surface of the coronoid process and often on the ramus as far as the body of the bone.

Nerve-supply.—Usually three branches from the anterior branch of the mandibular division of the trigeminal nerve curve upward over the temporal surface of the great wing of the sphenoid and enter the deep surface of the muscle. The posterior and middle nerves pass above the external ptergyoid; the anterior, which springs from the buccinator nerve, passes between the two heads of the external pterygoid before curving upward.

Relations.—The muscle is covered by the temporal fascia and the zygomatic arch. Below the temporal fossa the pterygoid muscles and the buccinator lie medial to it. The temporal fossa in front of the muscle is filled with a fatty areolar tissue and this also extends between the muscle and the temporal fascia. Fatty tissue likewise lies between the muscle and the buccinator. Medial to the muscle run the deep temporal vessels and nerves, the buccinator nerve and the sphenomandibular ligament. The masseteric nerve passes lateralward behind and below the tendon.

The **masseter** (figs. 375 and 378C) is composed of two layers. The **superficial layer** arises by an aponeurosis from the anterior two-thirds of the lower border of the zygomatic (malar) bone. The fiber-bundles arise from the deep surface of this aponeurosis and its tendinous prolongations pass obliquely downward and backward, and are inserted into the lower half of the external surface of the ramus, into the angle, and into the neighboring portion of the body of the mandible—the more anterior directly, the posterior by means of an aponeurosis. The **deep layer** arises from the lower border and internal surface of the zygomatic arch. The fiber-bundles pass nearly vertically downward, and are inserted upon the upper half of the external surface of the ramus. The origin and insertion are by tendinous bands, to which the fiber-bundles are attached in a multipenniform manner. The two layers are fused near the origin and insertion and in front. From the temporal surface of the zygomatic bone and the neighboring part of the deep layer of the temporal fascia there arises a fasciculus which is separated by a pad of fat from the main body of the temporal muscle, and is inserted into the lateral surface of the lower extremity of the tendon of the temporal muscle and into the anterolateral surface of the tip of the coronoid process. This fasciculus, sometimes described as a part of the temporal muscle, is innervated by the masseteric nerve.

Nerve-supply.—The branch arises in common with the posterior nerve to the temporal muscle from the motor root of the trigeminal (the masticator nerve). It passes above the external pterygoid, through the mandibular (sigmoid) notch, and enters the deep surface of the muscle near the dorsal margin.

Relations.—It is covered by the masseteric fascia (see above). It lies upon the ramus of the jaw and ventrally is separated by a pad of fat from the buccinator muscle. At the mandibular (sigmoid) notch the sigmoid septum separates it from the external pterygoid muscle. The parotid gland partly overlaps its posterior border.

pterygoideus externus (figs. 377 and 378C) consists of two fasciculi. Each is thick and ular. The superior is flattened in a horizontal, plane. At their hey are separated by a narrow cleft. Near the insertion they become more or less fused. perior fasciculus arises by short tendinous processes from the infratemporal (pterygoid) nd from the neighboring portion of the under surface of the great wing of the sphenoid. er-bundles converge toward the insertion, which takes place by short tendinous processes (1) the capsular ligament in front of the articular disk and (2) the upper third of the front neck of the condyle. The inferior fasciculus is the larger. It arises by short tendinous es from the lateral surface of the lateral lamina of the pterygoid process, from the pyrami- ocess of the palate bone, and from the adjacent portions of the maxillary tuberosity. er-bundles converge toward their insertion into a depression on the front of the neck of ndyle.

ve-supply.—A branch from the masticator nerve (motor root of the trigeminus) ap- es the muscle near the upper border of the medial surface of the superior fasciculus and ranches to both portions.

ations.—It is partly covered by the maxillary fasciculus of the internal pterygoid and by mporal and masseter muscles. Medial to it lies the chief fasciculus of the internal ptery- uscle. The masseteric and the posterior and middle temporal nerves usually pass above uscle, the anterior temporal and the buccinator nerves and frequently the internal maxil- tery between the two fasciculi. The internal maxillary vessels usually pass below the order of the muscle and across its external surface; and the auriculotemporal, lingual, ferior alveolar (dental) nerves cross the deep surface of the muscle.

e pterygoideus internus (fig. 377).—*Origin.*—From (1) the pterygoid fossa, and (2) from axillary tuberosity and the pyramidal process of the palatine, where these adjoin.

ucture and Insertion.—From the medial and lateral laminæ of the pterygoid process arise aponeuroses and from the palatine bone at the lower margin of the fossa, and from axillary tuberosity and palatine bone in front of the external pterygoid, there arise short s. From these aponeuroses and tendons and directly from the fossa the fiber-bundles nearly parallel course downward, backward, and outward, and are inserted in part in a enniform manner into the lower half of the internal surface of the ramus of the mandible. sertion extends to the mylohyoid ridge. The muscle is divided at its origin into two li by the margin of the external pterygoid.

ve-supply.—The internal pterygoid nerve arises from the back of the mandibular nerve e foramen ovale. It passes near or through the otic ganglion. and thence to the medial of the muscle near the dorsal edge. Both the buccinator and lingual nerves are also ed as sending filaments to this muscle.

ations.—Laterally the muscle is covered by the interpterygoid fascia and the spheno- ular ligament, the external pterygoid, temporal, and masseter muscles, and the ramus mandible. The inferior alveolar (dental) and lingual nerves and the corresponding run across this surface. Medial to the muscle lie the lateral pharyngeal fascia, the tensor latini muscle, and the superior constrictor of the pharynx.

ion.—The muscles of this group adduct the lower jaw and carry it forward and backward tate it. The elevation is produced by the masseter, temporal, and internal pterygoid s. The suprahyoid muscles and the external pterygoid are the feeble antagonists. rward movement of the jaw is produced by the simultaneous action of the two external oids (slightly by the superficial layer of the masseter, and the anterior fibers of the tem- while the inferior posterior portions of the temporal muscles carry the jaw at the tem- scoidal joint somewhat backward. Oblique lateral rotatory movements are produced by the action of one of the external pterygoids. The alternate action of these two s associated with the elevating action of the other muscles of the group, gives rise to the g movement of the molar teeth. Purely lateral movements of the jaw may be produced internal pterygoids, acting alternately.

riations.—The temporal muscle may have a more extensive cranial origin than usual. be formed of two superimposed layers. It may be more or less fused with the external oid, or send a fasciculus to the coronoid process. The masseter may be completely l into two fasciculi, a condition normal in many mammals. A special fasciculus may rom the temporomandibular articulation or from the zygomatic (malar) bone. Its t fibers may be fused with the temporal muscle. The two fasciculi of the external oid may be distinct, as in the horse. It has been seen fused with the temporal and with gastric muscle. The internal pterygoid may send a fasciculus to the masseter. It may rigin to the styloglossus. Inconstant fasciculi (*accessory pterygoids*) extending from the f the sphenoid to the pterygoid process represent perhaps remnants of the muscles which the movable pterygoids possessed by many inferior vertebrates.

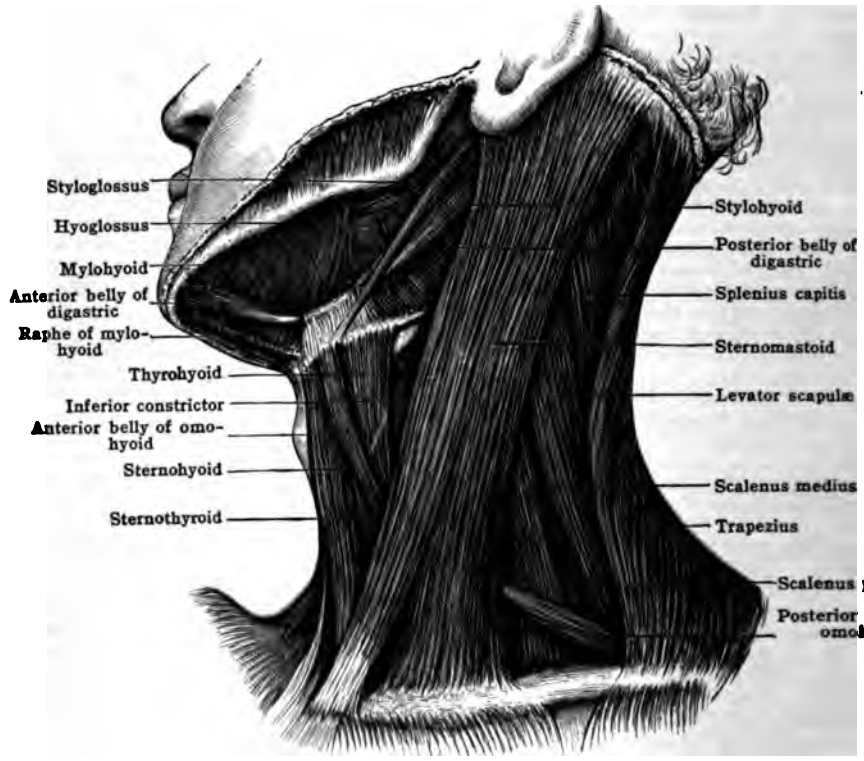
3. SUPRAHYOID MUSCULATURE

(Fig. 379)

om the hyoid bone there extend to the base of the skull on each side four es which form a fairly well-defined group. They are situated external to usculature of the tongue and pharynx. They elevate the hyoid bone and : and depress the mandible. The anterior part of this musculature pulls oid bone and larynx forward and opens up the pharynx, and therefore is of swallowing. The most superficial of the group is the slender, fusiform **yoid,** which arises from the styloid process of the temporal bone and is d into the body of the hyoid. Immediately behind this is the flattened

posterior belly of the **digastric,** which extends from its origin in the mastoid notch to a tendon that runs between two divisions of the tendon of the stylohyoid and is inserted into the hyoid bone by an aponeurotic process. From the digastric tendon the flat, triangular anterior belly is continued to the back of the anterior portion of the inferior margin of the mandible. Internal to this anterior belly the thin, quadrangular **mylohyoid** arises from the inner surface of the body of the mandible and is inserted into a median raphe extending from the mandible to the hyoid. Still more internally the triangular **geniohyoid** extends from the hyoid to the mental spine of the mandible. The last two muscles form the muscular floor of the mouth. The motor innervation of the posterior belly of the

FIG. 379.—ANTERIOR AND LATERAL CERVICAL MUSCLES.



digastric and of the stylohyoid is from the facial nerve, the sensory innervation probably from the glossopharyngeal. The mylohyoid and the anterior belly of the digastric are supplied by the masticator (fifth) cranial nerve; the geniohyoid from the hypoglossal by a branch, the fibers of which are possibly derived through anastomosis from the first cervical nerve.

From the morphological standpoint, therefore, the stylohyoid, and the posterior belly of the digastric belong to the facialis group; the anterior belly of the digastric and the mylohyoid to the group of mandibular muscles, and the geniohyoid to the muscles of the tongue innervated by the hypoglossal; or, if we consider the nerve-fibers of the nerve to the genio-hyoid as derived from the first cervical nerve, to the same group as the infrahyoid muscles. It is convenient, however, to follow the usual custom of considering these muscles as a suprahyoid group.

FASCIÆ

The muscles of this group lie internal to that portion of the external cervical fascia which extends above the hyoid bone. This fascia, which is described on p. 382, comes into contact merely with the tendon, the anterior belly, and to a slight extent with the posterior belly of the digastric muscle. Above the tendon it sends inward a process which curves down internal to the tendon, and is inserted into the external surface of the hyoid bone. The individual muscles of the group are covered by delicate adherent membranes. An aponeurotic membrane usually extends between the anterior bellies of the digastric muscle of each side.

MUSCLES
(Fig. 379)

The stylohyoideus.—*Origin.*—From the lateral and dorsal part of the base of the styloid process by a rounded tendon which soon becomes a hollow cone to the internal surface of which the fiber-bundles of the muscle are attached. *Structure and Insertion.*—The fiber-bundles are inserted on both sides of a slender tendon which divides to let the tendon of the digastric pass through and then is attached to the ventral surface of the body of the hyoid bone near its junction with the great cornu.

Nerve-supply.—From the facial nerve as it emerges from the stylomastoid foramen a small twig is given off which enters the proximal third of the deep surface of the muscle. The glossopharyngeal nerve also gives to it a small twig, probably sensory.

Relations.—It descends immediately in front of the posterior belly of the digastric. Externally lie the parotid and submaxillary glands. Medially it crosses the internal and external carotid artery, the hypoglossal nerve, the stylopharyngeus muscle, the superior constrictor of the pharynx, and the hyoglossus muscle. The posterior auricular artery passes between it and the posterior belly of the digastric and the external maxillary artery crosses over it.

The digastricus.—**The posterior belly** arises by tendinous processes from the mastoid (digastric) notch of the temporal bone. The fiber-bundles form a ribbon-like belly which converges on the intermediate tendon. This begins as a semiconical laminar process on the outer surface of the muscle a short distance above the hyoid bone. **The anterior belly** arises by short tendinous processes from the digastric fossa of the mandible. This attachment is often described as an insertion. The fibers converge on both surfaces of the flattened anterior end of the intermediate tendon. **The intermediate tendon** lies a variable distance above the hyoid bone, usually less than a centimeter. It curves upward toward each belly of the muscle. It is united to the outer surface of the body and to the base of the great cornu of the hyoid bone by an aponeurotic expansion from its inferior margin Other expansions are usually continued into the interdigastric aponeurotic membrane Occasionally the intermediate tendon of the digastric is bound to the hyoid bone by a fibrous loop which allows the tendon free play.

Nerve-supply.—The facial nerve near the stylomastoid foramen gives off a branch which enters the proximal third of the anterior margin of the muscle. From this a ramus may be continued through the muscle to the glossopharyngeal nerve The anterior belly is supplied by a branch of the nerve to the mylohyoid muscle This enters the middle of the lateral part of the deep surface Very rarely the vagus may supply the anterior belly, the hypoglossal, the posterior belly.

Relations.—The posterior belly of the digastric lies internal to the mastoid process and the longissimus capitis (trachelomastoid), splenius, and sternocleidomastoid muscles. Posteriorly near its origin are the rectus capitis lateralis and obliquus cap. sup. muscles, the occipital artery and the spinal accessory nerve. It helps to form the deep wall of the cavity in which the parotid gland is placed. Internally it crosses the origin of the styloid muscles, the carotid arteries, the internal jugular vein, and the hypoglossal nerve. The intermediate tendon of insertion lies below the inferior margin of the submaxillary gland, and crosses the hypoglossus and mylohyoid muscles. The relations to the stylohyoid muscle have been described above The anterior belly lies on the mylohyoid and is covered by the external cervical fascia and the platysma.

The mylohyoideus.—*Origin.*—From the mylohyoid ridge of the mandible. *Structure and Insertion.*—Its fiber-bundles take an oblique course and are inserted into—(1) a median raphe extending from the middle of the ventral surface of the hyoid bone nearly or quite to the posterior aspect of the inferior margin of the mandible, and (2) into the ventral surface of the hyoid bone. Some of the fiber-bundles may cross the median line. The muscles of the two sides form a sheet with a downward convexity which lies between the inner surface of the body of the mandible and the hyoid bone. On the diaphragm thus formed rests the tongue.

Nerve-supply.—From the mylohyoid branch of the inferior alveolar (dental) nerve several filaments enter the under surface of the muscle.

Relations.—The mylohyoid muscle is covered externally by the submaxillary gland, the anterior belly of the digastric, and the external cervical fascia. It is crossed by the submental artery. With the geniohyoid and the genioglossus muscles it helps to bound a compartment in which are lodged the sublingual gland, the duct of Wharton, and the deep portion of the submaxillary gland. Its deep surface also faces the styloglossus and hyoglossus muscles, the lingual and hypoglossal nerves, and to a slight extent the buccal mucosa.

The geniohyoideus (fig. 380).—*Origin.*—By short tendinous fibers from the mental spine of the mandible. *Structure and Insertion*—The fiber-bundles diverge and are inserted into the ventral surface of the body of the hyoid bone. Usually a special fasciculus goes to the great cornu of the hyoid bone.

Nerve-supply.—The hypoglossal nerve sends a filament to the middle third of the deep surface of the muscle. The nerve-fibers are thought to be derived chiefly from the first cervical nerve.

Relations.—It lies between the genioglossus and mylohyoid muscles. It adjoins its fellow of the opposite side and is often fused with it. Lateral to it lie the sublingual and submaxillary glands and the hypoglossal nerve.

Action.—The muscles of this group all elevate the hyoid bone and, through this, the larynx and inferior part of the pharynx, and thus play a part in the act of swallowing. The stylohyoid and posterior belly of the digastric serve also to draw the hyoid bone in a dorsal direction; the ventral belly of the digastric and the geniohyoid, in a ventral direction. The digastric geniohyoid, and mylohyoid depress the mandible, when the hyoid bone is fixed. The digastric acting on one side rotates the jaw toward that side. The two digastrics may retract the jaw. The posterior belly of the digastric has a slight power to bend the head backward.

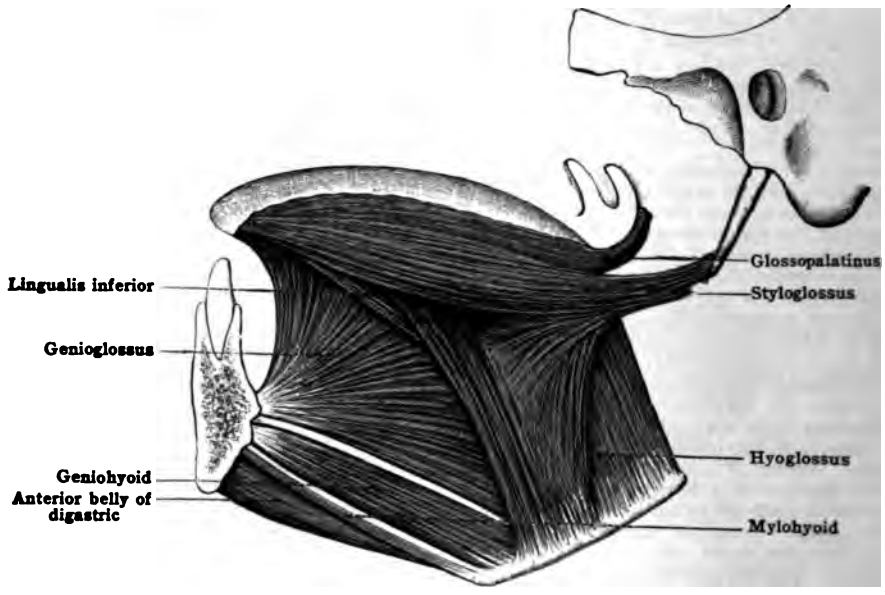
Variations.—The stylohyoid tendon frequently passes entirely in front of and less frequently

entirely behind the digastric muscle. Its insertion may be of greater extent than usual. A special fasciculus to the lesser cornu is not very infrequent; more rarely one extends to the angle of the jaw or to other regions. The muscle may arise from the petrous portion of the temporal or from the occipital bone, as in some lower vertebrates. It may be doubled or absent or fused with the posterior belly of the digastric. The anterior belly of the digastric may be missing; the posterior belly may be inserted into the angle of the jaw. The intermediate tendons of the digastric of each side may be connected by a fibrous arch. The anterior bellies of the muscles of each side may be united by a fasciculus or fused. The anterior belly is frequently doubled. The posterior belly may be divided by a tendinous inscription. Fasciculi may pass from either belly to neighboring structures. The mylohyoid may not extend quite to the hyoid bone. It may be more or less fused with neighboring muscles. Rarely it is absent. The geniohyoid is frequently more or less fused with the muscles of the tongue or with the geniohyoid of the opposite side. A considerable number of infrequently found muscles have been described superficial to the stylohyoid and digastric muscles. Most of them are innervated by the glossopharyngeal nerve or by the facial nerve.

4. MUSCLES OF THE TONGUE
(Fig. 380)

The tongue is a flexible organ, composed chiefly of various muscles, some of which lie entirely within its substance, while others extend to be attached to neighboring parts of the skeleton. To the former the term **intrinsic,** to the latter the term **extrinsic,** is frequently applied. In this section the extrinsic

FIG. 380.—SIDE VIEW OF THE MUSCLES OF THE TONGUE.



muscle will alone be taken up. The intrinsic muscles are described in the section on the DIGESTIVE SYSTEM. Certain pharyngeal and palatal muscles which are continued into the tongue are described in connection with the pharynx. The extrinsic musculature of the tongue is concealed below by the suprahyoid musculature and the sublingual gland. It is covered on the free surface of the tongue by the mucosa.

The musculature of the tongue is supplied by the hypoglossal nerve, which is in series with the motor roots of the spinal nerves. It is, primitively at least, derived from the ventral portion of myotomes in series with the spinal myotomes.

Four extrinsic muscles are recognized on each side. The **styloglossus** is a slender muscle, which arises from the styloid process and is inserted into the side of the tongue. It is cylindrical near its origin, flat and triangular near its insertion. The thin, quadrilateral **hyoglossus** arises from the body and great cornu of the hyoid bone and is inserted into the dorsum of the tongue. The **chondroglossus** arises from the lesser cornu of the hyoid bone and joins the superior and inferior longitudinal muscles of the tongue. The **genioglossus** (geniohyoglossus), which forms the main part of the body of the tongue, arises from the

ne of the mandible, from which the fiber-bundles radiate out toward the
th of the dorsum of the tongue and to the hyoid bone.
the mucous membrane of the tongue is a dense layer of fibrous tissue,
l fascia. In the body of the tongue there is a sagittal septum linguæ,
arates the two genioglossus muscles. A transverse fibrous lamella,
ssal membrane, helps to unite the tongue to the hyoid bone. Delicate
s invest the free portions of the extrinsic muscles of the tongue.

MUSCLES

loglossus.—This *arises* from the front of the lower end of the styloid process of
l bone and from the upper part of the stylomandibular ligament. *Insertion.*—It
ly downward, forward, and medially, with slightly diverging fiber-bundles, to the
in of the tongue, where it gives rise near the anterior (glossopalatine) arch to two
he larger, lateral, longitudinal fasciculus runs superficially along the lateral margin
e to the tip. The fiber-bundles are attached to the overlying mucosa and under-
ilature. The smaller, inferior, transverse fasciculus gives rise to diverging fiber-
ch pass medially through the hyoglossus into the base of the tongue. The most
these diverging bundles may extend to the hyoid bone.
glossus.—This *arises* from—(1) the lateral part of the ventral surface of the body
bone and (2) from the upper border of the great cornu. The fiber-bundles take a
llel course upward, diverging, however, slightly. Near the upper margin of the
the tongue they curve medianward and interlace with the intrinsic musculature of

ue described in Section X.
loglossus.—This *arises* from the mental (genial) spine of the mandible partly
tly by means of a short, triangular tendon. The more inferior fiber-bundles radiate
ip of the tongue; the intermediate extend directly toward the dorsum of the tongue,
are *inserted* into the lingual fascia and skeletal framework. The inferior curve
nserted on the median part of the superior border of the hyoid bone.
pply.—Twigs from the hypoglossal nerve enter the lateral surfaces of the muscles
).
-The chief of the muscles, the genioglossus, performs various services according to
ch contracts. The anterior portion serves to withdraw the tongue into the mouth
the tip; the middle portion to draw the base of the tongue forward, depress the
ion of the tongue, and make the tongue protrude from the mouth; the inferior fibers
ie hyoid bone and carry it forward. The styloglossus retracts the tongue, elevates
nd raises the hyoid bone and base of the tongue. The hyoglossus draws down the
ongue and is also a retractor. The chondroglossus aids in both these movements.
).—The main portion of the tongue is composed of the two genioglossus muscles
parated in the median line by the lingual septum. The genioglossus is covered
r the geniohyoid and the mylohyoid muscles; along the lateral margin of the tongue
opalatinus, the styloglossus, the longitudinalis inferior, and the glossopharyngeus
l posteriorly by the hyoglossus, and the chondroglossus. Below it forms a part of
wall of the space in which the sublingual gland is lodged. Over the dorsum and tip
ie it is covered by the mucosa. This likewise covers laterally, in the region of the
tongue, the styloglossus, hyoglossus, and the longitudinalis inferior. The lingual

glossus, and inferior longitudinal muscles. The hypoglossal nerve lies lateral to
portion of the hyoglossus muscle and then sinks into the genioglossus.
glossus muscle is covered laterally below the free portion of the tongue by the mylo-

5. SUPERFICIAL MUSCULATURE OF THE SHOULDER GIRDLE AND THE EXTERNAL CERVICAL FASCIA
(Figs. 379, 386)

The **sternocleidomastoid** is a strong, band-shaped muscle, bifurcated below, which arises from the medial third of the clavicle and the front of the manubrium and is inserted into the mastoid process of the temporal bone and the neighboring part of the occipital. The large, flat, triangular **trapezius** arises from the occipital bone and the spines of the cervical and thoracic vertebræ and is inserted into the lateral third of the clavicle and into the acromion and spine of the scapula. The two muscles lie in a well defined layer of fascia which ensheaths the neck beneath the platysma, the *external cervical fascia*. Both muscles bend the head and neck toward the shoulder, and rotate and extend the head. The sternocleidomastoid also elevates the thorax and flexes the neck. The trapezius draws the scapula medially and rotates the inferior angle lateralward. The upper part of the muscle elevates, the lower part depresses, the scapula.

These two superficially placed muscles represent differentiated portions of a musculature found in elasmobranchs and in the amphibia and all higher vertebrates. In sharks this musculature is associated with the musculature of the branchial arches, and, like them, is innervated by the vagus nerve. In the higher vertebrates it is innervated by the vagus or by the spinal accessory nerve, developed in connection with the vagus. To this innervation by a cranial nerve, innervation by cervical nerves is added in those higher vertebrates in which the musculature is more extensively developed. In the human embryo the muscles migrate from their origin in the upper lateral cervical region to the positions found in the adult.

FASCIÆ

The **fasciæ** of the neck and the relations of the muscles are shown in cross-section in figs. 378, 382, and 1090.

The **tela subcutanea** of the head and neck in the upper dorsal region is thick, fibrous, and closely adherent to the underlying muscle fascia. Ventrally in the cervical region it contains the platysma.

The **external cervical fascia** (fig. 381) lies beneath the subcutaneous tissue and the platysma, completely invests the neck and extends cranialward over the parotid gland to the zygoma and the masseteric fascia. The trapezius lies between two closely adherent laminæ of the fascia. From the ventral margin of the trapezius it is continued as a thin but strong membrane across the posterior triangle of the neck, between this muscle and the sternocleidomastoid, and is attached below to the clavicle. It invests the sternocleidomastoid with two adherent laminæ and extends from the ventral margin of this muscle across the anterior triangle to the mid-line where it is continued into that of the opposite side. In this triangle the fascia is bound to the hyoid bone, and is thus divided into a submaxillary and an infrahyoid portion. The infrahyoid portion is simple and is attached below to the front of the manubrium. The submaxillary portion is attached to the inferior margin of the mandible. It covers the submaxillary gland and along the inferior margin gives rise to a strong, membranous process which passes inward below the gland and, after extending around the tendon of the digastric muscle, becomes united to the superior margin of the hyoid bone. This process ventrally becomes fused with the perimysium of the ventral belly of the digastric. Dorsally it extends over the posterior end of the submaxillary gland and becomes attached to the angle of the jaw. Here it is strengthened by fibrous tissue which extends in from the ventral margin of the sternocleidomastoid and serves to separate the parotid from the submaxillary gland. This 'mandibular process' is continued into the stylomandibular ligament.

The **parotid gland** is enclosed between two laminæ of the external cervical fascia. These are continued over the gland from the fascial investment of the sternocleidomastoid, and unite anteriorly to become fused to the masseteric fascia along the anterior margin of the gland. They unite below the inferior margin of the gland, and are continued into the mandibular process mentioned above. The external layer, which is the thicker and stronger, is attached above to the cartilage of the auditory canal and to the zygoma. The inner lamina is attached above to the base of the temporal bone. It is incomplete and is more or less fused to the posterior belly of the digastric muscle, the styloid process, and the muscles arising from this process. Beween the styloid process and the angle of the jaw this lamina is strengthened to form the stylomandibular ligament.

In the back beyond the spine of the scapula, the fascia arising from the investing adherent fascial sheath of the trapezius muscle is continued laterally across the fascia investing the infraspinatus muscle, and becomes fused with the most superficial layer of this fascia and more distally with that of the latissimus dorsi muscle. Near this lateral line of fusion it is usually closely adherent to the tela subcutanea.

MUSCLES

The **sternocleidomastoideus** (fig. 379)—*Origin.*— By a medial (sternal) head from the front of the manubrium and by a lateral (clavicular) head from the upper border of the medial third of the clavicle. Between the two origins there intervenes a triangular area covered by the external cervical fascia. Its *insertion* is (1) on the anterior border and outer surface of the mastoid process, and (2) on the lateral half of the superior nuchal line of the occipital bone.

tructure.—The tendons are comparatively short, the longest being that on the anterior ce of the sternal attachment. The fiber-bundles of the muscle take a nearly parallel se from origin to insertion. Five fasciculi may be more or less clearly recognized. In a rficial layer—(1) a superficial sternomastoid;(2) a sterno-occipital; and (3) a cleido-occipital. deep layer—(4) a deep sternomastoid and (5) a cleidomastoid.

FIG. 381.—FASCIÆ OF THE NECK. (After Eisler.) The superficial fascia has been removed laces in order to show the deeper fasciæ; the sternocleidomastoid has been partly removed; submaxillary gland, almost wholly; the parotid gland, as far as the duct.
1. Submaxillary space. 2. Parotid space. 3. Sternocleidomastoid. 4. Supraclavicular a. 5. Suprasternal space. 6. External jugular vein. 7. Anterior jugular vein. 8. Me- colli vein. 9. N. occipitalis minor. 10. N. auricularis magnus. 11. Deltoid. 12. Proc. coideus. 13. Fascia coracoclavicularis.

Nerve-supply.—(1) From the spinal accessory nerve, which gives it branches during its rse through the deep portion of the muscle, and (2) by branches from the anterior primary isions of the second and sometimes the third cervical nerves. These branches enter the deep face of the upper half of the muscle.
Action.—To bend the head and neck toward the shoulder and rotate the head toward the osite side. When both muscles act, the neck is flexed toward the thorax and the chin is ed; or, with fixed head, the sternum is raised, as in forced respiration. When the head is t back, the two muscles may further increase the hyperextension.

Relations.—The muscle and its sheath are covered externally by the tela subcutanea, which here contains the platysma and the external jugular vein, as well as the superficial branches of the cervical plexus. Beneath the muscle lie the sternohyoid, sternothyroid, omohyoid, levator scapulæ, scaleni, splenius, and digastric muscles, the cervical plexus, the common carotid artery, internal jugular vein and the vagus nerve. The spinal accessory nerve usually runs through its deep cleidomastoid portion.

Variations.—There is considerable variation in the extent of independence of the main fasciculi of the muscle. In many of the lower animals the cleidomastoid portion of the muscle is quite distinct from the sternomastoid portion, and this condition is frequently found in man. The cleido-occipital portion of the muscle is that most frequently absent (Wood found it present in 37 out of 102 instances). The clavicular portion of the muscle varies greatly in width. The sternal head has been seen to extend as far as the attachment of the fifth rib. Slips from the muscle may pass to various neighboring structures. The main fasciculi of the muscle may be doubled. Sometimes one or more tendinous inscriptions cross a part or the whole of the superficial layer of the muscle.

The **trapezius** (fig. 386).—*Origin.*—By a flat aponeurosis from the superior nuchal line and external protuberance of the occipital bone, the ligamentum nuchæ, and the vertebral spines and supraspinous ligament from the seventh cervical to the twelfth thoracic vertebra. The aponeuroses of the right and left muscles are continuous across the middle line. Between the middle of the ligamentum nuchæ and the second thoracic vertebra, the aponeuroses give rise to an extensive quadrilateral tendinous area. At the distal extremity of the muscle they are also well developed.

Structure and insertion.—The superior fiber-bundles pass obliquely downward, lateralward and forward to the posterosuperior aspect of the lateral third of the clavicle; the middle-fiber bundles, transversely to the medial edge of the acromion and the upper border of the spine of the scapula; the lower fiber-bundles, obliquely upward and laterally to terminate through a flat triangular tendon on a tubercle at the medial end of the spine of the scapula.

Nerve-supply.—The external branch of the spinal accessory nerve descends for a distance near the superior border of the trapezius muscle and then along the ventral surface. Soon it gives rise to ascending branches for the superior portion of the muscle and descending branches for the middle and inferior portions. The main branches of distribution run about midway between the origin and insertion of the fiber-bundles. The branches from the (second) third and fourth cervical nerves anastomose with the trunk of the spinal accessory, sometimes as it passes along the margin of the muscle, at other times within the substance of the upper portion of the muscle.

Action.—When the whole muscle contracts, it draws the scapula toward the spine and turns it so that the inferior angle points laterally, the lateral angle upward. In addition the upper portion draws the point of the shoulder upward, and with the scapula fixed extends the head, bends the neck toward the same side, and turns the face to the opposite side. The lower portion of the muscle tends to draw the scapula downward and inward and at the same time to rotate the inferior angle of the scapula lateralward.

Relations.—It is covered merely by skin and fascia. It lies external to the semispinalis, splenii, rhomboidei, latissimus dorsi, levator scapulæ, supraspinatus, and a small portion of the infraspinatus muscles.

Variations.—The lower limit of attachment of the muscle may be as high as the fourth thoracic vertebra. The right and left muscles are seldom symmetrical. The upper attachment may not extend to the skull. The clavicular attachment may be much more extensive than normal or may be missing. The attachments to the scapula show considerable variations. Occasionally the cervical and thoracic portions are separate, a condition normal in many mammals. Ventrally the trapezius may become continuous with the sternocleidomastoid in the neck, or send a fasciculus to it or to the sternum. Aberrant fasciculi are not infrequent. Rarely a transverse tendinous inscription is found in the cervical or in the thoracic portion of the muscle. Sometimes a fasciculus is sent into the deltoid. The innervation of either the sternocleidomastoid or the trapezius may be by cervical nerves only. The *omocervicalis* (*levator claviculæ*) is a fasciculus frequent in the lower mammals, but rarely found in man. It usually extends from the acromial end of the clavicle to the atlas and axis, but may extend to more distal cervical vertebræ. It is innervated by a ramus from the cervical branches to the trapezius. The *supraclavicularis proprius* is a muscle rarely found. It extends on the cranial surface of the clavicle from the sternal to the acromial end and is innervated by the third cervical nerve. It is said to make tense the superficial layer of the cervical fascia.

A bursa is often found between the base of the spine of the scapula and the tendon of insertion of the thoracic portion of the trapezius. Another bursa is also frequently found between the insertion of the transverse portion and the supraspinous fascia.

6. INFRAHYOID MUSCULATURE

(Figs. 379 and 382)

The four infrahyoid muscles constitute a well-defined group of muscles which depress the hyoid bone, the larynx, and the associated structures. They lie beneath the sternocleidomastoid muscle and the external cervical fascia. Two strata may be recognized. In the superficial stratum are comprised the **omohyoid**, a narrow, ribbon-like digastric muscle which arises from the superior margin of the scapula and is inserted into the hyoid bone; and the thin, quadrangular **sternohyoid**, which arises from the superior margin of the sternum and

nedial end of the clavicle and is inserted into the hyoid bone. Between
two muscles is an aponeurotic membrane which constitutes the main part
ıe middle layer of the cervical fascia, and represents possibly a retrograde
ion of a single muscle, of which the two above named are but the ventral and
al margins. Beneath this superficial musculature the thin, quadrangular
hyoid descends from the hyoid bone to the thyroid cartilage, and the
on-like sternothyroid arises from the dorsal surface of the manubrium and is
ted into the thyroid cartilage.
All these muscles are supplied by branches from the ansa hypoglossi. The
e-fibers arise from the first three cervical nerves.

he muscles of this group are derived from the ventral portions of the ventrolateral divi-
of the first three cervical myotomes, and correspond with the rectus abdominis muscle,
is derived from the ventral portions of the eighth to the twelfth thoracic myotomes.
musculature is characterised by metameric segmentation, which may be more or less ob-
l, and by a general longitudinal direction taken by the component fiber-bundles. The
e of the fibers in the omohyoid may be looked upon as a secondary condition due to the
ıg laterally of the distal attachment of the muscle. Musculature of this nature is not
ed from the lower cervical and upper thoracic myotomes in man, but in some of the lower
rates it forms a continuous ventral band. Even in man occasional traces of this ventral
ılature may, however, be seen as muscular and aponeurotic slips on the upper part of the
cic wall, above the ribs and the aponeurosis of the external intercostal muscles.

FASCIA
(Figs. 382 and 388)

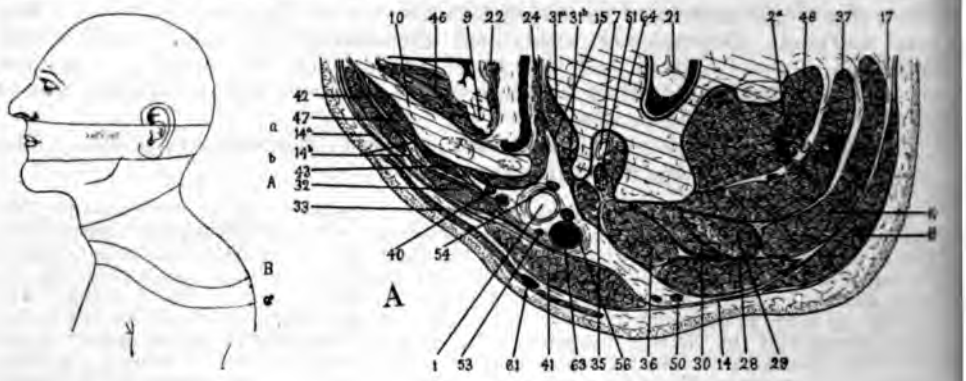
he middle cervical fascia is composed of two laminæ. Of these, the superficial, which
aths the sternohyoid and omohyoid muscles and fills in the intervening area, is much the
ger and better differentiated. The more delicate deep lamina ensheathes the thyrohyoid
ternothyroid muscles, and laterally extends out to become fused with the superficial
a. It is also more or less closely bound to the sheath which covers the internal jugular
carotid artery, and vagus nerve.
ıe middle cervical fascia is attached above to the hyoid bone. Beyond the lateral edge
omohyoid it becomes fused with the deep lamina of the external layer of the cervical
, beneath the sternocleidomastoid. Posterior to this muscle it usually terminates along
anial margin of the omohyoid in the areolar tissue of the neck. Its distal attachment
place into the dorsal surface of the upper margin of the sternum, and from here a process
t over the left innominate vein to the pericardium. Lateral to the sternum the fascia is
ıed for some distance to the inner margin of the clavicle, and gives rise to processes, one of
extends to the fascia of the subclavius muscle, while the others pass on each side of the
ıvian vein to the first rib. Still more laterally the fascia is fused along the lower margin
scapular belly of the omohyoid to the underlying dense, fatty areolar tissue.

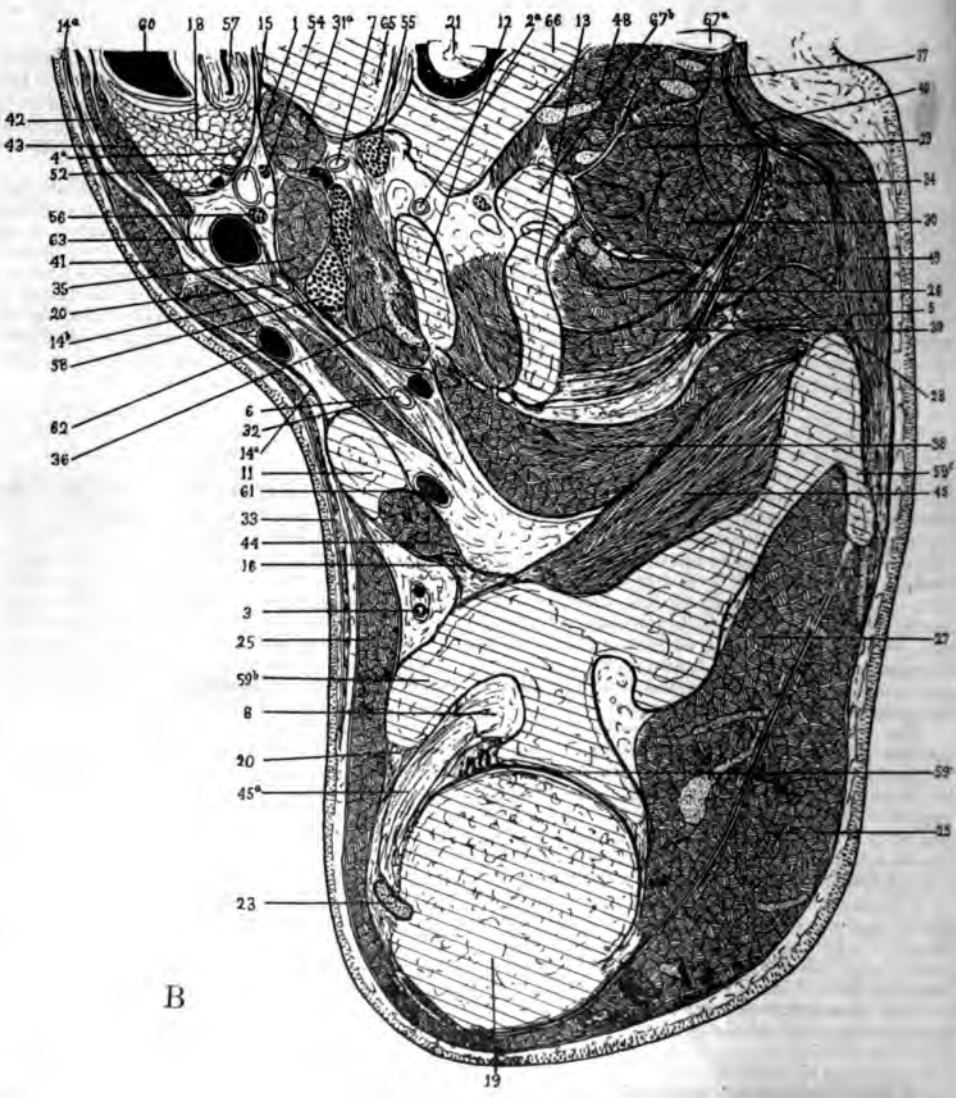
INFRAHYOID MUSCLES
(Figs. 379 and 382)

ıe sternohyoideus.—*Origin.*—From (1) the deep surface of the medial extremity of the
ıle; (2) the costoclavicular (rhomboid) ligament; and (3) the neighboring part of the
ım. The origin may extend to the cartilage of the first rib. *Structure and insertion*—
iber-bundles take a nearly parallel course upward. The muscle belly, however, contracts
ly in width and increases slightly in thickness and slants somewhat toward the median
The insertion takes place directly upon the inferior margin of the body of the hyoid
l to the midline. Not infrequently a tendinous inscription near the junction of the middle
nferior thirds more or less completely divides the muscle into two portions. A second
ption is sometimes found at the level of the oblique line of the thyroid cartilage. *Nerve-*
y.—One or more branches from the ansa hypoglossi enter the lateral margin of the muscle.
ıently one goes to the upper third, another to the lower third, of the muscle.
ıe omohyoideus.—*Origin.*—From the superior margin of the scapula near, and occa-
ly also from, the superior transverse ligament of the scapula. *Insertion.*—The lower
r of the hyoid bone lateral to the sternohyoid muscle. *Structure.*—The inferior belly of
ıuscle near its origin is thick and fleshy. It contracts as it passes ventrally across the
rior triangle of the neck. Beneath the sternocleidomastoid it is attached to a short ten-
rom which, as it bends upward toward the hyoid bone, the superior belly takes origin and
e expands toward the insertion. The tendon of attachment is short. The fiber-bundles
ch bellies take a nearly parallel course. The central tendon of the muscle is held in place
strong process in the middle layer of the cervical fascia. This process is attached to the
l surface of the clavicle and to the first rib. *Nerve-supply.*—The superior belly is sup-
by a branch which enters its deep surface near the medial margin somewhat below the
r; the inferior by a branch which enters the proximal third of its deep surface. These
hes arise from the ansa hypoglossi.
he sternothyroideus.—*Origin.*—Partly directly, partly by tendinous fibers, from—(1)
orsal surface of the manubrium from the middle line to the notch for the first rib; (2) the
l surface of the cartilage of the first rib. Occasionally also from the back of the cartilage
second rib or from the clavicle. *Structure and insertion.*—The fiber-bundles take a nearly
al course upward and slightly lateralward. The muscle is inserted by short tendinous

FIG. 382, A and B.—TRANSVERSE SECTIONS THROUGH THE LEFT SIDE OF THE NECK AND SHOULDER IN THE REGIONS INDICATED IN THE DIAGRAM.

a and *b* in the diagram indicate sections A and B of fig. 378. *a'* that of section A, fig. 388.





fibers into the oblique line on the lamina of the thyroid cartilage. A transverse tendinous inscription near the upper border of the interclavicular ligament not infrequently divides the belly of the muscle more or less completely into two parts. Sometimes a second transverse inscription is found at the level of the lower margin of the thyroid cartilage. *Nerve-supply.*—By one or two branches from the ansa hypoglossi, which enter the ventral surface of the muscle near the lateral margin. One branch usually goes to the upper, another to the lower, third of the muscle.

The **thyrohyoideus.**—*Origin.*—From the oblique line on the lamina of the thyroid cartilage. *Structure and insertion.*—The fiber-bundles take a parallel course and are inserted on the inferior margin of the lateral third of the body of the hyoid bone and the external surface of the great cornu. Many figer-bundles are continuous with those of the sternothyroid.

Nerve-supply.—By a branch of the hypoglossal which enters the muscle near the middle of its lateral border. The fibers are said to be derived from the first cervical nerve.

Action.—The sternohyoid and omohyoid depress the hyoid bone; the sternothyroid depresses the thyroid cartilage; and the thyrohyoid approximates the bone to the cartilage. The omohyoid tends to draw the hyoid bone somewhat laterally. In this is aided by the posterior belly of the digastric and the stylohyoid and is opposed by the sternothyroid and thyrohyoid muscles, and the anterior belly of the digastric.

Relations.—The muscles of this group lie beneath the external cervical fascia. The sternocleidomastoid muscle crosses the omohyoid, the sternohyoid, and sternothryoid muscles. The latter two muscles extend for a distance behind the manubrium of the sternum. The omohyoid is partly covered by the trapezius, crosses the scalene muscles, the brachial plexus, the internal jugular vein, carotid artery, and the sternothyroid and thyrohyoid muscles. The sternohyoid extends over the sternothyroid muscle, the thyroid gland, cricothyroid muscle, and the thyroid cartilage. The sternothyroid lies over the innominate vein, the trachea, and thyroid bland. It is partly covered by the sternohyoid and omohyoid muscles. The thyrohyoid is largely covered by the omohyoid and sternohyoid muscles, and lies upon the hyothyroid membrane and the upper part of the thyroid cartilage.

Variations.—The muscles vary in extent of development and may be more or less fused with one another. The sternal attachment of the sternohyoid is more frequently absent than the clavicular attachment. The region between the omohyoid and sternohyoid may be composed of muscle instead of fascia. Each of the muscles may be longitudinally divided into two distinct fasciculi, may send fasciculi to one another or to the middle layer of the cervical fascia, or may have an abnormal origin or insertion. The omohyoid is the one of the group most frequently absent. One of the bellies is much more frequently absent than both. The intermediate tendon of the omohyoid may be reduced to a tendinous inscription for even disappear entirely. The inferior attachment may take place on the scapular spine, the acromion, the coracoid process, or even the first rib or clavicle. An extra fasciculus from the clavicle is found in 3 per cent. of instances. (Le Double.). Not very infrequently a muscle innervated by a branch of the *descendens hypoglossi* is found extending from the sternum to the clavicle behind the origin of the sternocleidomastoid. It may also extend from the sternum or clavicle in various directions upward toward the head.

BURSÆ

The **bursa m. sternohyoidei** is in constantly found between the lower margin of the hyoid bone and median hyothyroid ligament and the sternohyoid muscle and external cervical fascia. It is better developed in men than in women and is found either on each side of the median line or fused in the median line.

The **bursa m. thyrohyoidei** is frequently found between the greater cornu of the hyoid bone and hyothyroid membrane and the thyrohyoid muscle.

7. SCALENE MUSCULATURE

(Figs. 379 and 383)

The three muscles which form this group constitute a triangular mass which extends in front of the levator scapulæ and intrinsic dorsal musculature and behind the prevertebral musculature from the first two ribs to the transverse processes of the cervical vertebræ. They cover laterally the apex of the pleural cavity. They bend the neck ventrolaterally and rotate it toward the opposite side, and fix the first two ribs or raise the thorax. In front lies the **scalenus anterior,** which extends from the first rib to the fourth to sixth vertebræ. Behind this the **scalenus medius** extends from the first rib to the lower six vertebræ. The most dorsal of the group, the **scalenus posterior,** extends from the second rib to the fifth and sixth vertebræ.

These muscles are supplied by direct branches of the cervical nerves. They are probably derived from the lateral portions of the cervical myotomes. According to Gegenbaur, the two more ventral are homologous with intercostal muscles, the dorsal with the levatores costarum. It is to be noted, however, that the anterior muscle lies in front of the brachial plexus, *i.e.*, in a position similar to that of the subcostal musculature. The scalene musculature is morphologically closely related to the deep shoulder-girdle musculature, p. 391.

FASCIA

(Figs. 382, 388)

From the front of the bodies of the cervical vertebræ the prevertebral fascia is continued laterally over the longus colli and the scalene muscles, and extends dorsally into the fascia covering the levator scapulæ. Between the muscles fascial processes are sent in to become attached to the cervical vertebræ. Inferiorly the fascia extends to the outer surface of the thorax.

SCALENE MUSCLES

(Fig. 383)

The **scalenus anterior.**—This *arises* from the ventral part of the inferior border of the transverse processes of the fourth, fifth, and sixth cervical vertebræ, usually also from the third, rarely from the seventh, by means of long, slender tendinous processes. From each tendon arises a fasciculus composed of nearly parallel fiber-bundles. The fasciculi soon fuse to form a muscle-belly which contracts somewhat toward the insertion. This takes place by means of a tendon which sends a fibrous lamina a short distance upward on the outer surface of the muscle. The tendon is *inserted* into the scalene tubercle on the upper surface of the body of the first rib.

The scalenus medius.—This *arises* usually from the third to the seventh, sometimes from all seven or from merely the last four or five cervical vertebræ. The origin take place from the posterior part of the lateral border of the transverse processes by means of a slender tendon from each of the upper and directly by a muscular fasciculus from each of the lower vertebræ. The fasciculi become combined into a compact muscle-belly which is *inserted* in a manner similar to the scalenus anterior into the upper surface of the first rib behind the subclavian groove. The insertion usually extend to the second rib.

The **scalenus posterior** *arises* by short tendons from the posterior tubercles of the transverse processes of the fifth and sixth cervical vertebræ. The origin may extend as high as the fourth vertebra, for as low as the seventh. It is *inserted* by a short tendon into the lateral surface of the second rib. Occasionally it extends to the third rib.

Nerve-supply.—The scalenus anterior is innervated by branches from the fifth, sixth, and seventh cervical nerves; the middle by the fourth, fifth, sixth, seventh, and eighth cervical nerves; the posterior by the seventh or eighth nerves.

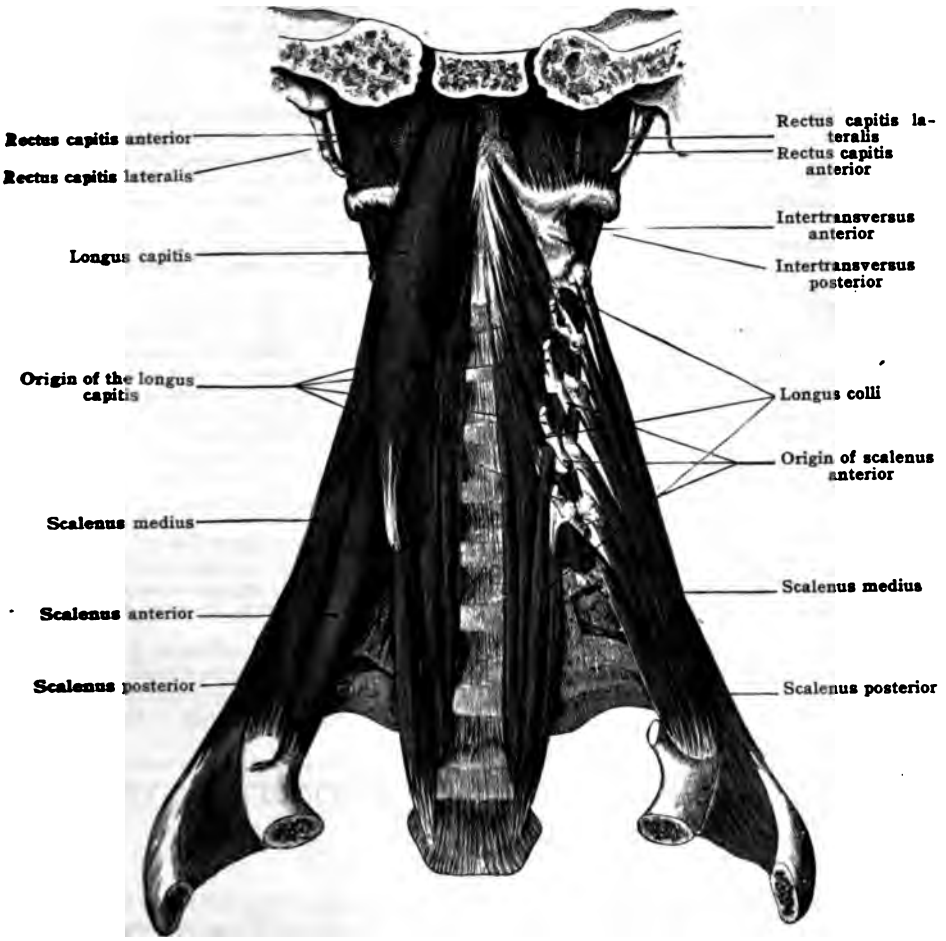
Action.—With the thorax fixed the scalene muscles bend the neck to the side and slightly forward and turn it slightly toward the opposite side. With the neck fixed they serve to lift the first two ribs and are of use in enforced inspiration. In quiet inspirations they serve to fix the first two ribs.

Relations.—The longus colli lies medial to the scalenus anterior. Dorsally the scalene muscles; medially the pharynx, thyroid gland, and trachea; ventrolaterally the sternocleidomastoid, infrahyoid, and subclavius muscles and the clavicle bound a space filled with dense fatty areolar tissue in which are contained the subclavian and carotid arteries, the subclavian and internal jugular veins, the vagus, phrenic, and sympathetic nerves, and numerous smaller blood-vessels and nerves. The main branches of the lower five cervical nerves pass laterally between the scalenus anterior and medius. The subclavian artery passes behind, the subclavian vein in front, of the attachment of the scalenus anterior. The scalenus medius above and the scalenus posterior below enter into relations dorsally with the levator scapulæ and the intrinsic dorsal musculature, from which they are separated by fascial septa.

Variations.—The scaleni present numerous variations in the extent of the costal and vertebral attachments. The degree of fusion of the various fasciculi likewise varies so much that different authors have described varying numbers of muscles into which the scalenus mass should be subdivided. A muscle frequently present is the **scalenus minimus.** This arises

from the anterior tubercle of the sixth or sixth and seventh cervical vertebræ, and is inserted into to the first rib behind the sulcus for the subclavian artery. It sends a process (Sibson's fascia) to the pleural cupola and serves to make the pleura tense. Zuckerkandl found it in 22 out of 60 bodies on both sides; 12 times on the right side only, 9 times on the left. It is innervated by the eighth cervical nerve. When absent, a ligamentous band takes its place. An *intertransversarius lateralis longus*, may extend from the posterior tubercles of the 3–5 transverse processes to the tip of the seventh transverse process and divide the muscle fasciculi near their origin into dorsal and ventral divisions.

FIG. 383.—THE DEEP VENTRAL MUSCLES OF THE NECK.



8. THE PREVERTEBRAL MUSCULATURE

(Fig. 383)

This deep-seated musculature extends along the ventrolateral surfaces of the three upper thoracic and the cervical vertebræ to the skull. It is composed of two muscles. **The longus colli** arises from the bodies of the first three thoracic and last three cervical vertebræ, and from the transverse processes of the third to the sixth cervical vertebræ. It is inserted into transverse processes and bodies of the cervical vertebræ. **The longus capitis** (rectus capitis anterior major) arises from the transverse processes of the third, fourth, fifth, and sixth cervical vertebræ and is inserted into the basilar process of the occipital bone. These muscles flex, abduct, and rotate the head and neck. All of them are supplied by direct branches from the anterior divisions of the cervical nerves. They are probably specialized from the ventrolateral portions of the cervical myotomes Similar muscles are found in all vertebrates with well-developed necks. The rectus capitis anterior (minor) represents an anterior cervical intertransverse muscle.

FASCIA

The muscles are firmly bound to the vertebral column by the prevertebral fascia described in connection with the scalene muscles and by the septa which extend in between the muscles of this group and between them and the scalenus anterior.

MUSCLES

(Fig. 383)

The **longus colli.** This muscle may be compared to a triangle, the base of which extends from the anterior tubercle of the atlas to the body of the third thoracic vertebra and the apex of which is the transverse process of the fifth cervical vertebra. The complex construction of the muscle makes it advisable to consider it as divided into three parts.

The **superolateral portion** consists of fasciculi which arise from the anterior tubercles of the transverse processes of the third, fourth, fifth, and sixth cervical vertebræ and from the body of the third thoracic and become fused into a belly which is inserted into the anterior tubercle of the atlas.

The **medial portion** is formed of muscle fasciculi which arise from the anterolateral parts of the bodies of the first three thoracic vertebræ and the last three cervical vertebræ by tendinous processes. These fasciculi fuse into a belly which terminates by three flat tendinous fasciculi on the anterolateral surfaces of the bodies of the second, third, and fourth cervical vertebræ.

The **inferolateral portion** is applied to the inferior lateral surface of the medial portion. It arises from the lateral parts of the bodies of the first three thoracic vertebræ and is inserted by tendinous processes into the transverse processes of the fifth and sixth cervical vertebræ.

Nerve supply.—By branches from the second to sixth cervical nerves which supply the various constituent fasciculi of the muscle.

The **longus capitis** (rectus capitis anterior major).—Origin.—By cylindrical tendons from the tips of the anterior tubercles of the third, fourth, fifth, and sixth cervical vertebræ. The tendons send up aponeurotic expansions on the outside of the fasciculi which arise from them. These fasciculi fuse into a dense muscle belly to which is usually added a fasciculus from the longus colli. ns.—In front lie the anterior primary division of the suboccipital nerve and the ugular vein. Behind the muscle lie the superior oblique and the longissimus capitis nastoid) muscles and the atlanto-occipital joint.

EEP MUSCULATURE OF THE SHOULDER-GIRDLE

(Figs. 379, 384, 385, 419)

his group belong four muscles which arise in the lateral cervical region mbryonic development and become secondarily attached to the vertebral of the scapula. One of these muscles, the band-like **levator scapulæ**), remains in the cervical region. It extends beneath the sternocleido-, the trapezius, and the intervening fascia from the transverse processes st four cervical vertebræ to the medial angle of the scapula. A second, , quadrilateral **serratus anterior** (magnus) (figs. 384, 385), comes to lie the scapula and wanders with this to the thoracic region. It arises, in the om the first nine ribs and is inserted into the vertebral margin of the

The flat, quadrangular **rhomboideus major** and **rhomboideus minor**) arise from the spines of the last cervical and first four or five thoracic , pass obliquely downward across the deep dorsal muscles beneath the s and are inserted into the vertebral margin of the scapula. The third venth cervical nerves supply this set of muscles. The levator scapulæ is by the third and fourth cervical nerves, the rhomboids by the fifth capular), the serratus anterior by the fifth to the seventh (long thoracic The muscles of this group elevate the scapula, rotate it, and draw it d (rhomboidei) or forward (serratus anterior). When all contract to-ney raise the thorax.

vator scapulæ and the serratus anterior (magnus) are two differentiated parts of a nich is a continous mass in many of the lower mammals. A muscle corresponding mboideus is found in some of the reptiles and many of the higher vertebrates. In ie mammals it has a more extensive cervical attachment than in man.

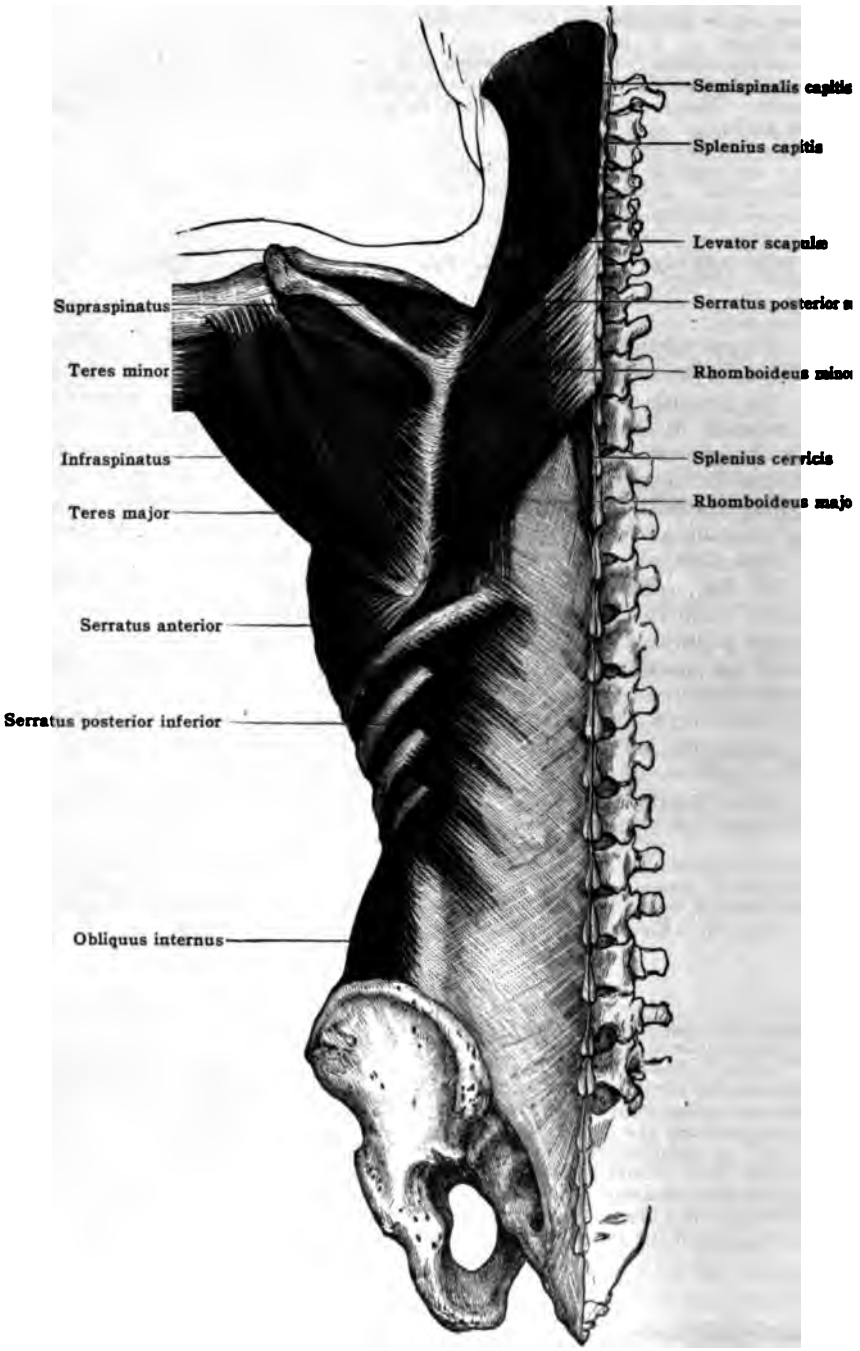
FASCIÆ

scia investing these muscles are shown in cross-section in fig. 388.
vator scapulæ is invested by fascial membranes, the external and stronger of which ied dorsally from the fascial investment of the scalene muscles. The thinner layer p surface lies next the fascial investment of the intrinsic muscles of the back. Cranial-n the rhombbid muscles the fascial investment of the levator scapulæ is fused dorsally **fascia** covering the splenius cervicis. Where the dorsal margin of the levator comes

spines the muscles arise by an aponeurosis which varies in width. The attachment to the ula is by short tendinous processes. The attachment of the rhomboideus major is firm ward the inferior angle of the scapula.

Nerve-supply.—The dorsal scapular nerve, which usually arises chiefly from the cervical nerve, enters the superior margin of the rhomboideus minor and then courses down

FIG. 384.—LEVATOR SCAPULÆ AND RHOMBOID MUSCLES.



near the deep ventral surface of the two muscles and about midway between the tend origin and insertion.

Action.—The two muscles drawn the scapula upward and medialward toward the spi rotate it so as to depress the shoulder.

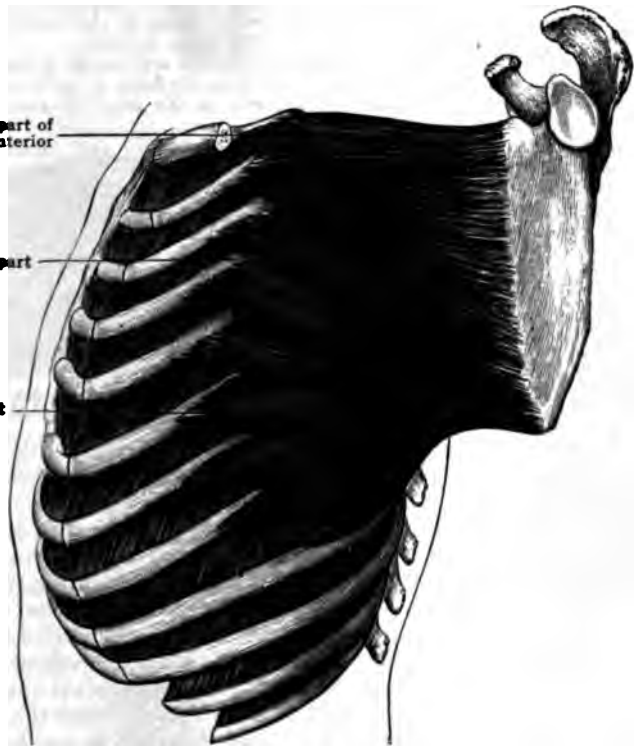
Relations.—Over the muscles lies the trapezius. Under them lie the serratus po rior and the splenius cervicis, the longissimus dorsi, the iliocostalis, levatores co

and external intercostal muscles. The descending ramus of the transverse cervical artery descends on the deep surface. Blood-vessels for the trapezius pass to this muscle between the two rhomboids.

Variations.—There is much variation in the extent of the vertebral attachment. The minor is frequently, the major occasionally, absent. The two rhomboids are frequently fused with one another or may be divided into several distinct fasciculi. Frequently (80 per cent., Balli) a fasciculus extends obliquely on the deep surface of the *R.* major from the cranial part of the origin to the distal part of the insertion. Slips may be sent to the latissimus dorsi or the teres major. An accessory slip may pass between the trapezius and splenius muscles to the occipital bone (**occipito-scapularis**). A muscle corresponding to this fasciculus is normally found in many mammals.

The **levator scapulæ** (figs. 384, 419).—*Origin.*—By short tendons from the dorsal tubercles of the transverse processes of the first four cervical vertebræ, between the attachments of the splenius cervicis and scalenus medius muscles. The tendons from the third and fourth cervical vertebræ are fused for a short distance with those of the longissimus cervicis. *Structure and*

FIG. 385.—SERRATUS ANTERIOR.



insertion.—The fibers run in parallel bundles in a dorsolateral direction downward to the vertebral border of the scapula opposite the supraspinous fossa. The fiber-bundles are inserted directly into the periosteum. As a rule, the flat fasciculi arising from the different vertebræ are easily separated.

Nerve-supply.—By rami chiefly from the third and fourth cervical nerves. These rami enter the ventral margin of the muscle and extend obliquely across the dorsal surface of the constituent fasciculi about midway between the tendons of origin and insertion. Frequently anastomosing branches pass between the nerves. The lowest fasciculus is usually supplied by branches from the nerve to the rhomboid muscles (dorsal scapular).

Action.—Draws the scapula upward and tends to rotate it so that the inferior angle approaches the spine. When the scapula is fixed, the muscle serves to bend the neck laterally and slightly to rotate it toward the same side and extend it.

Relations.—Externally the sternocleidomastoid and, in part, the splenius capitis cover it above; the trapezius, below; and the external cervical fascia, its middle portion. Internally lie the splenius cervicis, longissimus and iliocostalis cervicis (transversalis cervicis), and serratus posterior superior muscles and the ramus descendens of the transversa colli artery. In front lie the scalene muscles.

Variations.—The number of cervical vertebræ from which the muscle springs varies from two to seven. The most constant are the slips of origin from the first two vertebræ. The muscle may send slips to the temporal or the occipital bone or to the trapezius, the serratus anterior (magnus), serratus posterior superior, and other muscles, or to the clavicle, first or second rib, etc. Often the parts of the muscle running to each vertebra are separated for the whole distance. A bundle of fibers that appears to be a detached slip of the levator scapulæ may run from the first two or from lower cervical vertebræ to the lateral end of the clavicle and

to the acromion. This represents the **levator claviculæ** found normally in many vertebrates. According to Le Double, it is innervated by a branch from the cervical branches to the trapezius group.

The **serratus anterior** (magnus) (figs. 385, 419).—*First Part.*—The origin is by two digitations from the first and second ribs and from a fibrous arch uniting these two attachments. The fiber-bundles converge to be inserted on an oval space on the costal surface of the scapula near its medial angle. *Second Part.*—This arises by two or three digitations from the second, third, and sometimes the fourth ribs. The fiber-bundles spread out into a thin sheet which is inserted along the vertebral border of the scapula. *Third Part.*—This, the strongest part of the muscle, arises by digitations from the fourth or fifth to the eighth or ninth ribs. The attachments of the digitations are longest on the upper border of each rib They interdigitate with the attachments of the external oblique muscle of the abdomen. The fiber-bundles converge to be inserted on the large oval space on the costal surface near the inferior angle of the scapula.

Nerve-supply.—From the proximal portions of the anterior divisions of the fifth, sixth, seventh, and sometimes the eighth cervical nerves branches arise which fuse into the long thoracic nerve. This nerve usually passes laterally through or behind the scalenus medius muscle, courses along the outer surface of the serratus anterior midway between the origin and insertion, and gives rise to numerous twigs to supply the various divisions. The fibers to the upper portion come mainly from the fifth cervical nerve; those to the middle from the fifth and sixth; and those to the lower from the sixth and seventh.

Action.—The muscle holds the scapula against the thorax and draws it forward and laterally and, by its highly developed inferior portion, rotates the bone so as to raise the point of the shoulder. It is of especial importance in abduction of the arm. It also aids, to a slight degree, in forced inspiration.

Relations.—Superficial to the muscle lie the pectoralis major and minor, subscapularis, teres major, and latissimus dorsi muscles, the subclavian and axillary vessels, and the brachial plexus. Between the latissimus dorsi and pectoral muscles it is covered by skin and fascia inferiorly, and superiorly by the fatty areolar tissue of the axillary fossa. Under it lie the external intercostal, serratus posterior superior, and the lower extremity of the scalenus medius and posterior muscles.

Variations.—The digitations may extend to the tenth or only to the seventh rib. The muscle may be continuous with the levator scapulæ as it is in the carnivora, or some of its upper digitations may be wanting. Slips may be continued into neighboring muscles. The lower digitations may be partially replaced by digitations innervated by intercostal nerves.

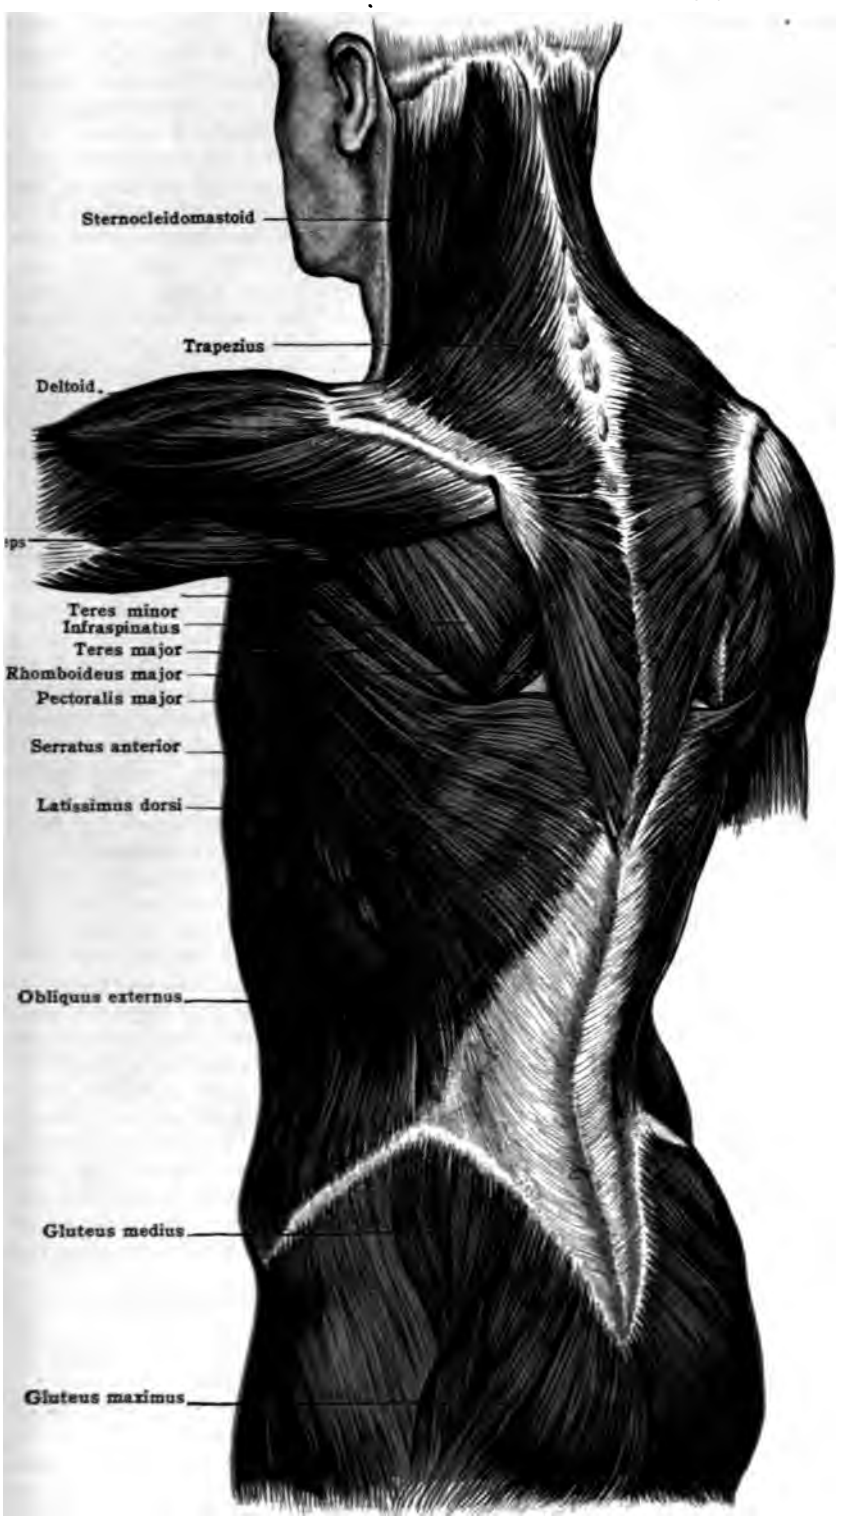
II. MUSCULATURE OF THE UPPER LIMB

The upper limbs in man, relieved of the function of locomotion which is their chief office in most of the lower mammals, have become endowed with great freedom of movement which permits their developing many important functions. Primitively of value in climbing, in seizing food, preparing it for eating and carrying it to the mouth, in attack and defense, their importance has been greatly increased through the invention and use of tools, at first simple but constantly increasing in complexity. They are also used as a means of social expression, as seen primitively in the shrugging of the shoulders, or in the varied movements of the arms which accompany heated discourse, and as finally developed in the art of writing. In order to understand the muscles which are called into play in the performance of these varied functions it is necessary to consider the various types of movement which take place at each of the joints. Since, however, most muscles act on more than one joint and the different parts of a muscle may act differently on the same joint, it is convenient to take up the muscles of each region of the limb in groups, based not so much upon the action of the muscles on any one joint as upon the development of the group and the innervation of the muscles composing it.

Physiology.—Movement of the scapula is of essential importance in the movements of the arm. The scapula is kept against the thorax by muscular attachments and atmospheric pressure, but it may be moved forward, backward, upward, and downward, and may be rotated so that the glenoid fossa, with which the head of the humerus articulates, is pointed forward when the arms are carried forward, lateralward when the arms are abducted, upward when the arms are raised high and somewhat downward when the arms are carried backward, thus greatly increasing the extent of movement in these various directions. The acromioclavicular and sternoclavicular joints both allow limited movements in various directions so that they resemble physiologically limited ball and socket joints. The part played by the superficial and deep shoulder-girdle muscles in the various movements has been described above in connection with these groups of muscles. The action of these muscles is aided by the pectoral muscles, (fig. 391) and by the latissimus dorsi (fig. 386) described below. These muscles depress the scapula. The upper sternal part of the pectoralis major, however,

ɾ alone elevates the scapula; the lastissmus dorsi draws the scapula back-
, the pectoral muscles draw it forward.
t the humeroscapular or shoulder-joint the arm may be carried outward or
cted, bodyward or adducted, forward or flexed and backward or extended.

FIG. 386.—FIRST LAYER OF MUSCLES OF THE BACK.



The last is much more limited in degree than the other two. The arm may also be partially rotated at this joint. These various movements are brought about by the scapulohumeral muscles (figs. 386, 387, 394) and by the latissimus dorsi (fig. 386) and the pectoralis major (fig. 391), assisted by the muscles of the arm which arise from the scapula. They are produced in association with the movements of the scapula described above. At the ulnohumeral joint the movements are relatively simple, consisting of flexion and extension. Extension is produced at the elbow by the dorsal muscles of the arm (fig. 394), flexion is produced not only by the ventral muscles of the arm, which are inserted into the radius and ulna (fig. 395), but also by the more superficial of both the main groups of muscles of the forearm. The pronation of the forearm, whereby the palm is turned downward, and supination, whereby it is turned upward, take place in the joints between the radius and ulna at each extremity and between the radius and the lower end of the humerus. At the upper radioulnar joint the radius is turned on its long axis, at the lower joint it is carried about the lower end of the ulna. Pronation is produced chiefly by muscles belonging to the ulnovolar group of forearm muscles (fig. 401); supination is produced by the biceps of the arm (fig. 395) in conjunction with some of the muscles of the radio-dorsal group of the forearm (fig. 398). At the wrist joints (radiocarpal, intercarpal), the movements are those of flexion, extension, radial abduction and ulnar abduction. Volar flexion takes place chiefly at the radiocarpal joint, dorsal flexion at the intercarpal joint (Frohse). Extension is produced by those muscles of the radiodorsal group of the forearm which send tendons to the wrist and digits, flexion by the corresponding muscles of the ulnovolar group, radial abduction is produced by the radial carpal extensor muscles (fig. 398), and ulnar abduction by the ulnar carpal extensor and flexor (fig. 401). The varied movements of the thumb and fingers, flexion, extension, abduction, and adduction are produced partly by muscles of the two chief groups of forearm muscles, partly by the intrinsic muscles of the hand. Of chief interest here are the free movements of the metacarpal of the thumb and the limited movements of the other metacarpals, that of the little fingers being the most movable, as seen in spreading or cupping the hand. In flexion and extension of the metacarpal of the thumb the movement is such as to bring the thumb into opposition to the fingers. In the metacarpophalangeal joints those of the fingers admit of much greater freedom of movement, flexion, extension, abduction, and adduction, than that of the thumb. The interphalangeal joints are pure hinge joints and permit merely flexion and extension.

Divisions.—The muscles described in this section as the muscles of the upper limb are all differentiated from the blastema of the embryonic limb bud. Most of them are differentiated in connection with the skeleton of the limb and extend between the various bones which compose it, but a few grow out from the limb bud over the trunk and become secondarily attached at one extremity to the trunk, while the other extremity remains attached to the skeleton of the limb. Thus the pectoral muscles (fig. 391), extend from the limb bud over the front of the thorax and the latissimus dorsi extends over the side and back of the trunk as far as the iliac crest (fig. 386). The muscles of the limb may be divided into two great divisions, a dorsal division, innervated by nerves arising from the back of the brachial plexus (supra- and subscapular, axillary and radial nerves) and a ventral division innervated by nerves arising from the front of the plexus (subclavian, anterior thoracic, musculocutaneous, median and ulnar). The former, which correspond with the musculature on the back of the shark's fin, are in the main extensors; the latter, which correspond with the musculature on the front of the shark's fin are in the main flexors. The bellies of the muscles of each division are found in the region of the shoulder and thorax, the arm, the forearm, and the hand.

The **shoulder muscles** belong to the dorsal division, the **pectoral** to the ventral division. In the **arm** the **dorsal division** is represented by the triceps and anconeus (fig. 394). The **ventral division** is made up of the coracobrachialis (fig. 396); the biceps (fig. 395); and the brachialis (fig. 396). The two main divisions of the musculature of the **forearm** give rise to the prominences on each side of the elbow-joint. Their peculiar arrangement with respect to the humerus is because in man, as in most tetrapods, the normal position of the forearm is one of pronation and in this position the back of the forearm is in line with the

icondyle, the front with the ulnar epicondyle. The dorsal or extensor springing from the lower end of the humerus (fig. 398), get the most rchase when attached to the radial epicondyle, and the ventral or flexor (fig. 401), the most direct purchase when attached to the ulnar epicondyle. divisions of the musculature may therefore here be designated the radio- nd the ulnarvolar or volar divisions. The main bulk of the muscula- ound in the upper part of the forearm. At the wrist numerous tendons r to the wrist, palm and digits. This arrangement facilitated move- the hand. In the **hand**, all intrinsic muscles belong to the **volar** division.

.—The muscle fasciæ of the upper extremities are well developed. The deltoid imus dorsi are contained in a fascial sheet which extends between them. The deeper hich arise from the scapula are covered by strong fasciæ. Of the pectoral muscles the major is covered by a delicate fascia, while the subclavius and pectoralis minor are within the dense *costocoracoid membrane* (fig. 389) which extends into the fascia the axillary fossa. The latter (fig. 390), is thin and is intimately fused to the tela a. The muscles of the arm are enveloped in a cylindrical sheath which in the lower e arm is united to the humerus by intermuscular septa.

forearm near the wrist and on the back of the hand the tela subcutanea contains The antibrachial fascia forms a cylindrical enclosure for the muscles of the forearm. wrist it becomes strengthened dorsally to form the dorsal ligament of the carpus annular ligament). This ligament converts the grooves on the back of the radius s for the tendons of the extensors of the wrist and fingers. On the back of the hand s the fascia is intimately connected with these tendons. On the volar side near the fascia is strengthened to form the volar ligament of the carpus. Beneath the ligament ansverse ligament of the carpus which extends from the pisiform and hamate bones to sities of the navicular and greater multangular bones. It completes an osteofibrous the tendons of the long flexors of the fingers. On the palm of the hand the fascia is nd to the bones by intermuscular septa, which separate the thenar and hypothenar om a central palmar region. On the volar sides of the fingers the fascia forms the gaments of the flexor tendons.

A. MUSCULATURE OF THE SHOULDER

(Figs. 386–388, 394, 419)

muscles belonging to this group are the deltoid, the teres minor, the infra- raspinatus, the latissimus dorsi, the teres major, and the subscapularis. **deltoid** (fig. 386) is a large, shield-shaped muscle which covers the shoul- arises from the spine of the scapula, the acromion, and lateral third of the and is inserted into the deltoid tubercle of the humerus. It abducts nd extends the arm.

teres minor, infra- and supraspinatus form a group of muscles (fig. 394) rise from the back of the scapula, pass over the capsule of the shoulder- s which their tendons are adherent, and, under cover of the deltoid, are l into the top and the dorsal margin of the great tubercle of the humerus. nd-like **teres minor** arises from the upper two-thirds of the axillary border scapula, and has the lowest insertion on the tubercle. The triangular **natus** (fig. 394) arises from the whole infraspinous fossa except the axillary and is inserted above the teres minor. The pyramidal **supraspinatus** 4) arises under cover of the trapezius from the supraspinous fossa, and highest insertion on the tubercle. The teres minor, supraspinatus and natus act as lateral rotators of the arm, the supraspinatus also as an or.

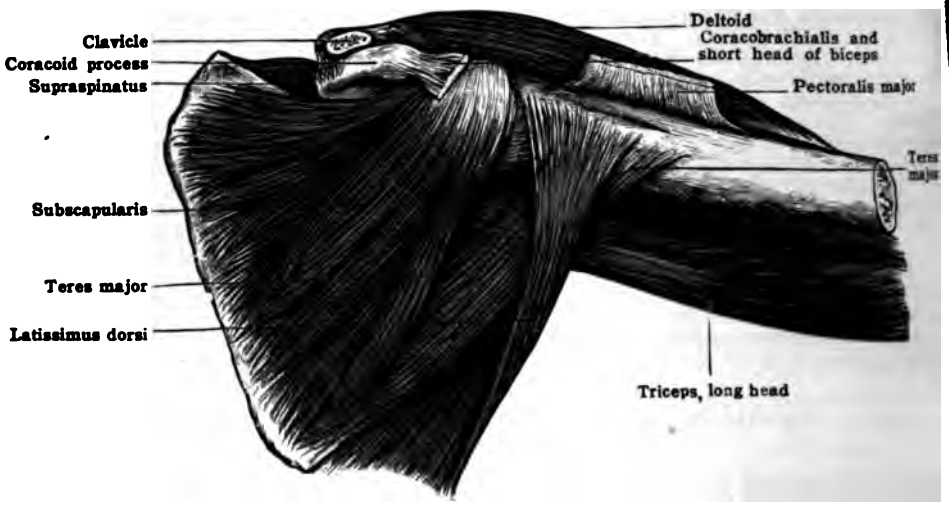
latissimus dorsi, the teres major, and the subscapularis form a group of attached to the lesser tubercle of the humerus and to the crest which distally from this on the medial side of the intertubercular (bicipital)

The **latissimus dorsi** (figs. 386, 387) is a large, flat, triangular muscle, rises from an aponeurosis covering the lumbar and the lower half of the regions of the back and from the posterior part of the iliac crest, and is l into the intertubercular (bicipital) groove. The **teres major** (figs. 7) is a thick, ribbon-shaped muscle which arises from the dorsal surface of rior angle of the scapula and is inserted behind the latissimus dorsi into tal two-thirds of the crest of the small tubercle of the humerus. The **ularis** (fig. 387) is a thick, triangular muscle which extends from the ular fossa to the small tubercle of the humerus. These muscles adduct and rotate it medialward. The latissimus dorsi is also the chief extensor rm.

Near their humeral attachments these two groups of muscles are separated below by the long head of the triceps. The supraspinatus is separated from the subscapularis by the base of the coracoid process and by the intertubercular (bicipital) groove. The tendons of the latissimus dorsi, teres major, and subscapularis are crossed ventrally by the main vessels and nerves of the arm and by the short head of the biceps and the coracobrachialis.

The supra- and infraspinatus muscles are supplied by the suprascapular nerve. The deltoid and the teres minor are supplied by the axillary (circumflex). The subscapularis, the teres major, and the latissimus dorsi are supplied by subscapular nerves. That to the latissimus dorsi is called the thoracodorsal nerve.

FIG. 387.—FRONT VIEW OF THE SCAPULAR MUSCLES.



The deltoid in many of the mammals and the lower vertebrates is represented by separate scapulohumeral and cleidohumeral portions. The cleidomastoid in some mammals is continued into the deltoid. The teres minor, which is innervated by the same nerve, may be looked upon as a derivative of the deltoid although in man it is anatomically more intimately connected with the infraspinatus. The teres major may be looked upon as a specialised portion of the more primitive latissimus dorsi. The comparative anatomy of the shoulder muscles throughout the vertebrate series is a somewhat intricate subject, owing to the great variations exhibited in the form and attachment of the shoulder girdle.

The muscles of this group show more or less marked resemblances to certain muscles of the lower limb. The deltoid and the teres minor probably represent the tensor fasciæ latæ, the gluteal fascia, and the upper part of the gluteus maximus; the latissimus dorsi and teres major, the lower portion of the gluteus maximus; and the subscapularis, the gluteus medius and minimus, and the piriformis. The subscapular and axillary nerves, which supply the arm muscles mentioned, therefore represent in the main the nerves to the gluteal muscles, and the gluteal branch of the posterior cutaneous nerve of the thigh. The infraspinatus muscle probably represents the iliacus; the supraspinatus possibly the pectineus muscle of the lower limb.

FASCIÆ

(Figs. 382, 388, 389, 390, 393)

The **tela subcutanea** covering the regions occupied by these muscles contains considerable fat. In most regions it is not readily separable into two distinct layers. In the neighborhood of the shoulder-joint it is adherent to the underlying musculature and the axillary fasciæ. Over the acromion there is a well-marked subcutaneous bursa, **bursa subcutanea acromialis.**

Muscle fasciæ.—The deltoid and latissimus dorsi muscles are throughout the greater part of their extent superficially placed. They are covered by an adherent fascial layer, which above is attached to the clavicle and to the spine of the scapula. Ventrally it is continued over and fuses with the fascia covering the pectoralis major, serratus anterior, and external oblique muscles. On the back it extends as a thin sheet between the dorsal margin of the deltoid and the upper margin of the latissimus dorsi, and is continued dorsally into the fascial investment of the rhomboid muscles. The lateral fascial extension of the trapezius becomes fused to the dorsal surface of this sheet. Toward the armpit the fascial investment of the deltoid and latissimus dorsi muscles is continued into the axillary fascia, and on the back of the arm it is continued into the fascial investment of the triceps.

The supraspinatus muscle lies beneath the trapezius. It is covered by a dense adherent fascial layer which is separated from the trapezius by loose connective tissue which usually contains a considerable amount of fat.

ıfraspinatus and the two teres muscles lie beneath the musculofascial layer composed ltoid, the latissimus dorsi, and the fascial sheet described above. Each of the three ıas a special fascal investment which is bound to the scapula about the region of attach- the muscle to the bone Where two of the muscles adjoin, their fasciæ give rise to ular septa. Septa of this nature are found between the infraspinatus and each of the scles, and between the teres minor and the teres major. The intermuscular septum the infraspinatus and teres minor muscles is often incomplete. The fascia covering major is so delicate as hardly to deserve the name, except near the origin of the muscle. spine the fascia covering the deep surface of the deltoid is often fused to that covering spinatus.

ubscapularis muscle is invested by a moderately dense fascia which is bound to the long the periphery of the attachment of the muscle. For a short distance this fascia ith the fascial investment of the teres major near the origin of the latter muscle, so that ıuscular septum is formed. From the ventrolateral margin of the fascia covering the laris muscle a sheet of fascia is contained below the axillary fascia into the fascia cover- ɜrratus anterior (magnus).

SHOULDER MUSCLES

leltoideus (figs. 386, 387, 391).—*Origin.*—Fleshy from the lateral border and upper f the acromion and from the ventral border and upper surface of the lateral third of the and tendinous from the spine of the scapula. Some fiber-bundles also at times arise deep fascia of the muscle where it overlies and is fused to the fascia of the infraspinatus ear the spine.

ion.—Into the deltoid tuberosity of the humerus by a strong tendon arising from s tendinous bands within the muscle (fig. 395).

ure.—In structure the deltoid muscle is complex. Three portions may be recognized: cular, an acromial, and a spinous. The first and last are composed of long fiber-bundles ke a slightly converging course and are inserted by aponeurotic tendons respectively ont and back of the V-shaped area of insertion of the muscle. The acromial portion, ther hand, is multipenniform in composition. Four or five tendinous expansions nto the muscle from the acromion, and three up into the muscle from the tendon of in- From the acromion and from the descending tendinous processes fiber-bundles run to ed on the sides of the ascending processes and into the tendons of insertion of the clavi- l spinous portions of the muscle.

-supply.—The axillary (circumflex) nerve passes across the costal surface of the ear the tendon of insertion and gives off rami which enter lateral to the middle of the The nerve fibers are derived from the (fourth), fifth, and sixth cervical nerves.

n. When the whole muscle contracts, the arm is abducted (raised laterally), to a al position. When the clavicular and acromial parts act, the arm is raised and flexed forward toward the chest). When the acromial and spinous parts act, the arm is id extended (carried toward the back), but in this instance the arm is not brought to a h the shoulder-joint, but only about 45° from the hanging position. The inferior part ɜrratus anterior and the trapezius act in conjunction with the deltoid in abduction. ɔn is greatest when the arm is rotated lateralward. The ventral portion rotates the dially, the dorsal portion laterally. When the arm is fixed, the deltoid carries ior angle of the scapula toward the spinal column and away from the thorax.

ions.—On its ventral border the deltoid is in contact with the pectoralis major muscle. e clavicle the cephalic vein and a small artery pass between the two muscles. Its dorsal s continued into a dense fascial sheet which overlies the infraspinatus muscle. Its ɔf insertion passes between the biceps and triceps muscles. The deltoid overlies the process and upper extremity of the humerus, the coracoclavicular and coraco acromial s, and the insertions of the supraspinatus, infraspinatus, and teres minor muscles, the f the biceps and coracobrachialis, and a part of the long and lateral heads of the triceps. it run the posterior circumflex artery and axillary (circumflex) nerve.

ıtions.—The clavicular portion is frequently separate from the rest of the muscle. The rtions may be distinctly separate—a condition normal in some of the lower mammals. icular and acromial portions have been found missing. The deep portion of the muscle separated as a distinct layer and inserted either into the capsule of the joint or into . Accessory fasciculi may pass into the muscle from the fascia over the infraspinatus ı the vertebral and axillary borders of the scapula. Not infrequently fasciculi are con- ıto the muscle from the trapezius—a condition normal in animals with ill-developed . An accessory tendon of insertion may extend to the radial side of the forearm. of fibers from the axillary border of the scapula have been seen to cross the deep surface leltoid and be inserted into the deltoid fascia. The deltoid may be fused with neigh- ıuscles, the pectoralis major, trapezius, infraspinatus, brachialis, brachioradialis.

teres minor (fig. 394).—*Origin.*—From the upper two-thirds of the axillary border of ıspinous fossa, and from the septa lying between it and the infraspinatus on the one the teres major and subscapularis on the other. The origin is in part fleshy, in part aponeurotic band on its ventral surface toward the subscapularis muscle.

ture and insertion.—The fiber-bundles from this origin take a slightly converging course a tendon of insertion which extends for some distance on the dorsal surface of the The muscle is adherent to the capsule of the joint, and terminates on the inferior of e facets of the great tubercle of the humerus and the posterolateral aspect of that two or three centimeters below the facet.

-supply.—From a branch of the axillary (circumflex) nerve which enters the muscle on al margin about midway between its extremities. A 'ganglion' is usually found upon

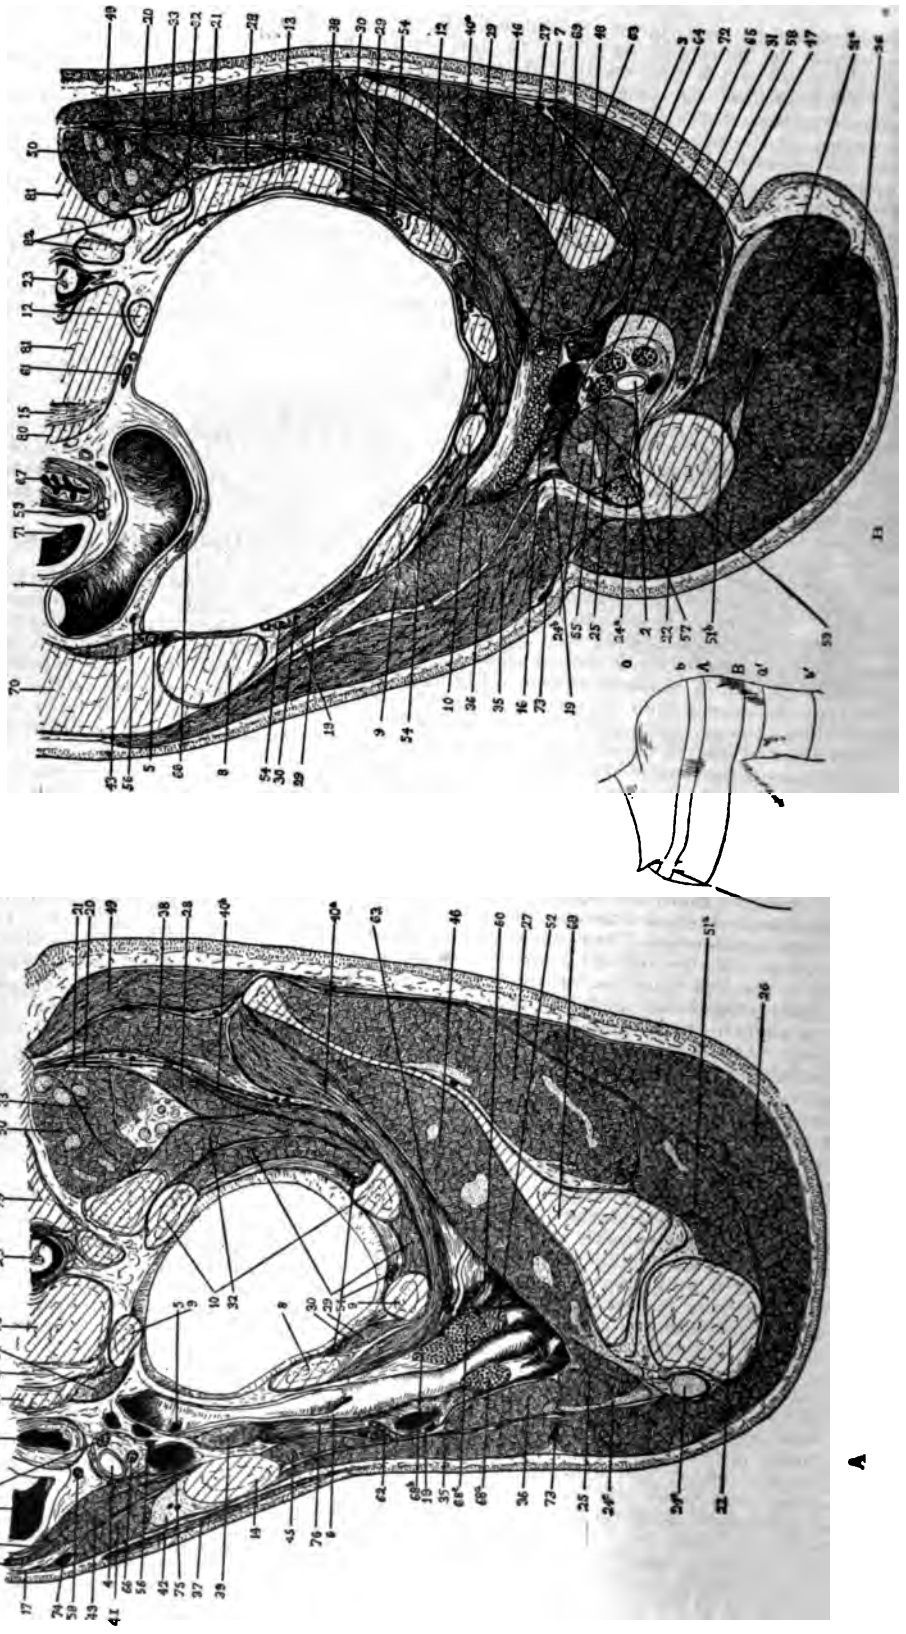


Fig. 388.

nerve. A branch from the nerve to the teres major has also been reported. The nerve rs are derived from the fifth cervical nerve.

Action.—It acts conjointly with the infraspinatus to rotate the arm laterally. It is a or when the arm is down and an extensor when the arm is abducted. It is also an adductor.

Relations.—The muscle is in part covered by the deltoid. Ventrally it enters into relations h the long head of the triceps, the teres major, and the subscapularis. Superiorly, the circnflex (dorsal) scapular vessels run between it and the axillary border of the scapula.

Variations.—Aside from its frequent fusion with the infraspinatus, there has also been ported an isolation of a special fasciculus to the subtubercular attachment.

The infraspinatus (fig. 394).—*Origin.*—From the vertebral three-fourths of the infrainous fossa, from the under surface of the spine, from the enveloping fascia and from interuscular septa between it and the two teres muscles.

Structure and insertion.—The fiber-bundles converge toward the lateral angle of the scapula be attached to a deep-seated tendon which is adherent to the capsule of the joint and is ttached to the middle facet of the great tubercle. The fiber-bundles arising from the inferior urface of the spine and the fascia near this form a distinct fasciculus which descends on and overs the tendon of insertion.

Nerve-supply.—From the suprascapular nerve, which passes beneath the supraspinatus nuscle and enters the deep surface of the infraspinatus in the lateral part of the middle third f its upper margin. From here rami spread out toward the vertebral border of the muscle nd toward the humeral insertion. The nerve fibers are derived from the fifth and sixth ervical nerves.

Action.—This muscle is the chief lateral rotator of the arm, a movement that can be carried hrough 90°. The upper part of the muscle is an abductor, the lower part an adductor of he arm. The muscle is also a flexor.

Relations.—The deltoid and trapezius, and sometimes the latissimus dorsi muscles, cover portion of the dorsal surface. Over most of it extends the complex fascia described above. aterally it adjoins the teres minor and major muscles. Under the muscle lie the transverse suprascapular) and circumflex (dorsal) scapular vessels.

Variations.—These are rare, aside from a greater or less independence of the bundles arising rom the spine and a greater or less complete fusion with the teres minor. A fasciculus has een seen extending to the muscle from the deltoid.

The supraspinatus (fig. 394).—*Origin.*—Fleshy from the medial two-thirds of the supraspinous fossa and from the deep surface of the enveloping fascia near the vertebral end.

Structure and insertion.—The fiber-bundles converge upon a deep-seated tendon nearly to its ttachment into the highest of the three facets on the great tubercle of the humerus.

Nerve-supply.—Two branches from the suprascapular nerve enter the middle third of the eep surface of the muscle. The nerve fibers are derived from the fifth cervical nerve.

Action.—It aids the deltoid in abducting the arm. It is also a weak lateral rotator and exor. It keeps the head of the humerus in place during abduction of the arm.

Relations.—The muscle is covered by the trapezius, the acromion, and the coracoacromial gament. Beyond the base of the spine of the scapula it comes into contact with the infraspinatus muscle. Beneath the muscle pass the suprascapular nerve and transverse scapular suprascapular) vessels.

IG. 388.—A AND B.—TRANSVERSE SECTIONS THROUGH THE LEFT SHOULDER IN THE REGIONS INDICATED IN THE DIAGRAM.

the neighborhood of the brachial plexus in each section some of the adipose and lymphatic tissue has been removed. In section B the fascia covering the apex of the axillary fossa is thus revealed from above. *a* and *b* in the diagram indicate the regions through which pass sections A and B, fig. 382; *a'* and *b'*, the regions through which pass sections A and B, fig. 393.

Vertebra V. 82. Vertebra VI.

Variations.—The muscle shows slight variations. Its tendon may be fused with that of the infraspinatus. Its belly may be reinforced by fiber-bundles from the coracoacromial ligament.

The **latissimus dorsi** (figs. 386, 387, 418, 419).—*Origin.*—(1) From an aponeurosis attached to the spines and interspinous ligaments of the five or six last thoracic and the upper lumbar vertebræ, to the lumbodorsal fascia, and to the posterior third of the external lip of the crest of the ilium; (2) from the external surface and upper margin of the last three or four ribs by muscular slips which interdigitate with those of the external oblique. In the lumbar region the aponeuroses of the right and left muscles are connected by fibrous fasciculi which cross the mid-dorsal line above the supraspinous ligament.

Structure and insertion.—From this extensive area of the origin fiber-bundles converge toward the tendon of insertion. In the region of the dorsal wall of the axillary fossa the muscle is concentrated into a thick, ribbon-like band which winds about the teres major and passes to the ventral surface of that muscle. As this takes place the fiber-bundles become applied to each surface of a flat tendon, which, after emerging from the muscle, is six to eight cm. long and three to five cm. broad, and is inserted into the ventral side of the crest of the lesser tubercle of the humerus and into the depth of the intertubercular (bicipital) groove immediately ventral to the tendon of the teres major. With this it is more or less closely bound, although between the tendons there lies a serous bursa. Some of the fasciculi of the tendon extend to the crest of the greater tubercle. Frequently a tendon slip passes from the inferior margin of the tendon to the tendon on the posterior surface of the long head of the triceps or into the brachial fascia (see *latissimo-condyloideus*, p. 412).

Like the teres major, with which it is closely associated, the latissimus dorsi muscle undergoes a torsion between its origin and its insertion, so that the dorsal surface of the muscle is continued into the ventral surface of the tendon and the most cranially situated of the fiber-bundles are most distally attached to the humerus, and *vice versa*. The muscle either directly or through its fascial extension is often adherent to the inferior angle of the scapula.

Nerve-supply.—From the thoracodorsal (long subscapular) nerve (from the sixth, seventh and eighth cervical nerves). This nerve, which may arise in conjunction with the axillary nerve, passes to the deep surface of the muscle in the lower part of the axilla, and here gives rise to rami which diverge as the muscle expands toward its tendons of origin. Though soon embedded in the muscle substance, two main branches may be followed for a considerable distance near the deep surface of the muscle. One usually extends near the lateral, the other near the superior, border of the muscle, and from these large rami pass into the intervening region. Branches of the dorsal thoracic artery and vein accompany the nerve.

Action.—With the trunk fixed, the latissimus dorsi draws the raised arm down and backward and rotates it medialward (swimming movement). When the arm is hanging by the side, the action of the muscle is on the scapula. The upper third of the muscle draws the scapula toward the spine, the inferior two-thirds depress the shoulder. When the humerus is fixed, the latissimus serves to lift the trunk and pelvis forward, as in climbing. It also aids in forced inspiration through its costal attachments.

Relations.—The trapezius covers a small portion of the muscle in the midthoracic region of the back. Over a large area it is subcutaneous, and its fascial investment is adherent to the skin. As it winds about the teres major its tendon comes to lie behind the coracobrachialis muscle. The main nerves and vessels of the arm here pass across its ventral surface. The muscle covers in part the rhomboideus major, the infraspinatus, teres major, serratus posterior inferior, the lower ribs, the external intercostal muscles, the dorsal border of the external and internal oblique muscles, and the lower dorsal part of the serratus anterior (magnus).

Variations.—It may show considerable variation in the extent of its fleshy portion and in the attachment of its aponeurosis to the vertebral column, crest of the ilium, the ribs, and the scapula. Its origin may be merely from the ribs. It may be divided into separate fasciculi. Frequently a fasciculus arises from the inferior angle of the scapula. The muscle is often intimately united to the teres major. For an account of the muscular slip which extends from the latissimus dorsi across the axillary fossa to the tendon of the pectoralis major near the intertubercular (bicipital) groove see the latter muscle (p. 407); and for the slip continued from the tendon of the latissimus dorsi to the olecranon see the TRICEPS MUSCLE (p. 412).

The **teres major** (figs. 387, 419).—*Origin.*—Directly from the dorsal surface of the inferior angle of the scapula and from the septa which lie between this muscle and the subscapularis, teres minor, and infraspinatus muscles.

Insertion.—For about five or six cm. from the lower border of the small tubercle of the humerus, along the medial lip of the intertubercular (bicipital) groove. Proximally the fiber bundles are attached directly to the tubercle; more distally the attachment is by means of a flat tendon which extends for some distance on the dorsal surface of the muscle.

Structure.—The nearly parallel fiber-bundles pass upward in a spiral direction so that the muscle undergoes a torsion on its axis. The fiber-bundles which have the highest attachment to the scapula have the lowest humeral attachment, and *vice versa*.

Nerve-supply.—By a branch of the lower subscapular nerve which enters the muscle near the middle of its scapular border. The nerve fibers are derived from the fifth, sixth (and seventh) cervical nerves.

Action.—It aids the latissimus dorsi in adducting the arm, and in some positions of the arm acts as a medial rotator and as an extensor.

Relations.—Dorsally the muscle is covered by the latissimus dorsi and by the fascia which extends from this muscle to the deltoid and rhomboid muscles. It is also crossed by the long head of the triceps. Its lower border and ventral surface are largely covered by the latissimus dorsi and its tendon. Its upper border helps to bound a triangular space the other sides of which are the borders of the scapula and the humerus. In front lies the subscapularis, and behind, the teres minor. Across this space passes the long head of the triceps. Lateral to this

ead lie the humeral circumflex vessels and axillary (circumflex) nerve; and medial, the circumflex (dorsal) scapular artery.

Variations.—The teres major may be connected with the latissimus dorsi by a fasciculus, or it may be fused with that muscle or its tendon. Slips have also been seen extending to the triceps and into the fascia of the arm. The muscle is rarely absent.

The **subscapularis** (figs. 387, 419).—*Origin.*—The fiber-bundles spring—(1) directly and by means of tendinous bands from the costal surface of the scapula, except near the neck and at the upper and lower angles; and (2) from intermuscular septa between it and the teres major and teres minor muscles.

Insertion.—The tendon of insertion as it passes over the capsule of the joint is intimately bound to this. It is inserted into the lesser tubercle of the humerus and into the shaft immediately below this.

Structure.—The fiber-bundles arising from the tendinous bands attached to the bone converge upon several tendinous laminæ which extend into the muscle from the tendon of insertion, thus forming small penniform fasciculi. The fiber-bundles arising directly from the bone converge toward the extremities of the tendinous laminæ, thus forming triangular bundles interdigitating with the penniform fasciculi. The fasciculus which arises highest on the axillary border goes directly to the humerus.

Nerve-supply.—By two or three subscapular branches from the back of the brachial plexus. One or more of these may arise in association with the axillary (circumflex) nerve. From the main nerves rami spread out to enter the ventral surface of the muscle near the junction of the lateral and middle thirds. The nerve fibers come from the fifth and sixth cervical nerves.

Action.—It is the chief medial rotator of the arm. It strengthens the shoulder-joint by drawing the humerus toward the glenoid cavity. It is an extensor when the arm is at the side, a flexor when the arm is abducted. The upper portion of the muscle, however, acts as a flexor in both positions. The upper part acts as an abductor but when the arm is abducted the muscle is an adductor.

Relations.—Ventrally it forms the greater part of the posterior wall of the axillary fossa, and enters into relation with the serratus anterior (magnus) and the combined tendon of the coracobrachialis and biceps. On it lie the axillary vessels, the brachial plexus, and numerous lymph-vessels and glands. At its lateral border lie the teres major, the humeral circumflex vessels, axillary (circumflex) nerve, and circumflex (dorsal) scapular vessels. Behind it lie the long head of the triceps and the teres minor muscle.

Variations.—It may be divided into several distinct segments. A fasciculus may be sent to the tendon of the latissimus dorsi and another to the brachial fascia. The **subscapularis minor** arises from the axillary border of the scapula and is inserted into the articular capsule (capsular ligament) of the shoulder-joint or into the crest of the lesser tubercle of the humerus

BURSÆ

B. subacromialis.—A large bursa, nearly constantly found, between the acromion and coracoacromial ligament and the insertion of the supraspinatus muscle and capsule of the joint. Processes extend over the greater and lesser tubercles.

B. supracoracoidea.—A bursa sometimes found between the coracoid process and the clavicle and the deltoid muscle.

B. m. subscapularis.—Between the glenoid border of the scapula and the subscapularis muscle. Communicates with the joint cavity. A small portion of this bursa may be isolated adjacent to the base of the coracoid process (*b. subcoracoidea*).

B. m. infraspinati.—Between the tendon of the infraspinatus and the capsule of the joint or the great tubercle.

B. m. latissimi dorsi.—Constant between the tendons of the latissimus dorsi and the teres major.

B. m. teretis majoris.—Under the insertion of the tendon of the teres major muscle.

B. PECTORAL MUSCLES AND AXILLARY FASCIA

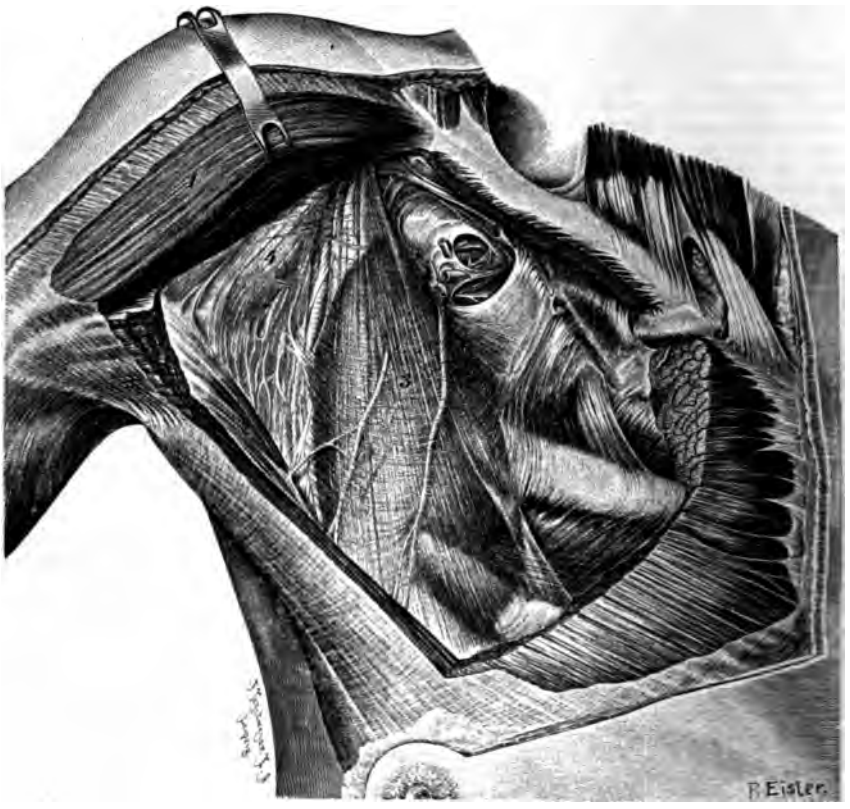
(Figs. 388–392, 419)

The muscles belonging to this group are the pectoralis major, pectoralis minor, and the subclavius. Of these, the largest and most superficial is the triangular **pectoralis major** (fig. 391), which arises from the second to the sixth ribs, the sternum, and the medial half of the clavicle and is inserted into the crest of the greater tubercle of the humerus (pectoral ridge). Its lateral margin adjoins the ventral margin of the deltoid. Beneath this muscle the much smaller triangular **pectoralis minor** (fig. 419) extends from near the ends of the second, third, fourth, and fifth ribs to the tip of the coracoid process, while the small **subclavius** (fig. 392) extends from the first rib upward and lateralward to the clavicle. The pectoralis major adducts and flexes the arm and rotates it medialward. The pectoralis major, pectoralis minor and subclavius muscles draw the shoulder downward and forward.

Of the muscles included in this group, the two pectoral muscles are morphologically the most closely related. They receive a nerve-supply from the same set of nerves, the anterior thoracic. With them the subclavius, which has a separate nerve of its own, is closely associated. Corresponding musculature, although variously modified in different forms, is found throughout the

vertebrate series. In the lower forms it seems to be differentiated directly from the segmental trunk musculature and secondarily attached to the shoulder-girdle, like the superficial and deep musculature of the shoulder-girdle previously described. In man, however, the muscle mass from which these muscles arise is at all times in intimate union with the skeleton of the upper limb, and the nerves which supply it are in much more intimate union with the brachial plexus than are those of the shoulder-girdle muscles. For these reasons the three muscles are classed with the intrinsic muscles of the arm. They have no certain representatives in the lower limb, although the clavicular portion of the pectoralis major is considered by some to represent certain adductor muscles of the thigh. Possibly they correspond in their embryonic origin with the obturator internus group of the lower limb.

FIG. 389.—DEEP FASCIA OF THE BREAST. (AFTER EISLER). THE PECTORALIS MAJOR HAS BEEN IN LARGE PART REMOVED. 1, DELTOID; 2, PECTORALIS MAJOR, ABDOMINAL PART; 3, PECTORALIS MINOR; 4, CORACOBRACHIALIS.



In many of the mammals a subcutaneous muscle arises from the pectoral muscle mass and extends over the axilla and the trunk. In man this musculature is frequently represented by abnormal slips of muscles, of which the 'axillary arch' and possibly the 'sternalis' are representatives. A list of some of the abnormal muscles which are innervated from the anterior thoracic nerves and are evidently derivatives of the pectoral muscle mass is given at the end of this section.

FASCIÆ

In the **tela subcutanea** of the pectoral region the mammary gland is embedded between two layers which ensheath the gland and are connected by dense fiber-bands. To a greater or less extent the platysma extends into the tela of this region from above the clavicle.

Muscle fasciæ.—The pectoralis major is invested with a thin, adherent membrane, **fascia pectoralis,** attached to the clavicle and the sternum and continued into the fascial investment of the external oblique, the serratus anterior (magnus), and the deltoid muscles, and in to the axillary fascia. More important is the **coracoclavicular (costocoracoid) fascia (fig. 389).** This arises from two fascial sheets which invest the subclavius muscle and are attached to the clavicle. From the inferior margin of this muscle the membrane is continued to the superior margin of the pectoralis minor. Between the coracoid process and the first costal cartilage it is strengthened to form the **costocoracoid ligament.** Between this and the pectoralis minor it is thin. At the superior margin of this muscle it again divides to form two adherent fascial sheets, which, at the axillary margin of the muscle, once more unite to form a firm membrane continued into the fascial investment of the coracobrachialis and short head of the biceps and into the axillary fascia. Above, dorsally, the membrane is adherent to the sheath of the axillary vessels and nerves

ıry fascia (figs. 389, 390).—The **axillary fossa** is a pyramidal space above the (external) **and** bounded by the pectoralis major and minor and coracobrachialis muscles in front; **atissimus** dorsi, teres major, and subscapularis muscles behind; by the subscapularis **oward** the joint; and by the serratus anterior (magnus) toward the thoracic wall. In **ve** between the coracobrachialis and the subscapularis and tendons of the latissimus **l** teres major muscles run the main nerves and vessels of the arm. These are surrounded **nsiderable** amount of connective tissue in which numerous blood- and lymph-vessels, **odes**, nerves, and masses of fat are embedded. For topography, see pp. 400, 1412.
this connective tissue the fascia covering the musculature of the neighboring portion **ıoulder** and thorax is continued into the fascia covering the musculature of the medial **he** arm. Thus the fascia covering the pectoralis minor, the coracoclavicular fascia, **ened** by a reflection of the fascial investment of the pectoralis major and deltoid muscles

FIG. 390.—(AFTER EISLER). FASCIA OF THE AXILLARY FOSSA.

ıued across the ventral margin of the axilla into the fascia which covers the coraco- **ıs** and biceps muscles in the arm. Similarly, dorsally, the fascia covering the latissimus **l** teres major is continued over the axilla into that covering the long head of the triceps **rm**. The ventral is connected with the dorsal fascia by a thin membrane which is **:** to the connective tissue filling the axillary space and to the subcutaneous tissue. **.runk** this membrane, the **fascia axillaris**, becomes fused below the axillary fossa with **a** of the serratus anterior (magnus). In the arm it becomes fused with the fascia over **ıs** muscle. Owing to its adherence to the skin and the connective tissue of the axillary **vestigators** have dissected out and figured the axillary fascia in different ways.

MUSCLES

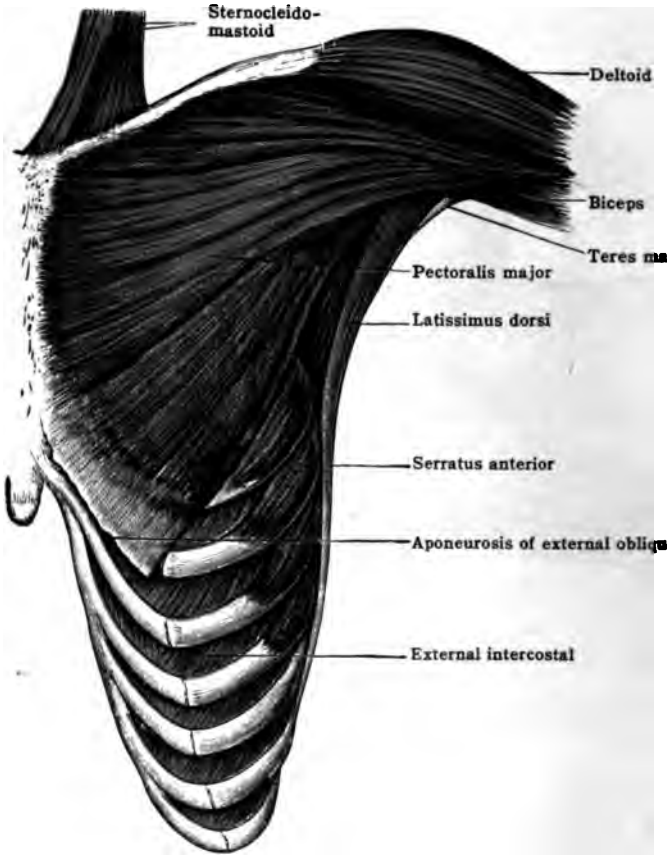
pectoralis major (fig. 391).—*Origin.*—(1) From the medial half of the clavicle; (2) **:** side and front of the sternum as far as the sixth costal cartilage; (3) from the front of **lages** of the second to the sixth ribs; and (4) from the upper part of the aponeurosis of **rnal** oblique where this extends over the rectus abdominis muscle. The costal origin **ıart** take place from the osseous extremities of the sixth and seventh ribs.
tion.—Crest of the greater tubercle (outer lip of the bicipital groove) of the humerus **:** tubercle to the insertion of the deltoid (fig. 211). Some of the tendon fibers are also **d** into the tendon of the deltoid and adjacent fibrous septa and into the fibrous lining **ntertubercular** sulcus.

Structure.—The muscle is divisible into a series of overlapping layers spread out like a fan. Of these, the clavicular portion forms the most cranial and superficial layer, and the portion of the muscle springing from the aponeurosis of the external oblique, the most caudal and deepest layer. This last layer has a special tendon, while the other layers are inserted into a combined tendon lying ventral to this. The two tendons are continuous at their distal margins. (W. H. Lewis.)

Nerve-supply.—From the external and internal anterior thoracic nerves, branches of which enter the sternocostal portion of the muscle about midway between the tendons of origin and insertion, and the clavicular portion in the proximal third. The nerve fibers are derived from the (fifth), sixth, seventh, and eighth cervical and first thoracic nerves.

Action.—With the thorax fixed, the muscle adducts and flexes the arm and rotates it medialward. The clavicular portion draws the arm forward, upward, and medialward; the sternocostal portion draws the arm downward, medialward, and forward. When the arm is pendent, the upper portion elevates, the lower depresses, the shoulder. With the arm fixed, the muscle draws the chest upward toward it. It is of value in forced inspiration.

FIG. 391.—THE PECTORALIS MAJOR AND DELTOID.



Relations.—It lies over the coracoid process, the subclavius, pectoralis minor, intercostal and serratus anterior (magnus) muscles, the coracoclavicular (costocoracoid) fascia, and the thoracoacromial vessels. It forms the main part of the ventral wall of the axillary fossa, and laterally it enters into relation with the deltoid, biceps, and coracobrachialis muscles.

Variations.—In considering variations the muscle may be looked upon as composed of four portions—a clavicular, a sternal, a costal, and an abdominal, the last being that portion which arises from the aponeurosis of the external oblique. These portions vary in the extent of their attachments and in the degree of separation which they present. The abdominal portion may extend to the umbilicus. Huntington considers this portion a derivative of the panicular muscle of the lower mammals. On the sternum the muscles of the two sides may decussate across the middle line. The sternocostal portions of the muscle are more frequently deficient or missing than the clavicular, but in rare cases the entire muscle is absent. The clavicular portion of the muscle may be fused with the deltoid. The sternocostal may extend laterally to the latissimus dorsi. There may be an intimate fusion of the abdominal portion with the rectus abdominis or the external oblique. Sometimes a slip may run from the pectoralis major to the biceps, the pectoralis minor, coracoid process, capsule of the joint, or brachial fascia.

The **pectoralis minor** (fig. 419).—*Origin.*—By aponeurotic slips from the second, third, fourth, and fifth ribs near the costal cartilages.

Structure and insertion.—The fiber-bundles converge upward and outward to a flattened tendon which is attached to the medial border and upper surface of the coracoid process of the scapula.

Nerve-supply.—From the internal anterior thoracic nerve which enters the upper part of the middle third of the deep surface by several branches. Some of the branches extend through to the pectoralis major. The nerve fibers arise from the seventh and eighth cervical nerves.

Action.—When the thorax is fixed, the pectoralis minor pulls the scapula forward, the lateral angle of the bone downward, and the inferior angle dorsalward and upward. When the scapula is fixed, the muscle aids in forced inspiration.

Relations.—It is covered by the pectoralis major. Near its insertion the fibrous investment of the chief nerves and vessels of the arm is adherent to its enveloping fascia.

Variations.—The origin may extend to the sixth rib or may be reduced to one or two ribs. In the primates below man the insertion of the muscle takes place normally into the humerus. In man its insertion may be continued (in more than 15 per cent. of bodies—Wood) over the coracoid process to the coracoacromial or coracohumeral ligaments, to the tendon of the subscapularis muscle, or to the great tubercle of the humerus. It may be divided into two superimposed fasciculi. Fasciculi may extend from the muscle to the subclavius or the pectoralis major.

The **subclavius** (fig. 392).—*Origin.*—From a flat tendon attached to the first rib and its cartilage near their junction.

Structure and insertion.—The fiber-bundles arise in a penniform manner from the tendon of origin which extends for some distance along the lower border of the muscle. They are inserted in a groove which lies on the lower surface of the clavicle between the costal tuberosity and the coracoid tuberosity. The medial fiber-bundles are inserted directly, the lateral by a strong tendon.

FIG. 392.—THE SUBCLAVIUS AND THE UPPER PORTION OF THE SERRATUS ANTERIOR.

Nerve-supply.—By a branch which arises usually from the fifth or fifth and sixth cervical nerves and enters the middle of the back part of the muscle.

Action.—When the first rib is fixed, the subclavius depresses the clavicle and the point of the shoulder. When the clavicle is fixed, the muscle aids in forced inspiration. It also serves to keep the clavicle against the sternum.

Relations.—It is concealed by the clavicle and pectoralis major muscle. Behind it lie the subclavian vessels and the brachial plexus.

Variations.—It may be replaced by a ligament or by a pectoralis minimus muscle (see below). It may be doubled or may be inserted into the coracoid process, coracoacromial ligament, the acromion, or the humerus. The *subclavius posticus* arises near the subclavius, passes backward over the subclavian vessels and brachial plexus and is inserted into the cranial margin of the scapula near the base of the coracoid process.

Abnormal Muscles of the Pectoral Group

The following muscles are usually innervated by the anterior thoracic nerves and are probably generally abnormal derivatives of the pectoral mass. Frequently they represent muscles normally found in lower mammals.

The sternalis.—A flat muscle somewhat frequently seen on the surface of the pectoralis major, usually nearly parallel to the sternum. It arises from the sheath of the rectus and from some of the costal cartilages (third to seventh) and terminates on the sternocleidomastoid, on the sternum, or on the fascia covering the pectoralis major. When present on both sides, the two muscles may be fused across the sternum. This muscle is found in 4 per cent. of normal individuals and 48 per cent. of anencephalic monsters. (Eisler.) Rarely, corresponding muscle slips have been found innervated by the intercostal nerves. These probably represent remains of a thoracic 'rectus' muscle.

The pectorodorsalis (axillary arch).—This muscle in its most complete form extends from the tendon of the pectoralis major over the axillary fossa to the tendon of the latissimus dorsi, to the fascia covering the latissimus dorsi, to the teres major or even more distally. It may, however, be more or less fused with either of the last two muscles mentioned, and it presents a great variety of forms. It may extend from the latissimus dorsi to the brachial fascia over the coracobrachialis or biceps, to the long tendon of the biceps, to the axillary fascia, to the axillary margin of the pectoralis minor, or to the coracoid process, etc. It is found in about 7 per cent.

of bodies. (Le Double.) When supplied from the anterior thoracic nerves, it probably represents a portion of the thoracohumeral subcutaneous (pannicular) muscle of the lower primates. It is also sometimes supplied by the medial brachial cutaneous or the intercostobrachial (humeral) nerve and frequently is partly or wholly supplied by the thoracodorsal (long subscapular) nerve. The part of the muscle supplied by the thoracodorsal nerve is probably derived from the latissimus dorsi musclature.

The **costocoracoideus.**—A muscular slip which arises from one or more ribs or from the aponeurosis of the external oblique between the pectoralis major and latissimus dorsi muscles and is inserted in the coracoid process.

The **chondrohumeralis** (epitrochlearis).—This is a slip which springs from one or two rib cartilages or from the thoracoabdominal fascia beneath the pectoralis major, or from its lower border or tendon, and extends on the medial side of the arm to the intertubercular (bicipital) groove, the brachial fascia, the intermuscular septum, or the medial epicondyle. It is found in 12 to 20 per cent. of bodies (Le Double), and occurs normally in many of the lower mammals.

The **pectoralis minimus (sternochondroscapularis).**—From the cartilage of the first rib and sternum to the coracoid process.

The **sternoclavicularis.**—From the manubrium of the sternum to the clavicle between the pectoralis major and the coracoclavicular (costocoracoid) fascia. In 2 per cent. to 3 per cent. of bodies. (Gruber.)

The **scapuloclavicularis.**—From the coracoid process of the scapula to the lateral third of the clavicle.

The **infraclavicularis.**—From above the clavicular part of the pectoralis major to the fascia over the deltoid.

Bursæ

B. m. pectoralis majoris.—Between the tendon of insertion of the pectoralis major and the long head of the biceps. Frequent.

C. MUSCULATURE OF THE ARM

(Figs. 386, 387, 393–396, 398, 401, 403)

The muscles included in this section are the triceps and anconeus, coracobrachialis, biceps, and brachialis. The *triceps* and *anconeus* (fig. 394) constitute a mass of musculature extending along the back of the arm from the scapula and humerus to the olecranon of the ulna. The *coracobrachialis*, *biceps*, and *brachialis* (figs. 395, 396) constitute a similar mass of musculature extending along the front of the arm from the scapula and the humerus to the humerus, and to the radius and ulna near the elbow. In the upper half of the arm the two groups are separated on the lateral side of the arm by the deltoid, pectoralis major, teres minor, supra- and infraspinatus muscles, and by the greater tubercle of the humerus. On the medial side they are separated by the chief nerves and blood-vessels of the arm and by the tendons of the latissimus dorsi, teres major, and subscapularis muscles. In the distal half of the arm they are separated medially by the medial intermuscular septum (described below) and by the medial epicondyle and the ulnovolar group of muscles of the forearm. On the lateral side of the arm they are separated by the lateral intermuscular septum, by the lateral epicondyle, and by the brachioradialis and the extensor muscles of the forearm which take origin from the lateral epicondyle.

FASCIÆ

The **fasciæ** and the general relations of the muscles of the arm are shown in the cross-sections in fig. 393.

The **tela subcutanea** of the arm is fairly well developed and contains a considerable amount of fat, especially near the shoulder. It is but loosely bound to the muscle fascia, except near the insertion of the deltoid, where the union may be more intimate.

Bursæ.—B. subcutanea epicondyli lateralis.—Between the lateral epicondyle and the skin. Rare. **B. subcutanea epicondyli medialis.**—Between the medial epicondyle and the skin. Inconstant. **B. subcutanea olecrani.**—Between the olecranon process of the ulna and the skin. Nearly constant.

The **brachial fascia** forms a cylindrical sheath about the muscles of the arm. It contains circular and longitudinal fibers, the former being the better developed. The fascia is strong over the dorsal muscles, especially near the two epicondyles of the humerus. Proximally the fascia of the arm is continued into the axillary fascia and into the fascial investment of the pectoralis major, deltoid, and latissimus dorsi muscles; distally it is continued into the fascial investment of the forearm. It is intimately bound to the epicondyles and to the dorsal surface of the olecranon. It is separated by loose areolar tissue from the bellies of the muscles which it covers. From the tendons of the deltoid, pectoralis major, teres major, and latissimus dorsi muscles, however, fibrous bundles are continued into the brachial fascia. There are a number of orifices in the fascia for the passage of nerves and blood-vessels. Of these, the largest is that for the basilic vein and two or three large branches of the medial antibrachial (internal)

taneous nerve. This lies on the ulnar margin of the arm in the lower third. On the radial margin lie the cephalic vein in a double fold of the fascia, orifices for branches of the musculocutaneous nerve, and more dorsally orifices for branches of the radial. From the fascia septa descend between the muscles which it invests. Of these septa, the most important are the medial and lateral intermuscular septa, which separate the dorsal group of muscles from the ventral in the distal half of the arm. The **medial intermuscular septum** is the stronger. It is attached to the medial epicondyle and to the medial margin of the humerus proximal to this. It is continued proximally into the tendon of insertion of the coracobrachialis and the investing fascia of this muscle. Into it longitudinal bundles of fibers descend from the tendon. It separates the brachialis and pronator teres muscles from the medial head of the triceps. The **lateral intermuscular septum** is attached to the lateral epicondyle and to the lateral margin of the humerus. It is continued proximally into the dorsal surface of the tendon of insertion of the deltoid muscle, and into the septa between the deltoid and the triceps. It separates the triceps from the brachialis in the third quarter of the arm and from the brachioradialis and extensor carpi radialis longus in the distal quarter. The median nerve and brachial vessels lie in front of the medial septum. The ulnar nerve and the superior ulnar collateral (inferior profunda) artery are bound to its dorsal surface.

ARM-MUSCLES

1. Dorsal or Extensor Group (Fig. 394)

Two muscles are included in this group, the triceps brachii and the anconeus. The triceps is a complex muscle in which proximally three heads, a long or scapular, a lateral humeral, and a medial humeral, may be distinguished. The long head arises from the infraglenoid tuberosity of the scapula, the lateral head from the humerus above and laterally to the groove for the radial nerve (musculospiral groove), the medial head from the lower half and medial margin of the posterior surface of the humerus. Distally these heads fuse and are inserted by a common tendon into the olecranon of the ulna. The **anconeus** lies chiefly in the forearm, but physiolgoically and morphologically it belongs with the triceps, and hence is described in connection with the muscles of the arm. It is a triangular muscle, which arises from the lateral epicondyle and is inserted into the olecranon and adjacent part of the shaft of the ulna. Both muscles are supplied by branches of the radial (musculospiral) nerve. They extend the forearm. The long head is also an adductor of the arm.

The triceps, variously modified, is found in the amphibia and all higher vertebrates. The anconeus is found in the prosimians and all higher forms. The triceps muscle is homologous with the quadriceps of the thigh. The long head is equivalent to the rectus femoris. The anconeus is not represented in the lower limb.

The triceps brachii (figs. 386, 387, 394).—The **long head** *arises* from the infraglenoid tuberosity of the scapula by a strong, broad tendon, some of the fibers of which are connected with the inferior portion of the capsule of the shoulder-joint. The tendon soon divides into two lamellæ, which extend distally, one a short distance on the deep surface, the other much farther on the superficial surface of this head. The parallel fiber-bundles which arise from these lamellæ form a thick muscle-band which twists upon itself so that the ventral surface at the origin becomes dorso-medial at the insertion. At the insertion the long head becomes applied to an aponeurosis which extends upward from the main tendon of insertion of the triceps. The fiber-bundles extend for some distance on the medial side of this tendon and terminate about three-fourths of the way down the arm.

The **lateral head** has a tendinous *origin* from the superior lateral portion of the posterior surface of the humerus along a line extending from the insertion of the teres minor as far as the groove for the radial (musculospiral) nerve, and from the aponeurotic arch formed by the lateral intermuscular septum as it crosses this groove. The constituent fiber-bundles descend, the superior vertically, the inferior obliquely, to be inserted on the dorsal and ventral surfaces of the proximolateral margin of the common tendon of insertion of the triceps.

The **medial head** has a fleshy *origin* from the posterior surface of the humerus below the radial (musculospiral) groove and from the dorsal surfaces of the medial and lateral intermuscular septa. The greater part of the fiber-bundles arising from this extensive area are inserted into the deep surface of the common tendon, but some extend directly to the olecranon and the articular capsule of the elbow. The slip attached to the capsule is sometimes called the **subanconeus** muscle.

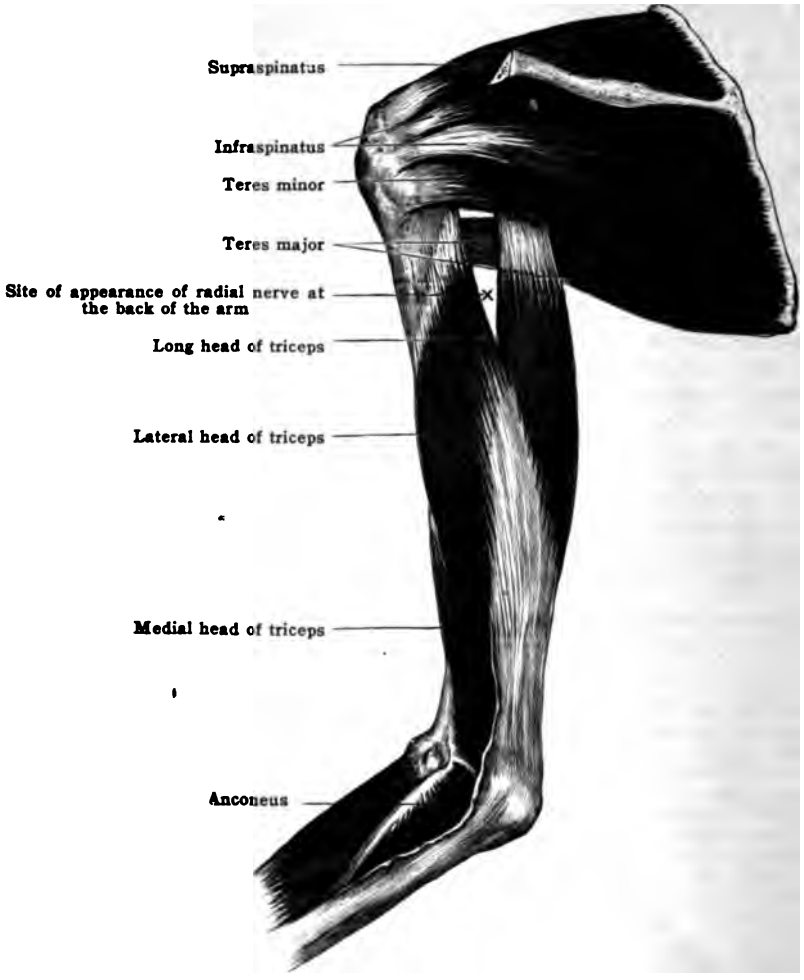
Insertion.—The tendon of insertion of the triceps forms a flat band covering the dorsal surface of the distal two-fifths of the muscle. It also extends proximally between the long and lateral heads and on the deep surface of the former. This tendon is inserted into the olecranon and laterally, by a prolongation over the anconeus, into the dorsal fascia of the forearm.

Nerve-supply.—From the radial (musculospiral) nerve. The branch to the long head arises in the axilla and enters that margin of the muscle which is prolonged down from the lateral edge of the tendon, but which, because of the torsion of the muscle, comes to lie on the medial side. The nerve usually enters through several rami about the middle of the free portion of the long head. Somewhat more distally the radial nerve gives off a branch that enters, by two or three branches, the proximal portion of the medial head. A similar branch is given to the

lateral head and other branches are given to the lateral and medial heads from that portion of the radial (musculospiral) nerve lying in the radial (musculospiral) groove. The nerve fibers arise from the sixth, seventh, and eighth cervical nerves.

Relations.—Near the shoulder the triceps is covered by the deltoid muscle. The long head passes between the teres major and teres minor muscles. The circumflex (dorsal) scapular vessels here pass medial, the circumflex humeral vessels and the axillary (circumflex) nerve lateral, to this head. More distally the muscle lies beneath the brachial fascia. It covers the radial groove of the humerus, in which run the radial (musculospiral) nerve and (superior) profunda brachii artery. Ventrolateral to the muscle lie the deltoid, brachialis, brachioradialis, and extensor carpi radialis muscles; ventromedial, the coracobrachialis, biceps, and brachialis muscles.

FIG. 394.—DORSAL VIEW OF THE SCAPULAR MUSCLES AND TRICEPS.



Action.—It extends the forearm. The leverage is of such a nature that force is sacrificed for speed of movement. The long head of the triceps also serves to extend and to adduct the arm and to hold the head of the humerus in the glenoid cavity.

Variations.—The scapular attachment may extend for a considerable distance down the axillary border of the scapula. Each of the heads may be more or less fused with neighboring muscles. Frequently a fourth head is found. This may arise from the humerus, from the axillary margin of the scapula, from the capsule of the shoulder-joint, from the coracoid process, or from the tendon of the latissimus dorsi.

The *latissimo-condyloideus* (dorsoepitrochlearis).—This muscle is found in about 5 per cent. of bodies. When well developed, it extends from the tendon of the latissimus dorsi to the brachial fascia, the triceps muscle, the shaft of the humerus, the lateral epicondyle, the olecranon, or the fascia of the forearm. It is innervated by a branch of the radial (musculospiral) nerve. It is a muscle normally present in some one of the forms above mentioned or in some similar form, in a large number of the inferior mammals. In the human body it is normally represented by a fascial slip from the tendon of the latissimus to the long head of the triceps or the brachial fascia.

The anconeus.—*Origin.*—By a short narrow tendon from the distal part of the back of the eral epicondyle and the adjacent part of the capsular ligament of the elbow-joint.

Structure and insertion.—The tendon of origin is prolonged on the deep surface and lateral border of the muscle. From this the fiber-bundles spread, the proximal transversely, the more distal obliquely, to be inserted into the radial side of the olecranon and an adjacent impression on the shaft of the ulna. Its superior fiber-bundles are usually continuous with those of the medial head of the triceps.

Nerve-supply.—By a long branch which arises in the radial (musculospiral) groove from the radial (musculospiral) nerve, passes through the medial head of the triceps, to which it gives branches, and enters the proximal border of the anconeus. The nerve fibers arise from the seventh and eighth cervical nerves.

Action.—It aids the triceps in extending the forearm and draws the ulna laterally in pronation of the hand.

Relations.—The muscle lies immediately beneath the antibrachial fascia. It extends over the head of the supinator (brevis) and the elbow-joint and upper radioulnar joint.

Variations.—The extent of fusion of the muscle with the medial head of the triceps varies a good deal. It may also be fused with the extensor carpi ulnaris. It has been reported missing.

BURSÆ

B. intratendinea olecrani.—Within the tendon of the triceps near its insertion. More frequent than the following:—

B. subtendinea olecrani.—Between the tendon of the triceps and the olecranon and dorsal ligament of the elbow-joint. Inconstant.

B. epicondyli medialis dorsalis.—Between the medial epicondyle, the edge of the triceps, and the ulnar nerve. Rare.

B. m. anconei.—Between the tendon of origin of the muscle and the head of the radius. Frequent.

2. VENTRAL OR FLEXOR GROUP

(Figs. 395, 396, 401, 402, 403)

The muscles of this group are the coracobrachialis, the biceps, and the brachialis. The **coracobrachialis** (fig. 396) is a band-like muscle which arises from the coracoid process and is inserted into the middle third of the shaft of the humerus. The **biceps** (fig. 395) arises by two heads: a short head, closely associated with the coracobrachialis, from the coracoid process; a long head, by an extended tendon, from the supraglenoid tuberosity of the scapula. The fusiform belly which arises from the fusion of these two heads is inserted into the radius and into the fascia of the forearm. The **brachialis** (fig. 396) extends under cover of the biceps from the lower three-fifths of the shaft of the humerus to the coronoid process of the ulna. The muscles of this group are supplied by the musculocutaneous nerve. The brachialis also usually receives a branch from the radial nerve. The coracobrachialis and short head of the biceps flex and adduct the arm at the shoulder; the biceps and brachialis flex the forearm at the elbow. The long head of the biceps abducts the arm at the shoulder. The biceps is a powerful supinator of the forearm.

The muscles of this group are found in most of the limbed vertebrates. In many of the lower forms the coracobrachialis, which appears farther down in the vertebrate series than the biceps, has a more extensive insertion than in man. It may extend to the ulna (lizards) and may be subdivided into various muscles which correspond with the adductors of the thigh. The biceps, the place of which is taken in the lower vertebrates by a coracoradial muscle, in most of the mammals presents two heads, the more lateral of which is attached by a tendon to the scapula above the shoulder-joint. This long tendon of the biceps lies primitively outside capsule of the shoulder-joint, but in some of the higher mammals has come to lie within the capsule. In the biceps four elements may be recognized:—a coracoradial, coracoulnar, glenoradial, and glenoulnar. (Krause.) The development of these elements varies in different mammals.

The coracobrachialis (fig. 396).—*Origin.*—(1) By a short tendon from the tip of the coracoid process of the scapula and (2) from the tendon of the short head of the biceps.

Insertion.—(1) By means of a strong tendon into the medial surface of the humerus immediately proximal to the middle of the shaft, and (2) often above this also into an aponeurotic band which extends from the tendon along the medial margin of the humerus, arches over the tendons of the latissimus dorsi and teres major, and is attached to the lesser tubercle of the humerus. When the attachment to the tubercle does not take place, the band becomes closely applied to the deep surface of the muscle.

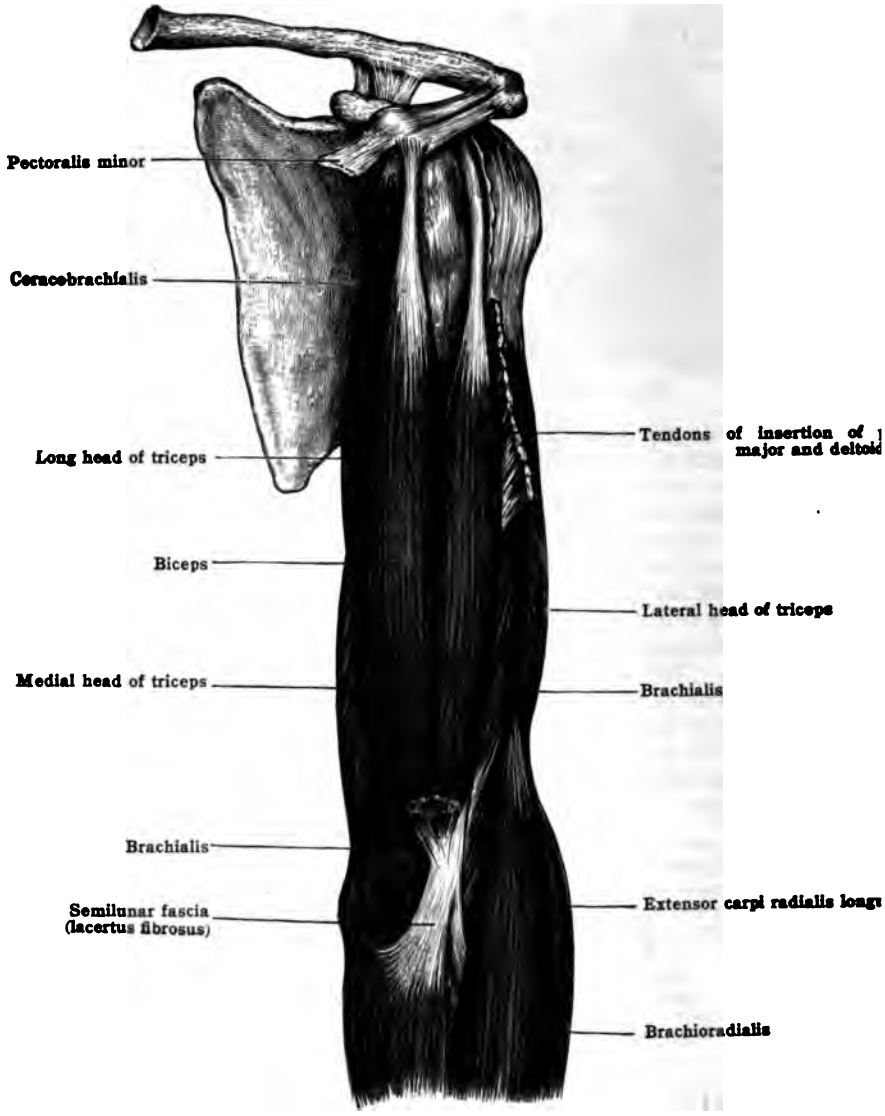
Structure.—From the tendons of origin, which are usually closely associated, the fiber-bundles take an oblique, nearly parallel, course and are attached to the aponeurotic band above mentioned and to both surfaces of the flat tendon of insertion. This extends high into the muscle. The belly of the muscle usually shows some separation into a superficial and a deep portion, between which runs the musculocutaneous nerve. When this separation is well marked, the tendon of origin of the superior fasciculus may be distinct from that of the inferior fasciculus and the short head of the biceps, and the tendon of insertion may give a separate lamina to each fasciculus.

Nerve-supply.—A branch of the musculocutaneous nerve, or of the brachial plex the origin of this nerve, enters the upper third of the medial border of the muscle, and across the constituent fiber-bundles about midway between their attachments. Th fibers arise from the sixth and seventh cervical nerves.

Action.—Adducts and flexes the arm at the shoulder and helps to keep the head humerus in the glenoid fossa. When the arm has been rotated lateralward, it acts as a rotator. It may help to increase extreme abduction.

Relations.—The coracobrachialis is largely covered by the deltoid and pectoralis muscles. Below the inferior border of the latter it becomes superficial. Near its orig

FIG. 395.—SUPERFICIAL MUSCLES OF THE FRONT OF THE ARM.



between the pectoralis minor and the subscapularis muscles. More distally it lies medi humerus and in front of the chief brachial vessels and nerves. The musculocutaneo usually runs through it.

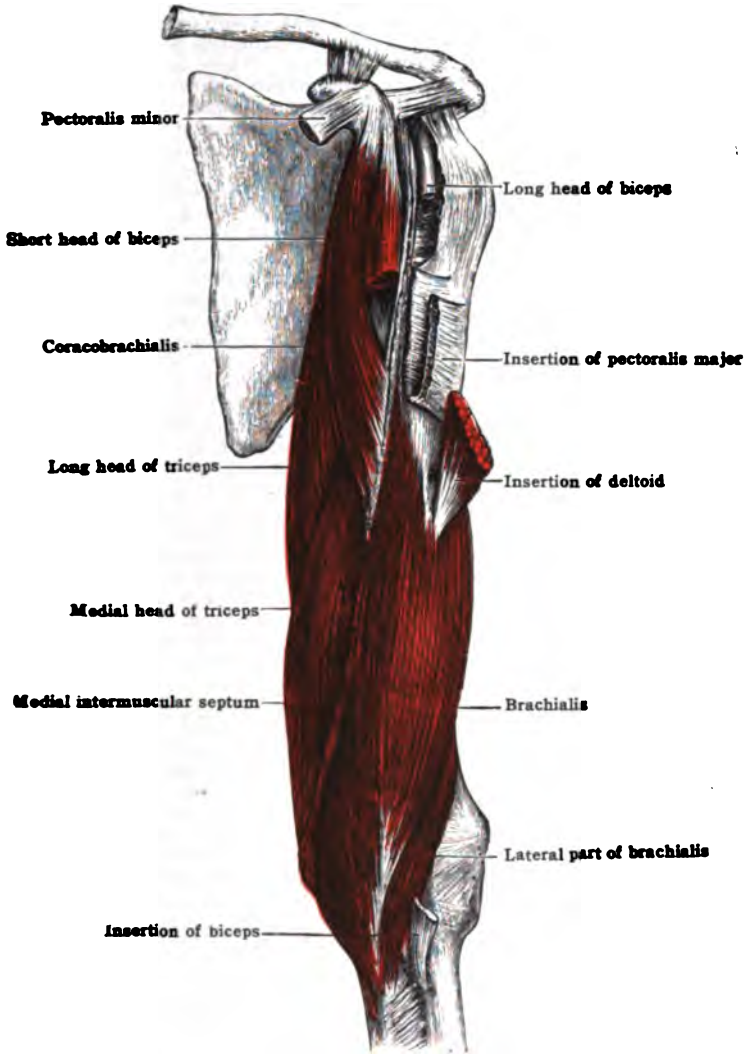
Variations.—The humeral insertion of the muscle varies considerably. According t the coracobrachialis consists primitively of three parts, which arise from the coracoid and are inserted respectively into the upper, the middle, and the distal part of the l along the medial side. The superior division is most deeply, the inferior the most supe placed. In man the muscle is composed of parts of the middle and inferior division inferior division may be completely developed as far as the medial epicondyle. The division of the muscle is occasionally found. Slips from the coracobrachialis to the b have been seen. Complete absence of the muscle has been recorded.

The biceps brachii (figs. 395, 401).—The **short head** *arises* by a flat tendon close [redacted]ed with that of the coracobrachialis from the coracoid process. From the dor

surface of this tendon the fiber-bundles descend nearly vertically, though increasing in number, toward their attachment to the tendon of insertion. The fiber-bundles which arise highest on the tendon of origin are inserted highest on the tendon of insertion, while those which have the lowest origin have the lowest insertion.

The long head *arises* from the supraglenoid tuberosity and from the glenoid ligament by a long tendon (9 cm.) bifuracted at its origin. The tendon at first passes over the head of the humerus within the capsule of the joint, and then passes into the intertubercular(bicipital) groove, which is covered by the capsule of the joint and an expansion from the tendon of the pectoralis major. To this point the tendon is surrounded by the synovial membrane of the joint. After emerging from this the tendon slowly expands and from its dorsal concave surface

FIG. 396.—DEEP MUSCLES OF THE FRONT OF THE ARM.



arise fiber-bundles which, increasing in number, extend, somewhat obliquely, toward the tendon of insertion. As in case of the short head, here also the fiber-bundles which arise highest the tendon of origin have the highest insertion.

Insertion.—The tendon of insertion begins usually in the distal quarter of the arm as a vertical septum between the two heads of the muscle. More distally this broadens out on each side into a flattened aponeurosis. The fiber-bundles are inserted into the sides of the septum and on each surface of the aponeurosis—those of the long head chiefly on the deep surface, those of the short head chiefly on the superficial surface. The aponeurosis is continued into a strong, flattened tendon which descends between the brachioradialis and pronator teres muscles to be inserted on the dorsal half of the bicipital tuberosity of the radius. From the medial border of the tendon an aponeurotic expansion, the **lacertus fibrosus** (semilunar fascia), is continued into the fascia of the ulnar side of the forearm.

Nerve-supply.—By a branch from the musculocutaneous nerve for each head. These branches may be bound in a common trunk for some distance. They enter the deep surface the muscle in the proximal part of the middle third of each belly often by several rami. Usually

there is a distinct intramuscular fissure for the reception of the branches to each head and blood-vessels which accompany them. The nerve fibers come from the fifth and sixth cervical nerves.

Action.—It is a flexor of the arm at the elbow and is the strongest supinator of the forearm. This last action is most marked when the forearm is flexed and pronated. Both heads are flexors and medial rotators of the arm at the shoulder. The long head is an abductor, so also is the short head when the arm is greatly abducted, otherwise the short head is an adductor.

Relations.—The tendons of origin are concealed by the pectoralis major and deltoid muscles. Beyond this the muscle is covered by the fascia brachii. In the lower part of the arm it lies upon the brachialis muscle. Upon the medial margin lie the coracobrachialis muscle, brachial vessels, and the median nerve.

Variations.—Variations are frequent (cf. fig. 213). The whole muscle or either head may be missing, but such cases are rare. The long head may extend only to the bicipital groove. Frequently the muscle is partially divided into the four primitive portions mentioned above. The two heads may be separate from origin to insertion. There may be an accessory head (in 3 subjects—Le Double) which arises from the coracoid process, the capsule of the joint, the tendon of the pectoralis major, or the shaft of the humerus near the insertion of the coracobrachialis. In most instances the origin takes place above the origin of the brachialis from the humerus. Sometimes several accessory heads are seen. Marked variation of insertion is less frequent, but occasionally a supernumerary slip may go to the medial intermuscular septum or the medial epicondyle. The fusion of the biceps with neighboring muscles (pectoralis major and minor, coracobrachialis, brachialis, palmaris longus, pronator teres, brachioradialis) by means of tendinous or muscular slips has been frequently reported.

The **brachialis** (fig. 396).—*Origin.*—(1) From the distal three-fifths of the front of the humerus, (2) from the medial intermuscular septum, and (3) from the lateral intermuscular septum proximal to the heads of the brachioradialis and extensor carpi radialis longus. Proximally it sends up a pointed process on the lateral side of the insertion of the deltoid and another between the insertions of the deltoid and the coracobrachialis. Distally the area of origin stops a little above the capitulum and the trochlea.

Structure and Insertion.—The fiber-bundles arise directly from this area of origin, except near the insertion of the deltoid and on the medial margin, where tendinous bands are developed. The fiber-bundles descend, the middle vertically, the medial obliquely lateralward, the lateral still more obliquely medialward. The tendon of insertion appears on the dorsal side of the lateral edge of the muscle in its lower fourth. Continuous with this stronger lateral portion of the tendon more distally a thinner band appears upon the ventral surface of the muscle above the joint. The tendon becomes thick as it passes distally, is closely united to the capsule of the elbow-joint, and is attached to the ulnar tuberosity. In addition to the main tendon, some of the deeper fiber-bundles of the muscle and some of these coming from the lateral intermuscular septum are attached by short tendinous bands to the coronoid process.

Nerve-supply.—From the musculocutaneous nerve by a branch which enters the ventral surface of the muscle near the junction of the upper and middle thirds of the medial border. In addition the radial (musculospiral) nerve usually sends a small branch into the distal lateral portion of the muscle. A branch from the median nerve frequently supplies the medial side of the muscle near the elbow-joint (Frohse).

Action.—To flex the forearm.

Relations.—It lies behind the biceps, on each side of which it projects. The distal lateral portion of the muscle is grooved by the brachioradialis, which here is closely applied to it. The radial (musculospiral) nerve runs between these two muscles. On the medial side run the brachial vessels and median nerve.

Variations.—It may be divided into two distinct heads continuous with the projections on each side of the deltoid tuberosity. A great number of supernumerary slips have been recorded. These may be attached to the radius, ulna, fascia of the forearm, capsule of the joint, brachioradialis, and extensor carpi radialis muscles. It may be partially fused with neighboring muscles. It has also been reported absent.

Bursæ

B. m. coracobrachialis.—Between the subscapularis muscle, the tendon of the coracobrachialis, and the coracoid process. Frequent.

B. bicipitoradialis.—Between the ventral half of the radial tuberosity and the tendon of the biceps. Constant.

B. cubitalis interossea.—Between the tendon of the biceps and the ulna and the neighboring muscles. Frequent.

D. MUSCULATURE OF THE FOREARM AND HAND

(Figs. 397–410)

The muscles of the forearm arise in part from the **humerus, in part from the** radius and ulna. Their bellies lie chiefly in the **proximal half of the forearm.** They are divisible into two groups:—a radiodorsal, **composed of extensors of the** hand and fingers and supinators of the forearm; and an **ulnovolar, composed of** flexors of the hand and fingers and pronators of the **forearm. The brachio-**radialis, which belongs morphologically with the former **group, is physiologically** a flexor of the forearm.

The two groups are separated on the medial side of the back of the forearm by the dorsal margin of the ulna (figs. 397, 400). Ventrally they are separated by the insertions of the biceps and brachialis and by an intermuscular septum (figs. 397, 401).

In the **hand**, in addition to the tendons of the muscles of the forearm mentioned above (fig. 407), there are several sets of intrinsic muscles. About the metacarpal of the thumb (figs. 406–408) is grouped a set of muscles which arise from the carpus and metacarpus and are inserted into the metacarpal and first phalanx of the thumb. A similar set of muscles is grouped about the metacarpal of the little finger (figs. 406, 407.) These sets of muscles give rise respectively to the thenar and hypothenar eminences. Between the metacarpals lies a series of dorsal and palmar interosseous muscles (figs. 408–410) which are inserted into the first row of phalanges and into the extensor tendons. From the tendons of the deep flexor of the fingers a series of lumbrical muscles passes to the radial side of the extensor tendons (figs. 404, 406). These various muscles abduct, adduct, flex, and extend the digits. In addition to these deeper skeletal muscles of the hand there is a subcutaneous muscle over the hypothenar eminence (fig. 406). Of the muscles of the hand, all are supplied by the ulnar nerve except most of those of the thumb and the two more radial lumbricals, which are supplied by the median nerve.

An arrangement of the muscles of the forearm in which the dorsal extensor-supinator musculature extends proximally on the radial side of the arm to the distal extremity of the humerus and the volar flexor-pronator musculature similarly on the ulnar side, is chararteristic of all limbed vertebrates and is associated with the pronate position of the forelimb characteristic of quadrupeds. In amphibia and reptiles the musculature terminates distally on the carpus and in the aponeuroses of the hand. In the higher forms special tendons are differentiated for those muscles of the forearm which act on the fingers. On the back of the hand in many vertebrates short extensor muscles are found running from the carpus to the phalanges. On the volar surface a complex musculature is found in all forms which have freely movable fingers. In animals which walk on the ends of the fingers, especially in the hoofed animals, the intrinsic musculature of the hand is greatly reduced. The phylogenetic development of the muscles of the forearm and hand is too complex a subject to be briefly summarized. The phylogeny of the forearm flexors and the palmar musculature has been studied by McMurrich. In his papers a summary of the literature on the subject may be found.

FASCIÆ

The **fasciæ** and the general relations of the musculature of the forearm and hand may be followed in the cross-sections, fig. 397.

The **tela subcutanea** contains a moderate amount of fat in the upper part of the forearm. This grows less in amount as the wrist is approached. On the back of the hand it contains little fat. In the palm and on the volar surface of the fingers a moderate amount of fat is embedded between dense vertical bundles of fibers which unite the skin to the fascia. Except on the volar surface of the hand and on the backs of the terminal phalanges, the tela is but loosely united to the underlying fascia.

The **bursa subcutanea olecrani** lies over the dorsal surface of the olecranon. Subcutaneous bursæ are also frequently found over the knuckles (**b. subcutaneæ metacarpophalangeæ dorsales**) and the proximal joints of the fingers (**b. subcutaneæ digitorum dorsales**).

The **antibrachial fascia** encloses the muscles of the forearm in a cylindrical sheath, composed in the main of circular fiber-bundles, but strengthened by longitudinal and oblique bundles extending in from the epicondyles of the humerus, the olecranon, the lacertus fibrosus of the biceps, and the tendon of the triceps. The fascia of the forearm is attached to the dorsal surface of the olecranon and to the subcutaneous margin of the ulna. Above, it is continued into the fascia of the arm; below, into the fascia of the hand. From the antibrachial fascia in the upper half of the forearm a fibrous septum extends between the radiodorsal and the ulnovolar muscle group to the radius. In the radial septum below the elbow a branch of communication extends between the superficial and deep veins of the arm. That part of the fascia overlying the radiodorsal group of muscles is much denser than that covering the volar group, except where the latter is strengthened by the lacertus fibrosus. In addition to the main radial septum other septa descend between the underlying muscles from the antibrachial fascia. These septa are best marked near the attachment of the muscles to the humerus. Here the fascia is firmly fused to the muscles.

Dorsally the antibrachial fascia is strengthened at the wrist by transverse fibers which extend from the radius to the styloid process of the ulna, the triquetrum (cuneiform), and pisiform, and give rise to the **dorsal ligament of the carpus** (posterior annular ligament). From this ligament septa descend to the radius and ulna and convert the grooves in these bones into **osteofibrous canals** which lodge the tendons of the various muscles extending to the wrist and hand.

On the **back of the hand** there is spread a fascia composed of two thin fascial sheets between which the extensor tendons are contained. Between the tendons these sheets are more or less

fused. On the backs of the fingers the fascia blends with the extensor tendons and the associated aponeurotic expansions from the interosseous and lumbrical muscles. Between the fingers it is continued into the transverse fasciculi of the palmar aponeurosis. At the sides of the hand the fascia is continued into the thenar and hypothenar fasciæ. Each dorsal interosseous muscle is covered by a special fascial membrane which is separated by loose tissue from the fascia investing the extensor tendons.

On the **volar side of the forearm** for some distance above the wrist the tendons of the flexor carpi radialis, the palmaris longus, and the flexor carpi ulnaris run between two layers of the fascia. The fascia is much strengthened at the wrist by transverse fibers which give rise to the **volar ligament of the carpus.** Beneath it lies the **transverse ligament of the carpus** (anterior annular ligament). This dense band is broader than the volar ligament but like it extends from the pisiform bone and the hamulus of the hamatum (unciform) to the tuberosity of the navicular and the tuberosity of the greater multangular (trapezium). It serves to complete an osteofibrous canal through which pass the flexor tendons of the fingers. Between the two ligaments which are partially fused with one another run the ulnar artery and nerve.

On the **palm of the hand** the ensheathing fascia presents three distinct areas—a central, a lateral, and a medial.

The central portion, the **palmar aponeurosis,** is composed chiefly of bundles of fibrous tissue which radiate superficially toward the fingers from the tendon of the palmaris longus or from a corresponding region of the forearm fascia when this muscle is absent. Between these bundles are others which arise from the transverse ligament. The deep surface of the fascia is composed of a thin incomplete layer of transverse fibers which continue the transverse fibers of the forearm fascia. Near the capitula of the metacarpals this layer becomes much stronger and constitutes a ligamentous band (**superficial transverse ligament** of Poirier). Near the bases of the digits bundles of transverse fibers (**fasciculi transversi**) lie in the webs of the fingers and constitute an incomplete transverse ligament separated by a distinct interval from the superficial transverse ligament.

From the palmar aponeurosis processes are sent in toward the deeper structures. Of these, the most important are those continued into a fibrous sheath which surrounds the space containing the long flexor tendons and the lumbrical muscle. This dense fibrous sheath is united by fibrous processes to the third, fourth, and fifth metacarpals. As the flexor tendons diverge and the ends of the metacarpals are approached, numerous processes descend from the palmar aponeurosis to the transverse capitular ligament. These hold the tendons in place. On the volar surface of the fingers the fascia serves to complete osteofibrous canals for the long flexor tendons. The ventral surface of the first and second phalanges of each finger is slightly grooved. The fascia is firmly united on each side to the margin of the groove, and over the groove forms a semicylindrical, strong, fibrous sheath, the **vaginal ligament** of the finger. This sheath is strengthened by transverse bands over the bases of the first and second phalanges (**annular ligaments**) and by cruciate bands over the shafts of the phalanges (**cruciate ligaments**). Over the interphalangeal joints the sheath is thin, but is strengthened by crucial bands which permit of freedom of motion.

The **thenar fascia** is a thin membrane covering the short muscles of the thumb. It is continued above into the fascia of the forearm, medially is fused with the tendon of the palmaris

---

the various intrinsic muscles of the hand.

MUSCLES

1. Radiodorsal Division

uscles of this group lie in two chief layers, a superficial and a deep.

a. Superficial Layer

(Figs. 398, 401, 402)

uscles of this layer, closely associated at their origins, extend from the
of the distal end of the humerus to the distal extremity of the radius,
s and the fingers. They are divisible into a radial, an intermediate,
ıar set.

set.—To this belong three muscles, the brachioradialis, extensor carpi
ngus and brevis. The **brachioradialis** (fig. 401), a forearm flexor, is a
fusiform muscle which arises from the lateral epicondylar ridge of the
ınd is inserted into the base of the styloid process of the radius. The
arpi radialis longus (fig. 402) is a narrow, fusiform muscle which extends
radial margin of the forearm, partly under cover of the brachioradialis.
rom the lateral epicondylar ridge of the humerus, and is inserted into
l metacarpal bone. The **extensor carpi radialis brevis** (fig. 398) is a
muscle more dorsally placed than the last at the radial side of the arm.
rom the lateral epicondyle and is inserted into the bases of the second
metacarpals. These muscles are supplied by branches of the radial
ch arise proximal to the passage of the deep radial (posterior inter-
hrough the supinator muscle. Distally this set of muscles is separated
ntermediate set by the long abductor and the extensors of the thumb,
s from an origin under the latter set over the tendons of the radial
to the thumb.

termediate set.—This consists of the thick, flattened **extensor digitorum**
and the slender **extensor digiti quinti proprius** (fig. 398). They arise
ateral epicondyle, and are inserted into the backs of the fingers.

nar set consists of one muscle, the fusiform **extensor carpi ulnaris** (fig.
:h arises from the lateral epicondyle of the humerus and is inserted into
of the base of the fifth metacarpal.

termediate and ulnar sets of muscles are supplied by branches from the
fundus of the radial nerve after this has passed through the supinator

g the lateral set of the superficial layer is represented by the tibialis anterior. The
e set is represented by the long extensors of the toes. The single muscle which
the medial set is represented by the peroneal muscles.

chioradialis (supinator radii longus) (figs. 398, 401).—*Origin.*—From the upper
of the lateral epicondylar ridge of the humerus and from the front of the lateral
ar septum.

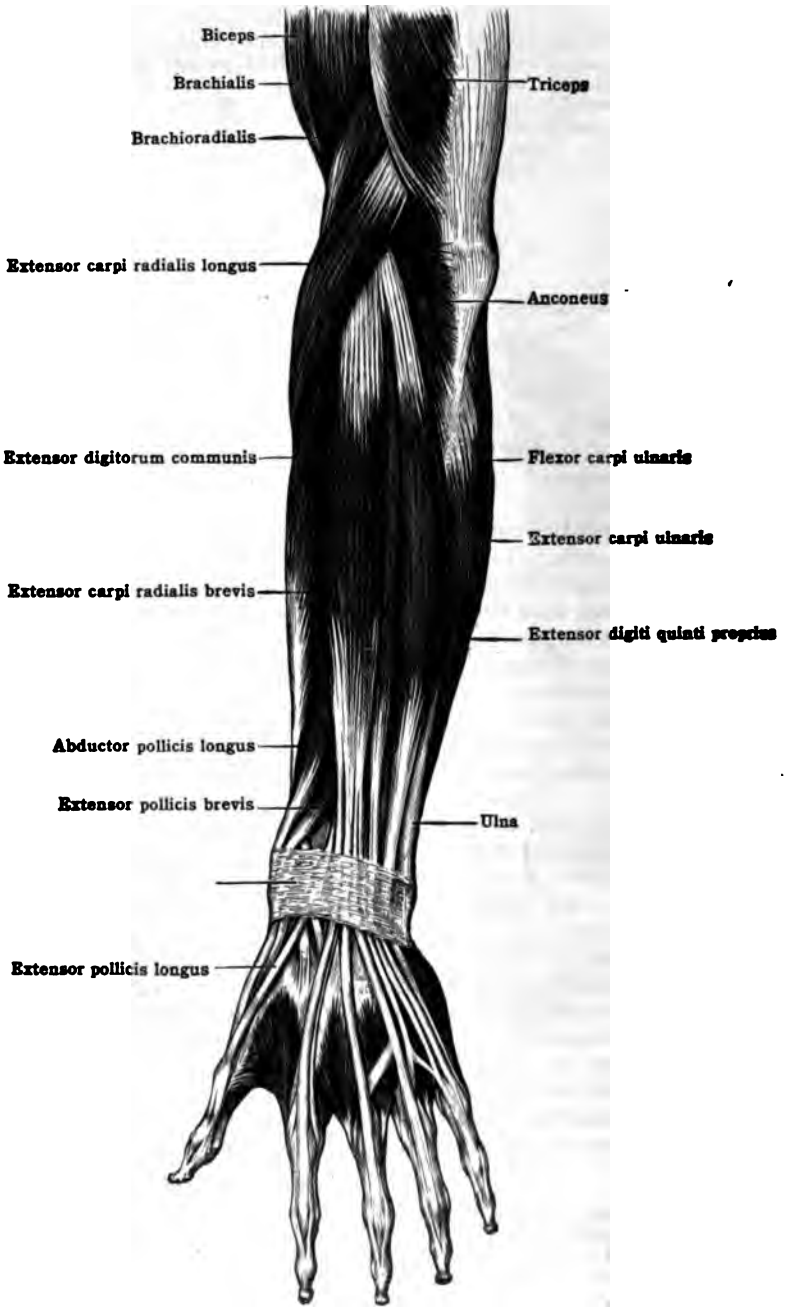
.—Into the lateral side of the base of the styloid process of the radius.

.—The constituent fiber-bundles arise directly from the septum and by short
ands from the epicondylar ridge, extend downward and ventrally, and terminate
rm manner on a tendon which extends high on the deep surface of the muscle.
becomes free about the middle of the forearm as a broad, flat band. This be-
w as the tendon winds about the radius from the volar to the lateral surface. Be-
rtion it expands laterally and is connected with neighboring ligaments. The free
he muscle faces laterally at its origin, but, owing to the torsion, ventrally in the

forearm. The tendon, however, is turned again so that at the insertion it faces laterall more.

Nerve-supply.—From a branch of the radial nerve (musculospiral) which enters the mal third of the muscle on its deep surface. The nerve fibers arise from the fifth and cervical nerves.

FIG. 398.—MUSCLES OF THE RADIAL SIDE AND THE BACK OF THE FOREARM.



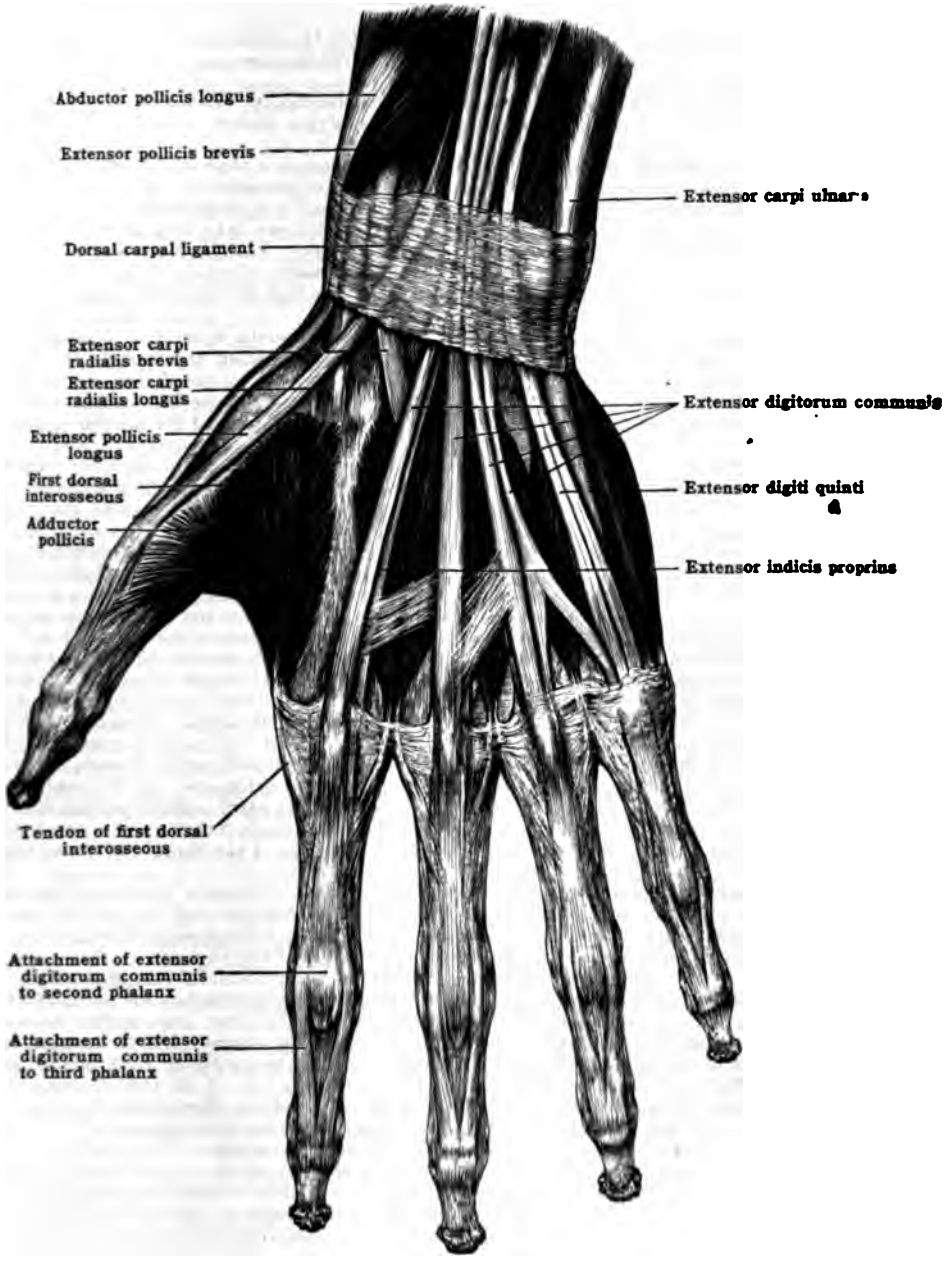
Action.—To flex the forearm. This action is strongest when the forearm is pı It acts as a supinator only when the arm is extended and pronated. It then serves to arm in a state of semipronation. When the forearm is flexed and supinated, it acts a nator.

Relations.—The muscle is superficially placed on the ventrolateral surface of the f Its tendon of insertion, however, is covered by the long abductor and the short extenso thumb. Near its origin (fig. 398) it lies lateral to the brachialis. In the intervening ti the radial nerve and the terminal branch of the profunda brachii artery. Dorsally and l

lies the medial head of the triceps. More distally the muscle overlies the extensor carpi radialis longus. It crosses the supinator, pronator teres, and flexor pollicis longus muscles. Beneath its medial edge lie the radial vessels and nerve.

Variations.—The humeral origin may extend half-way up the shaft. The radial insertion may be as high as the middle of the shaft or descend to the lesser multangular, navicular, or third metacarpal. In about 7 per cent. of bodies (Le Double) the tendon of insertion divides

FIG. 399.—TENDONS UPON THE DORSUM OF THE HAND.



nto two or three slips which are inserted on the styloid process of the radius. Occasionally the radial nerve passes between these slips. An accessory slip may pass to the fascia of the forearm. The muscle may be doubled throughout its length and it may be missing. It may be connected by accessory slips with neighboring muscles, the deltoid, brachialis, long abductor of the thumb, or long radial carpal extensor. The slip most frequently found goes to the brachialis.

The extensor carpi radialis longus (figs. 398, 399, 402).—*Origin.*—From the lower third of the lateral epicondylar ridge, the lateral intermuscular septum, and from the front of the tendons of the extensor carpi radialis brevis and the extensor communis digitorum which arise from the lateral epicondyle.

Structure and insertion.—The fiber-bundles are inserted in a penniform manner on both surfaces of a tendon which first appears on the lateral border of the deep surface of the muscle, becomes free above the middle of the forearm, and descends, closely applied to the tendon of the short radial carpal extensor, to the second compartment beneath the dorsal carpal ligament, through which it passes to its insertion into the base of the second metacarpal near the radial border. The outer surface of the muscle faces at first laterally, then ventrally.

Nerve-supply.—By one or two branches which arise from the radial (musculospiral) nerve as it passes between the brachialis and brachioradialis. The nerve enters the deep surface of the muscle in the proximal third. The nerve fibers arise from the (fifth), sixth and seventh cervical nerves.

Action.—To extend and abduct the hand. It steadies the wrist when the flexors act on the fingers. It is a flexor of the forearm; a supinator when the forearm is extended and pronated, a pronator when it is flexed and supinated.

Relations.—It is covered by the brachioradialis near the elbow. Below it becomes superficial except where crossed by the tendons of the muscles of the thumb. (For the relations to the short radial carpal extensor see below.)

Variations.—The humeral attachment may be more extensive than that indicated above. The tendon of insertion may send a band to the third or to the fourth metacarpal or to the multangulum majus (trapezium). The muscle may be fused, partly or completely, with the short radial extensor. It may send a slip to the abductor pollicis longus or to some of the interossei.

The extensor carpi radialis brevis (figs. 398, 399).—*Origin.*—From a band which descends on its deep surface from the common extensor tendon attached to the lateral epicondyle, from the intermuscular septa surrounding its head, and from the radial collateral ligament of the elbow-joint.

Structure and insertion.—The fiber-bundles converge obliquely toward a tendon which appears high up on the dorsolateral surface of the muscle. Toward the lower third of the forearm this tendon becomes a free, strong band closely applied to the under surface of the tendon of the long radial extensor, and with this passes through the second compartment beneath the dorsal ligament of the carpus, diverging as it does so toward its insertion into the back of the bases of the second and third metacarpal bones.

Nerve-supply.—A branch is supplied to the muscle from the deep radial (posterior interosseous) nerve before this enters the supinator (brevis). The branch enters the middle third of the medial margin of the muscle by several rami. The nerve fibers arise from the (fifth), sixth and seventh cervical nerves.

Action.—To extend the hand radialward and, to a slight extent, to flex the forearm.

Relations.—In its proximal portion the muscle is placed with a medial surface toward the common extensor, a deep toward the supinator (brevis) and pronator teres, and a dorsolateral toward the long radial extensor. More distally the muscle and its tendon become flattened about the radius and partly covered by the long radial extensor and its tendon.

In the distal quarter of the forearm the tendons of these two muscles are crossed by the long abductor and the short extensor of the thumb. Beneath the dorsal carpal ligament the tendon of the short radial extensor is crossed by the tendon of the long extensor of the thumb.

Variations.—The tendon often sends no slip to the second metacarpal. Fusion of the two radial extensors is frequent. The fused muscle may have from one to four tendons. The **extensor carpi radialis intermedius** of Wood is a muscle which arises, rarely directly from the humerus, but not infrequently as a slip from one or both radial extensors. It is inserted into the second or third metacarpal bone or into both. The **extensor carpi radialis accessorius** is a muscle which has an origin like the extensor intermedius, but which terminates on the base of the metacarpal or first phalanx of the thumb, the short abductor of the thumb, or some neighboring structure.

The extensor digitorum communis (figs. 398, 399).—*Origin.*—From a tendon attached to the lateral epicondyle, and from intermuscular septa which lie between the head of the muscle and the short radial extensor, the extensor of the little finger, and the supinator muscle.

Insertion.—By four tendons into the bases of the phalanges of the fingers.

Structure.—The fiber-bundles arise from the interior of the pyramidal case formed by the tendon, the fascia, and intermuscular septa, and pass distally to converge on four tendons which begin in the middle of the forearm, become free a little above the wrist, pass under the dorsal carpal ligament in a groove common to them and the tendon of the extensor indicis proprius, and diverge to the backs of the fingers. Opposite the metacarpophalangeal joint each tendon gives rise on its under surface to a band which becomes attached to the base of the first phalanx of its respective digit. The tendon is also closely bound to the joint by fibrous bands connected with the palmar fascia. On the dorsum of the first phalanx the tendon expands and is bound to an aponeurotic extension from the interosseous and lumbrical muscles. The tendon divides into three bands. The middle band passes to the base of the second phalanx, the lateral bands pass laterally around the joint to be inserted into the back of the base of the third phalanx. The lateral bands are bound to the second joint by a thin layer of transverse and oblique fibers.

An obliquely transverse band usually passes from the tendon of the index to that of the middle finger above the heads of the metacarpals. The tendon to the index finger is united to the tendon of the extensor indicis proprius opposite the metacarpophalangeal articulation. The tendon to the ring finger usually sends a slip to join the tendon of the middle finger. The fourth tendon lies near that of the ring finger and divides into two slips, one of which joins the tendon of the ring finger and one goes to the little finger to join the tendon of the extensor digiti quinti proprius.

Nerve-supply.—From a branch which arises from the deep radial (posterior interosseous) nerve as it emerges from the supinator (brevis) muscle. From this several twigs enter the deep surface of the middle third of the belly. Often the nerve is bound up with the nerve to the extensor of the little finger and the ulnar extensor. On the other hand, there may be several

separate branches to the muscle. The nerve fibers arise from the sixth, seventh, and eighth cervical nerves.

Action.—The muscle extends the two terminal phalanges on the basal, the basal on the metacarpus, and the hand at the wrist. The extensor action is strongest on the first phalanx. The cross-bands between the tendons hinder the independent extension of the middle and ring fingers, while the special extensors of the index and little fingers makes the movements of these fingers freer. When the hand is abducted toward the radial side, the extensor muscles tend to draw the fingers ulnarward. When the hand is abducted toward the ulnar side, the muscles tend to draw the fingers toward the thumb. When the hand is in the mid-position the ring finger and little finger are abducted and the index-finger is adducted. (Frohse.)

Relations.—It is superficially placed. Under it lie the deep muscles of the back of the forearm, the interosseous vessels, and the deep radial (posterior interosseous) nerve. It lies between the short radial carpal extensor and the extensor of the little finger.

Variations.—There is considerable variation in the extent of isolation of the parts going to the various fingers. That to the index-finger is the one most frequently isolated. At times the tendon to the index or little finger may be wanting. More frequently one or more of the tendons subdivides to be attached to two or more fingers or to the thumb. The connections between the tendons on the back of the hand vary greatly.

The **extensor digiti quinti proprius** (extensor minimi digiti) (figs. 398, 399).—*Origin.*—Chiefly from the septum between it and the common extensor, but also in part from the septum between it and the extensor ulnaris and from the overlying fascia.

Structure and insertion.—The fiber-bundles descend in a narrow band which begins near he neck of the radius. They are inserted into the side of a tendon which begins high on the lnar margin of the muscle. The most distal fiber-bundles extend nearly to the wrist-joint. he tendon passes through the fifth compartment beneath the dorsal carpal ligament, and xtends on the back of the fifth metacarpal to the base of the first phalanx of the little finger, here it is joined by a slip from the fourth tendon of the common extensor. The insertion of ie tendons is like that of the tendons of the common extensor.

Nerve-supply.—By a branch or branches from the deep radial (posterior interosseous) nerve. he nerve filaments enter the middle third of the fleshy portion of the muscle on its deep rface. The innervation of this muscle is intimately related to that of the preceding.

Action.—It acts as a portion of the common extensor, but, owing to its separation, in-ependent movement of the little finger is possible.

Relations.—It lies between the common extensor and the ulnar extensor and upon the deep uscles of the back of the forearm.

Variations.—Absence is not very frequent; blending with the common extensor is frequent. s tendon often divides into two or more slips. The belly may also be doubled. It may have supplementary origin from the ulna. A tendon slip to the ring-finger is frequently found.

The **extensor carpi ulnaris** (figs. 398, 399).—*Origin.*—By two heads: one from the inferior rsal portion of the epicondyle by an aponeurotic band attached below the tendon of the mmon extensor, from the enveloping fascia, and from the septa between it and the extensor giti quinti, anconeus, and supinator (brevis); the other from the proximal three-fourths of ie dorsal border of the ulna.

Structure and insertion.—The fiber-bundles descend in an osteofascial compartment bounded r the dorsal surface of the ulna, the fascia of the forearm, the dense fascia overlying the nar origin of the muscles of the thumb, and the origin of the extensor indicis. The tendon mmences high in the muscle and appears on the radial border of the middle third of the back its belly. The fiber-bundles are inserted in a penniform manner on the ulnar border and ep surface of the tendon as far as the wrist. Here the tendon enters the sixth osteo-fibrous nal beneath the dorsal carpal ligament in a special groove on the outer side of the styloid rocess of the ulna. It is inserted into the base of the fifth metacarpal.

Nerve-supply.—By a branch which arises from the deep radial (posterior interosseous) nerve this emerges from the supinator (brevis) muscle. Several filaments enter the deep surface the muscle in the middle third. The nerve fibers arise from the sixth, seventh and eighth rvical nerves.

Action.—To extend and abduct the hand ulnarward. It also abducts and extends the th metacarpal.

Relations.—It occupies a superficial position on the ulnar side of the extensors of the fore-m. Beneath it lie the deep muscles of the back of the forearm and the posterior surface of ie ulna.

Variations.—It may receive a slip from the triceps or be fused with the anconeus or with ie extensor of the little finger. More frequently it is doubled, partially or completely. An cessory tendon may go to the first phalanx of the little finger, to the head of the fifth meta-rpal, to the fourth metacarpal, to the extensor tendon of the little finger, or to the fascia over ie opponens digiti quinti. The muscle may be reduced to a fibrous band. The **ulnaris digiti inti** is a rare muscle arising from the dorsal surface of the ulna and inserted into the base of ie first phalanx of the little finger. It may be represented by a fasciculus or an extra tendon om the ulnar extensor.

b. Deep Layer

(Fig. 400)

The muscles of this group extend from the ulna to the radius, thumb, and dex-finger. They are the supinator, abductor pollicis longus, extensor pollicis ngus brevis, and extensor indicis proprius. The **supinator** is a rhomboid mus-e which arises from the lateral epicondyle of the humerus and the supinator crest

of the ulna, winds laterally around the radius and is inserted into its volar surface. The **abductor pollicis longus** is a fusiform muscle which arises from the middle third of the ulna, the interosseous membrane, and the radius, and is inserted into the base of the first metacarpal. The **extensor pollicis brevis** arises from the radius distal to the preceding muscle, and is inserted into the base of the first phalanx of the thumb. The **extensor pollicis longus** is a narrow muscle which arises from the middle third of the dorsal surface of the ulna and is inserted into the base of the second phalanx of the thumb. The **extensor indicis proprius** is a narrow, fusiform muscle arising from the shaft of the ulna and inserted into the dorsal aponeurosis of the index-finger. These muscles are supplied from branches of the deep radial (posterior interosseous) nerve while this is passing through or after its exit from the supinator.

The extensor pollicis longus is represented by the extensor hallucis longus of the leg. The abductor pollicis longus and extensor pollicis brevis are represented by the abnormal abductor hallucis longus and extensor primi internodii hallucis muscles, the rudiments of which are perhaps normally present in the tibialis anterior. The supinator and the extensor indicis muscles are not represented in the leg. On the other hand, the extensor digitorum brevis, normal in the foot, is only occasionally found on the back of the hand.

The supinator (brevis) figs. 397, 400, 403).—*Origin.*—From (1) the inferior dorsal portion of the lateral epicondyle by a tendinous band which is adherent to the deep surface of the tendons of origin of the radial and common extensors and to the radial collateral ligament of the joint; and (2) the ulna by a superficial aponeurosis and by fiber-bundles attached directly to the depression below the radial notch and to the supinator crest.

Insertion.—The lateral and volar surfaces of the radius from the tuberosity to the attachment of the pronator teres.

Structure.—From their origin the fiber-bundles descend spirally in a musular sheet which enwraps the radius (fig. 397). The attachment extends to the oblique line. The muscle is divided into a superficial and a deep plane by a septum in which the deep radial (posterior interosseous) nerve runs. The radial attachments of these two portions are separated by an osseous area into which no fiber-bundles are inserted. The fiber-bundles of the superficial layer have a much more vertical course and are longer than those of the deep layer.

Nerve-supply.—By branches which arise from the deep radial (posterior interosseous) nerve before it passes between the two layers of the supinator muscle. The nerve fibers arise from the fifth, sixth, and seventh cervical nerves.

Action.—To supinate the forearm.

Relations.—The supinator is covered by the superficial group of extensor muscles above described and by the anconeus.

Variations.—The extent of separation of the muscles into two portions varies. Accessory fasciculi of origin are not uncommon. These may spring from the annular ligament, **tensor ligamenti annularis anterior** (5 per cent. or more of bodies—Le Double), the lateral epicondyle, the tendon of the biceps, the tuberosity of the radius, etc. A sesamoid bone may lie in the tendon of origin. The **tensor ligamenti annularis posterior** is a slip generally present and often independent of the supinator. It runs from the ulna behind the radial notch to the annular ligament of the radioulnar joint.

The abductor pollicis longus (extensor ossis metacarpi pollicis) (fig. 400).—*Origin.*—From (1) the lateral margin of the dorsal surface of the ulna in the proximal portion of the middle third, and the adjacent interosseous membrane, (2) the dorsal surface of the radius distal and medial to the attachment of the supinator, and (3) at times, from the septa lying between it and the supinator, extensor carpi ulnaris, and extensor pollicis longus.

Structure and insertion.—The fiber-bundles from this extensive area of origin converge in a bipenniform manner upon a tendon which appears as an aponeurosis on the deep surface of the muscle about the middle of the forearm. The tendon as it descends becomes rounded. The insertion of fiber-bundles continues nearly to the wrist. Here, together with the tendon of the short extensor, it enters the first osteofibrous canal beneath the dorsal carpal ligament upon the lateral surface of the distal extremity of the radius. Upon leaving this canal the tendon extends to be inserted on the radial side of the base of the first metacarpal bone.

Nerve-supply.—By one or more branches from the deep radial (posterior interosseous) nerve after it has emerged from the supinator. The branches enter the muscle on the superficial surface in the proximal third. The nerve fibers come from the sixth, seventh (and eighth) cervical nerves.

Action.—It abducts the first metacarpal. At the height of its contraction it flexes and abducts the hand at the wrist.

Relations.—Near its origin the muscle is covered by the superficial extensors of the forearm More distally, accompanied by the short extensor, it passes radially, becomes superficial, and crosses the tendons of the two radial carpal extensors.

Variations.—The muscle or its tendon may be doubled. An accessory tendon may be applied to the multangulum majus (trapezium), the transverse ligament of the carpus, the superficial muscles of the thenar eminence, or the first metacarpal. Of these, the attachment to the short abductor and short flexor is the most frequent (7 out of 36 bodies—Wood). There may be three or more tendons. The muscle may be fused with the short extensor.

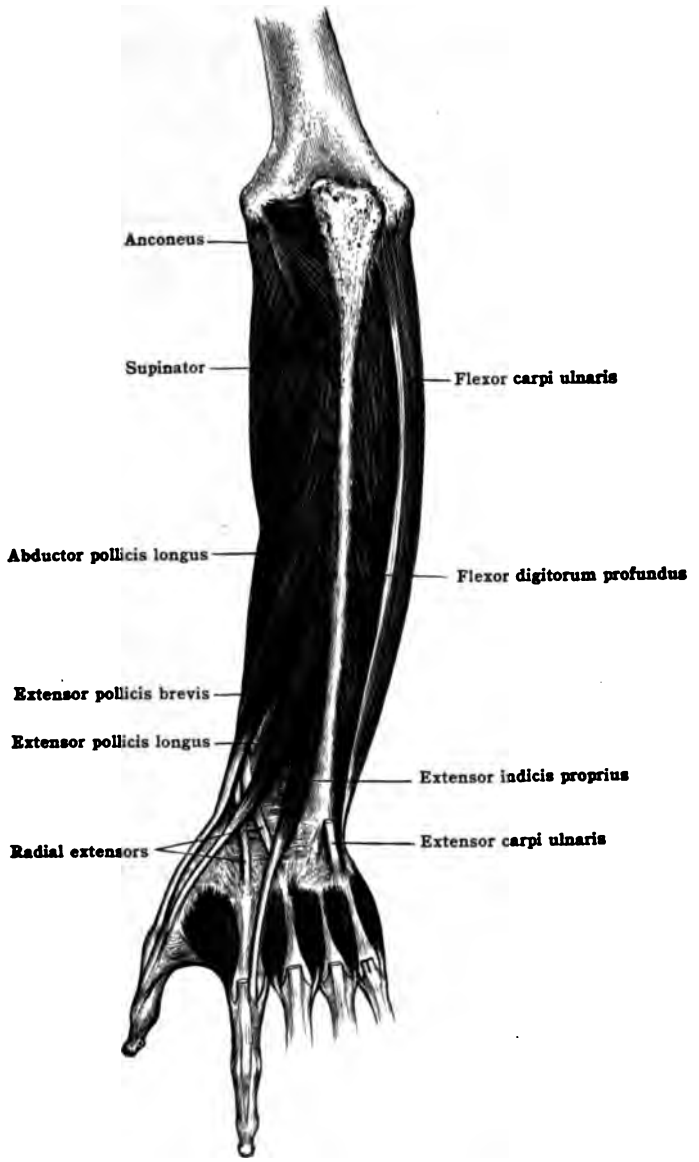
The extensor pollicis brevis (fig. 400).—*Origin.*—From the distal part of the middle third of the medial portion of the dorsal surface of the radius and from the neighboring portion of the interosseous membrane. Rarely its origin extends to the ulna.

Structure and insertion.—The fiber-bundles converge on a tendon which appears on the radial

er. The fibers are inserted as far as the dorsal carpal (posterior annular) ligament. The on lies parallel to the ulnar side of that of the abductor pollicis longus, and, in close con- ion with it, passes through the first compartment beneath the dorsal carpal ligament, and es the metacarpophalangeal joint on the radial side of the long extensor tendon. It erted on the base of the first phalanx of the thumb or into the capsule of the metacarpo- angeal joint.

erve-supply.—From a branch derived from the deep radial (posterior interosseous) nerve, branch is usually given off in common with or near the nerve to the abductor pollicis longus. may traverse that muscle to reach the extensor pollicis brevis, which it enters in the proxi- third of its radial border. The nerve fibers come from the sixth, seventh (and eighth) cal nerves.

FIG. 400.—THE DEEP MUSCLES OF THE BACK OF THE FOREARM.



ction.—To extend the thumb at the metacarpophalangeal joint and to abduct the first acarpal. It is a radial abductor of the hand at the wrist-joint.

Relations.—It lies between the abductor pollicis longus and the extensor pollicis longus, rhich its origin is partly overlapped. In company with the former muscle it passes medially ı beneath the common extensor of the fingers and over the tendons of the radial carpal nsors to reach its osteofibrous canal under the dorsal carpal ligament.

Variations.—The head of the muscle may be fused with the long abductor. Its tendon nsertion may give rise to a slip inserted on the first metacarpal (in 2 out of 85 bodies—Le ble) or into the terminal *phalanx. Its tendon is often* united with that of the long extensor.

It may be fused with the long abductor of the thumb and has been found missing. It may be doubled.

The extensor pollicis longus (fig. 400).—*Origin.*—From the middle third of the lateral part of the dorsal surface of the ulna; from the neighboring part of the interosseous membrane; and from the septa between it and the extensor indicis proprius and the extensor carpi ulnaris.

Structure and insertion.—The fiber-bundles converge in a bipenniform manner on the two sides of a tendon which appears high on the dorsal surface of the muscle. They extend as far as the dorsal carpal (posterior annular) ligament. The fusiform body of the muscle descends somewhat obliquely on the dorsal surface of the forearm. The tendon enters the third osteofibrous canal beneath the dorsal carpal (posterior annular) ligament. On emerging from the canal it passes very obliquely across the dorsal surface of the carpus, over the tendons of the radial extensors, to the ulnar side of the first metacarpal. It passes along this and, on the dorsal surface of the first phalanx, expands to be inserted into the base of the second phalanx. The aponeurosis of insertion receives tendinous slips from the short muscles of the volar surface of the thumb.

Nerve-supply.—By a twig from the deep radial (posterior interosseous) nerve. The branch gives rise to twigs which enter the proximal third of the radial border of the muscle. The fibers arise from the sixth, seventh, and eighth cervical nerves.

Action.—To extend the second phalanx on the first, and this on the metacarpal. It also draws the whole thumb when extended toward the second metacarpal. It is a radial abductor of the hand at the wrist-joint.

Relations.—The head of the muscle is partly overlapped by the long abductor of the thumb. It lies between this and the extensor pollicis brevis on one side, and the extensor indicis proprius on the other. Over it lie the extensors of the fingers and the ulnar carpal extensor.

Variations.—The tendon may give a slip to the base of the first phalanx of the thumb to the dorsal carpal ligament, or to the index finger. It may receive an accessory slip from the common extensor of the fingers or the short extensor of the thumb. It is frequently doubled. An additional extensor is found in about 6 per cent. of bodies between the extensor of the index finger and that of the thumb. It has a double tendon and insertion into both digits (**extensor communis pollicis et indicis**).

The extensor indicis proprius (fig. 400).—*Origin.*—From the proximal part of the distal third of the posterior surface of the ulna, medial and distal to that of the preceding muscle, from the adjacent interosseous membrane, and from the septum between it and the extensor pollicis longus.

Structure and insertion.—The fiber-bundles are inserted on a tendon which first appears on the radial border of the muscle. The insertion of fiber-bundles extends nearly to the dorsal carpal (posterior annular) ligament. Here the tendon passes beneath that of the extensor of the little finger and enters the fourth osteofibrous canal beneath the lateral tendons of the common extensor. It passes across the wrist beneath the tendon from the extensor communis to the index finger, and is inserted on the ulnar side of this into the dorsal aponeurosis of the index finger opposite the base of the first phalanx.

Nerve-supply.—By a twig from the deep radial (posterior interosseous) nerve. This twig enters the proximal third of the radial border of the muscle. It frequently arises from a branch to the extensor pollicis longus. The nerve fibers come from the sixth, seventh, eighth cervical nerves.

Action.—To extend the first phalanx on the metacarpal. Like the common extensor it has a limited action on the two terminal phalanges. It also abducts the index finger.

Relations.—It is covered by the superficial extensor group.

Variations.—These are frequent. It may be absent. There may be two heads, or the muscle may be completely doubled. It may receive an accessory slip from the ulna or the carpus. The tendon may give accessory slips to the middle finger, the ring finger, or the thumb. The accessory tendon to the middle finger is the most frequent. The tendon to the index finger may be inserted on the metacarpus.

Abnormal Muscles of the Back of the Wrist and Hand

The **extensor medii digiti** is a small muscle which arises from the ulna beneath the extensor of the index finger, with which it is more or less fused. It sends a tendon to the extensor aponeurosis of the middle finger or slips both to this finger and the index finger. It is present in about 10 per cent. of bodies (Le Double).

The **extensor digiti annularis** is a muscle similar to the extensor medii digiti, but much rarer.

The **extensor digitorum brevis**, which resembles the muscle of corresponding name on the dorsum of the foot, may have from one to four fasciculi, but most frequently one. The most common fasciculus is one which sends a tendon to the extensor tendon of the index finger. One for the middle finger is nearly as frequent. Others are rare. A fasciculus for the thumb has not been reported. (Le Double.) The fasciculi usually arise from the bones of the ulnar half of the carpus—lunatum (semilunar), triquetrum (cuneiform), hamatum (unciform), and capitatum (magnum), and from the dorsal ligaments uniting these bones. The tendons are inserted either into the corresponding extensor tendons or into the metacarpals. The muscle is found in about 10 per cent. of bodies (Wood).

Bursæ

B. m. extensoris carpi radialis brevis.—Between the tendon and the base of the third metacarpal.

B. m. abductoris pollicis longi.—Between the tendons of the long and short radial extensors and the tendons of the abductor pollicis longus and extensor pollicis brevis. Another bursa lies beneath the tendon of insertion of the abductor.

B. intermetacarpophalangeæ.—Between the lateral surfaces of the heads of the metacarpal bones of neighboring fingers dorsal to the transverse capitular ligament.

B. tendinum m. extensoris digitorum communis.—Small bursæ are sometimes found beneath the tendons to the index and little fingers near where they begin to diverge from the common tendon.

B. m. extensoris carpi ulnaris.—A small bursa may be found under the tendon of origin of this muscle.

B. m. supinatoris.—Between the supinator and the tendon of the extensor muscles.

B. m. extensoris pollicis longi.—Between the tendon and the first metacarpal.

Synovial Tendon-sheaths

Vagina tendinum mm. extensorum carpi radialium.—Synovial sheaths cover the tendons of the two radial carpal extensors as they pass beneath the dorsal carpal (posterior annular) ligament. In the adult these sheaths usually are more or less fused and communicate with the sheath of the extensor pollicis longus where this crosses them.

Vagina tendinum mm. extensoris digotorum communis et extensoris indicis.—A synovial sheath surrounds the tendons of these muscles as they pass beneath the dorsal carpal (posterior annular) ligament. This sheath extends for some distance on the tendons as they diverge.

Vagina tendinis m. extensoris digiti quinti.—A synovial sheath extends on the tendon of this muscle from above the dorsal carpal (posterior annular) ligament to the base of the metacarpal.

Vagina tendinis m. extensoris carpi ulnaris.—This sheath commences above the carpal (posterior annular) ligament and extends to the insertion of the tendon.

Vagina tendinum mm. abductoris pollicis longi et extensoris pollicis brevis.—The sheaths which surround these two tendons beneath the dorsal carpal (posterior annular) ligament usually communicate freely.

Vagina tendinis m. extensoris pollicis longi.—A long synovial sheath surrounds this tendon. Where it crosses the tendons of the radial extensors, a communication is found with the sheath of the latter.

2. Ulnovolar Division

The muscles on the volar side of the forearm lie in four layers.

a. First Layer

(Fig. 401)

Of the four muscles of associated ulnar epicondylar origin which constitute this layer the **pronator teres** is a strong, band-like muscle which is inserted into the lateral surface of the middle third of the shaft of the radius; the fusiform **flexor carpi radialis** sends a tendon to the base of the second metacarpal; the slender **palmaris longus** is inserted into the palmar fascia; and the medially situated, fusiform **flexor carpi ulnaris** into the pisiform bone and the palmar fascia. The pronator teres is the most powerful pronator of the forearm. When the hand is slightly flexed the ulnar carpal flexor abducts ulnarward. When the hand is greatly flexed lateral movement is difficult. The ulnar flexor is supplied by the ulnar nerve, the other muscles by the medial.

The pronator teres probably corresponds with the popliteus of the leg. The flexor carpi radialis and flexor carpi ulnaris probably represent in the main the two heads of the gastrocnemius; and the palmaris longus, the plantaris.

The pronator teres (fig. 401).—*Origin.*—By two heads:—(1) the *humeral* or chief head arises by a tendon from the superior half of the ventral surface of the medial epicondyle and directly from the overlying fascia and from the intermuscular septa between it and the medial head of the triceps and the flexor carpi radialis. (2) The *ulnar*, deep or accessory, head arises by an aponeurotic band attached to the inner border of the coronoid process medial to the tendon of the brachialis. Between the humeral and ulnar heads is a fibrous arch beneath which the median nerve passes.

Structure and insertion.—The fiber-bundles of the humeral head are inserted in a penniform manner on a tendon which begins near the middle of the belly of the muscle on the superficial surface along the radial border. The tendon gradually becomes broader, winds about the volar surface of the radius, and is inserted into the middle third of its lateral surface. The attachment of fiber-bundles continues nearly to this insertion. The fiber-bundles of the ulnar head form a slender fasciculus which is inserted into the radial side of the deep surface of the humeral head.

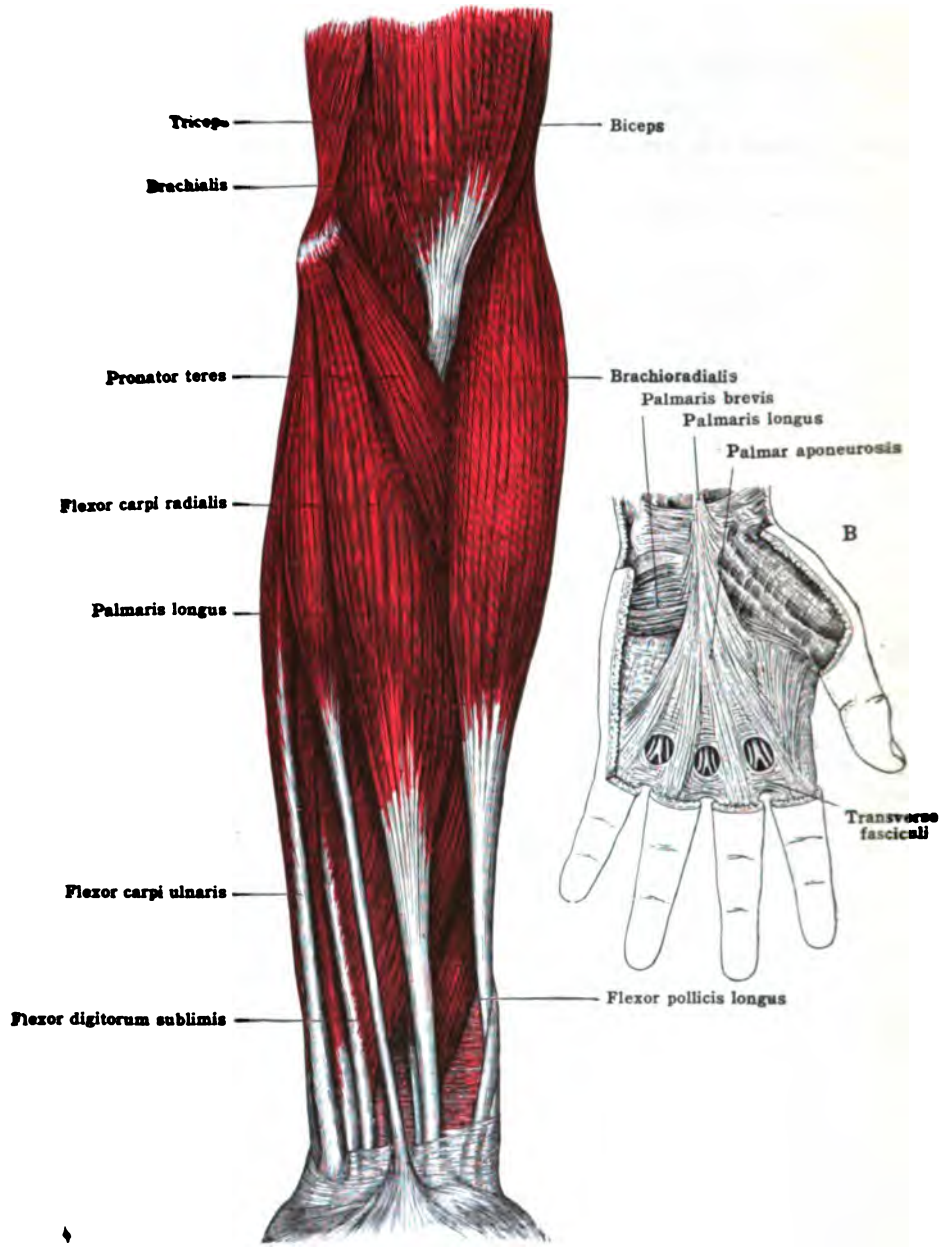
Nerve-supply.—By a branch derived from the median nerve before it passes between the two heads of the muscle. The nerve enters the proximal part of the middle third of the main belly of the muscle on its deep surface near the radial border. The branch to the ulnar head usually enters this portion of the muscle somewhat proximal to its fusion with the humeral head. The nerve fibers arise from the sixth and seventh cervical nerves.

Action.—To pronate and flex the forearm.

Relations.—The muscle is superficially placed. Near its origin it is covered by the lacertus fibrosus of the biceps, and near its insertion by the radial vessels and nerve and the brachio-

uscles. It is the most radial of the group of muscles under con-
r helps to bound an angular space, the cubital fossa, in which lie
nerve, and the tendon of the biceps. The median nerve passes
r heads. The muscle overlies the supinator, the brachialis, and
digitorum sublimis muscles and the ulnar artery.
ry fasciculi may arise from the humerus, the medial intermuscular
carpi radialis, the flexor sublimis, or the brachialis muscles. The

FIG. 401.—FRONT OF THE FOREARM: FIRST LAYER OF MUSCLES.



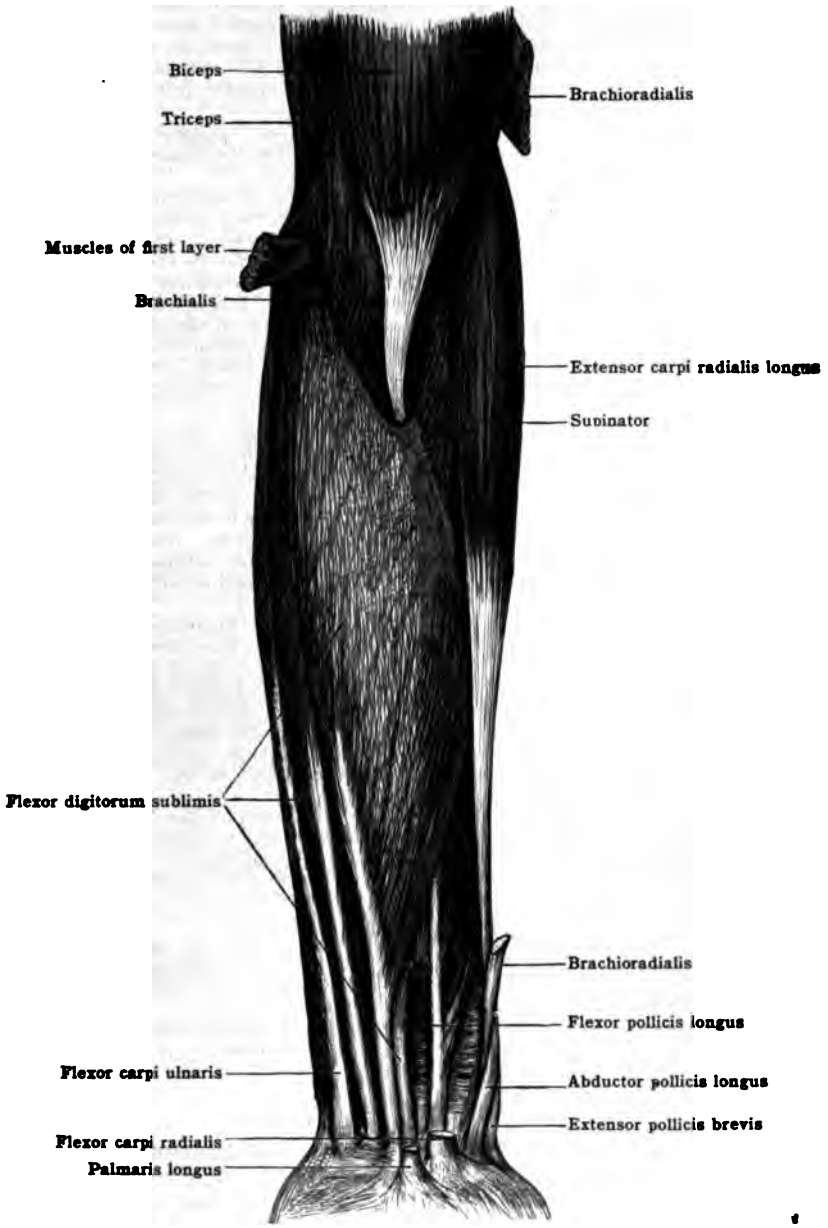
two portions of the muscle may be distinct from origin to insertion. Either part of the muscle may be doubled. The ulnar head may be absent. The radial insertion may be extensive. Fasciculi may extend to the long flexor of the thumb. There may be a sesamoid bone in the tendon of origin from the humerus.

The flexor carpi radialis (fig. 401).—*Origin.*—From (1) the common tendon attached to the medial epicondyle; and (2) the septa between its head and the pronator teres, the flexor sublimis, and the palmaris longus.

Structure and insertion.—The fiber-bundles descend to converge upon a tendon at first intramuscular, but which in the middle of the arm appears on the volar surface of the muscle and

becomes free from the attachment of fiber-bundles. The fiber-bundles from the epicon- descend nearly vertically to the front and sides of the tendon, while those from the inter- cular septa take an oblique course to the deep surface of the tendon. The tendon is at first , but soon becomes cylindrical, bound to the superficial muscle fascia, and enters the hand ough a special osteofibrous canal formed mainly by the groove in the os multangulum jus (trapezium) and the transverse carpal (anterior annular) ligament. It is inserted into base of the second metacarpal. It usually also sends a tendon slip to the third.

FIG. 402.—FRONT OF THE FOREARM: SECOND LAYER OF MUSCLES.



Nerve-supply.—By a branch from the median nerve which divides into several twigs that the muscle near the junction of its proximal and middle thirds on the deep surface. The usually arises near the elbow. The nerve fibers arise from the sixth, seventh (and eighth) cal nerves.

ction.—To flex the hand at the wrist. To a slight extent it may also act as a pronator e forearm and a flexor of the forearm on the arm.

Relations.—It is superficial except near its insertion. The belly of the muscle lies between pronator teres and the palmaris longus and upon the flexor digitorum sublimis. The tendon e muscle passes over the flexor pollicis longus, and near the wrist is a guide to the radial

artery, which here lies lateral to it. In the hand the tendon lies beneath the thenar muscles and is crossed by the tendon of the long flexor of the thumb.

Variations.—It may receive a fasciculus from the brachialis or biceps muscles or from the radius or ulna. It may send tendon slips to the multangulum majus (trapezium), navicular, the transverse carpal (anterior annular) ligament, or the fourth metacarpal. The insertion may take place variously into these structures.

The palmaris longus (fig. 401).—*Origin.*—From the common tendon attached to the medial epicondyle and from the surrounding intermuscular septa.

Structure and insertion.—The fiber-bundles take a nearly parallel course to a tendon which appears high in the middle third of the forearm on the volar surface of the muscle. In the middle of the forearm the attachment of fiber-bundles usually ceases, the tendon becomes bound to the overlying fascia, and descends parallel with that of the radial flexor. Near the proximal border of the transverse carpal (anterior annular) ligament the tendon expands into radiating bundles of fibers of which the medial and lateral are attached to the fascia over the intrinsic muscles of the thumb and little finger, while the middle, much more developed, constitute the chief portion of the palmar aponeurosis.

Nerve-supply.—From a branch which usually arises in company with the nerve to the proximal part of the flexor sublimis. It frequently traverses the superficial fibers of the flexor sublimis. The nerve enters the middle third of the muscle.

Action.—To flex the hand. It is also a weak flexor and pronator of the forearm.

Relations.—It is placed between the radial and ulnar flexors over the flexor sublimis. In the distal part of the forearm the tendon lies over the median nerve.

Variations.—It is absent in 11.2 per cent. of all cases (Le Double). It may be highly developed or reduced to a tendinous band. The belly of the muscle may lie in the distal instead of in the proximal part of the forearm. It may be digastric. It may be fused with neighboring muscles. It may arise from the medial intermuscular septum of the arm or from the lacertus fibrosus, from the radius, from the coronoid process, from the radial or ulnar flexor, or from the flexor sublimis muscles. The tendon may terminate in the fascia of the forearm, the thenar eminence, the carpus, or the abductor of the thumb. The muscle may be partly or wholly doubled.

The flexor carpi ulnaris (fig. 401).—*Origin.*—By two heads:—(1) the **humeral head** arises from the common flexor tendon attached to the lower ventral part of the medial epicondyle. Fiber-bundles of this head are also attached to the surrounding intermuscular septa and the deep fascia of the forearm. (2) The **ulnar head** arises by short tendinous fibers from the medial side of the olecranon and by an aponeurotic band common to it and the flexor digitorum profundus from the upper two-thirds of the dorsal border of the ulna. Proximally the two heads of the muscle are united by a fibrous arch extending from the olecranon to the medial epicondyle. Beneath this band pass the ulnar nerve and the dorsal recurrent ulnar artery. (See EPITROCHLEO-OLECRANONIS, p. 436.)

Structure and insertion.—The fiber-bundles of the humeral head descend nearly vertically, those of the ulnar head obliquely distally in a radial direction. They are inserted in a penniform manner on a tendon which appears in the proximal part of the middle third of the belly of the muscle on the radial margin of the deep surface, and in the distal third of the forearm forms the radial border of the muscle. On the ulnar side the insertion of fiber-bundles continues nearly to the pisiform bone. The insertion of the tendon takes place chiefly into the pisiform bone, but from it tendinous bundles extend to the palmar aponeurosis, volar ligament of the carpus, to the pisohamate (pisounciform), ligament, and to the bases of the fifth, fourth, and third metacarpals.

Nerve-supply.—From two or three branches of the ulnar nerve, the most proximal of which arises near the elbow-joint. These branches, which may arise by a single trunk, enter the deep surface of the proximal third of the muscle and send long twigs distally across the middle third of the constituent fiber-bundles. The nerve fibers arises from the seventh and eighth cervical and first thoracic nerves.

Action.—To flex the hand and to abduct the hand ulnarward.

Relations.—It is superficially placed. Its aponeurotic origin is adherent to the fascia of the forearm. It lies medial to the palmaris longus and flexor sublimis and upon the flexor profundus. Beneath the muscle lies the ulnar nerve. The ulnar artery extends along the radial border of the tendon near the wrist.

Variations.—These are rare. Slips from the tendon may pass to the metacarpophalangeal articulation of the little finger. (See, however, ABNORMAL MUSCLES, p. 436.)

b. SECOND LAYER

This is composed of one muscle, the **flexor digitorum sublimis,** which, although in part covered by the muscles of the preceding layer, is in part superficial. It arises from the medial epicondyle of the humerus, and from the radius and the ulna, and sends tendons to the second row of phalanges of the fingers. It corresponds probably to the soleus and the tendons of the flexor digitorum brevis in the leg and foot.

The flexor digitorum sublimis (figs. 402, 404, 406).—*Origin.*—By two heads: the **ulnar or chief head** arises (1) by the tendon common to it and the superficial group of muscles from the medial epicondyle, and by short tendinous bands from the ventral surface of the epicondyle; (2) from the ulnar collateral ligament of the elbow, the ulnar tuberosity, the medial border of the coronoid process, and the inferior extremity of the tendon of the brachialis; and (3) from the intermuscular septum between the flexor sublimis and the overlying muscles. The **radial**

head arises from an oblique line on the volar surface of the radius, and from the middle third of the anterior border.

Insertion.—Into the sides of the volar surface of the shafts of the second row of phalanges of the fingers.

Structure.—The fiber-bundles of the ulnar head and the upper part of the radial head converge, the ulnar fiber-bundles nearly vertically, the radial obliquely, to form a common belly the deep surface of which on the ulnar side is backed by a dense tendinous band. On the radial side of this a less dense membrane covers over an oval canal which passes distally along the line of junction of the two heads and lodges the ulnar artery and the median nerve.

The fiber-bundles of the ulnar head form a superficial and a deep group. The superficial portion near the middle of the forearm divides into a lateral and a medial division, the former being inserted on a tendon that goes to the middle and the latter on one that goes to the ring finger. The fiber-bundles of the radial head join with the lateral division of the superficial layer of the ulnar head and are inserted on the tendon of the middle finger nearly as far as the wrist. A small muscle fasciculus of the superficial portion of the ulnar head is usually united by a tendon to the long flexor of the thumb.

The deep portion of the ulnar head about the middle of the forearm terminates in large part on the volar surface of the dense tendinous band above mentioned. From this in turn two muscle bellies arise. One of these is inserted in a bipenniform manner on a tendon going to the index finger, the other on a tendon going to the little finger. A muscle fasciculus also usually passes from the region of the tendon band to that portion of the superficial fasciculus which terminates on the tendon of the ring finger.

The four tendons pass together through the carpal canal under the transverse carpal (anterior annular) ligament, those to the middle and ring fingers lying at first superficial to the other two. The tendons then diverge, and each tendon, together with and above a tendon of the flexor profundus, passes over the metacarpophalangeal joint into an osteofibrous canal on the palmar surface of the first phalanx of the finger for which it is destined. Here the tendon becomes flattened about the round tendon of the flexor profundus. Opposite the middle of the phalanx the tendon divides into two slips, between which the tendon of the flexor profundus passes. The divided halves of the sublimis tendon fold about the profundus tendon so that their lateral edges come to meet in the mid-line beneath this tendon opposite the phalangeal joint (figs. 406, 407). They then again separate, extend distally, and are attached one on each side into a ridge at the middle of the lateral border of the second phalanx. The tendons are also attached by **vincula tendinum**, a **ligamentum breve**, between the tendon and the head of the first phalanx and the joint, and a **ligamentum longum**, between the tendon and the volar surface of the first phalanx.

Nerve-supply.—Before the median nerve passes between the two heads of the pronator teres a branch arises which accompanies the nerve through the pronator and sends several branches into the proximal third of the ulnar head of the muscle. As the median nerve passes beneath the muscle, one or more branches are given to the radial head, and a long branch is given to the fasciculus of the second and from this one to that of the fifth digit. Occasionally, the median nerve in the distal third of the forearm gives rise to branches for these fasciculi. The nerve fibers arise from the seventh and eighth cervical and first thoracic nerves.

Action.—Chiefly to flex the second phalanx of each finger on the first; secondarily, to flex the fingers on the hand and the hand on the forearm.

Relations.—The belly of the muscle is covered by the pronator teres, flexor carpi radialis, and palmaris longus, but is superficial along a narrow strip between the flexor carpi ulnaris and the palmaris longus, and on each side of the tendon of the flexor carpi radialis. The muscle rests on the flexor pollicis longus and flexor digitorum profundus, the median nerve (see description given above) and ulnar vessels. The median nerve emerges from beneath the radial border of the muscle in the lower third of the forearm. In the palm the tendons lie beneath the palmar aponeurosis, the superficial palmar arch, and the branches of the median nerve, while they lie in front of the tendons of the flexor profundus, with which they are closely associated into a common bundle by loose fibrous tissue. The digital relations of the tendons are described above.

Variations.—The whole muscle may be rendered digastric by a transverse tendon. A fasciculus of the flexor sublimis may replace the palmaris longus or the two may coexist. A fasciculus may terminate in the fascia of the forearm or in the transverse carpal ligament, the palmar aponeurosis, etc. Various parts of the muscle may be absent or more independent than usual. The extent of the radial attachment varies greatly and may be missing. A special fasciculus may be received from the coronoid process of the ulna. A fasciculus may be sent to the flexor profundus or to other muscles. There may be some fusion with neighboring muscles.

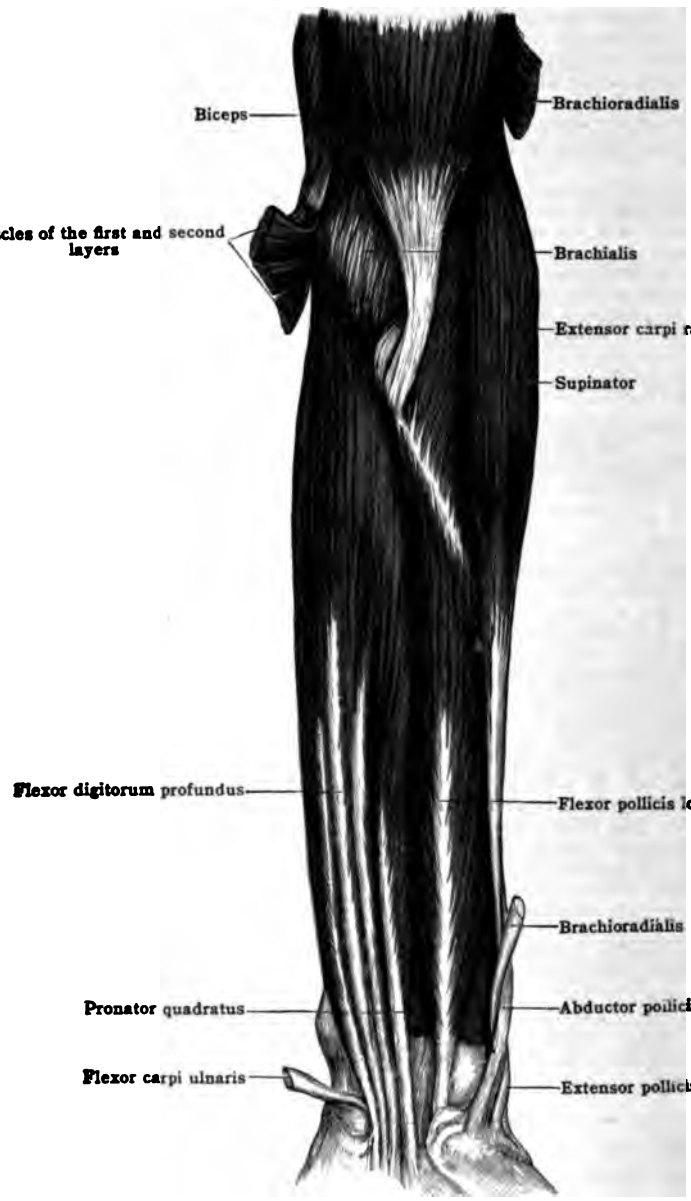
c. Third Layer
(Figs. 403–407)

The two muscles which constitute this layer may be looked upon as differentiated from a single deep flexor muscle. The **flexor digitorum profundus** is a strong, broad muscle which arises from the upper three-fourths of the volar surface of the ulna and gives rise to tendons which are inserted into the bases of the third row of phalanges of the fingers. The **flexor pollicis longus**, likewise broad and flat, arises from the volar surface of the radius and is inserted into the base of the second phalanx of the thumb. Both muscles are supplied by the median nerve and the flexor profundus is also supplied by the ulnar nerve.

These muscles correspond to the flexor digitorum longus and the flexor l cis longus of the leg.

The flexor digitorum profundus (figs. 403–407).—*Origin.*—(1) Through an apone septum between it and the flexor carpi ulnaris from the dorsal border of the ulna; (2) di from the proximal two-thirds of the medial surface and the proximal three-fourths of the surface of the ulna and from the adjacent interosseous membrane; and (3) inconstantly, f small area on the radius below the bicipital tuberosity.

FIG. 403.—FRONT OF THE FOREARM: THIRD LAYER OF MUSCLES.



Structure and insertion.—The fiber-bundles descend nearly vertically and give ris common belly which soon divides into four portions, each of which is attached about n down the forearm in a semipenniform manner to the dorsal surface of a tendon. The ment of fiber-bundles continues nearly to the wrist. The digital divisions of the muscle v the height to which they extend. That belonging to the index finger is usually the one m tensively isolated, and that to the little finger is the next most so. The tendons pass side under the transverse carpal (anterior annular) ligament, and then diverge to the bases fingers. At the metacarpophalangeal joints, they enter the osteofibrous canals des above (p. 433). On the volar surface of the first phalanx each tendon passes through in the sublimis tendon. The tendon then is continued over the second phalanx to the base

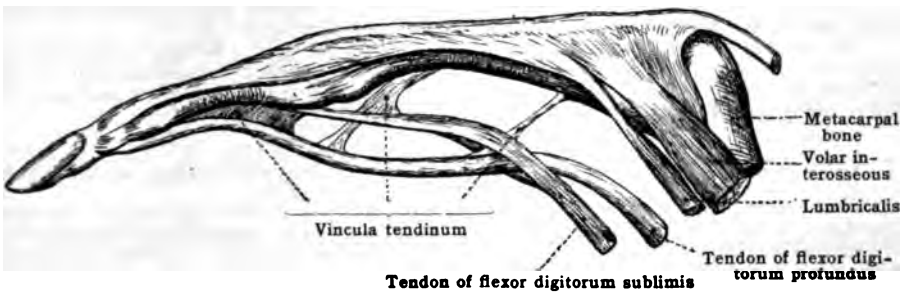
ird. **Vincula tendinum** are described passing to the capsule of the second interphalangeal int(**ligamentum breve**) and to the tendon of the flexor sublimis (**ligamentum longum**). The mbrical muscles arise from the tendons while they are in the palm.

Nerve-supply.—The interosseous branch of the median nerve arises usually before the rve passes through the pronator teres and accompanies the main trunk. This branch as it ses beneath the flexor sublimis gives off a branch (or two) from which several twigs spring. hese twigs enter the muscle near the radial border and pass in across the middle third of the onstituent fiber-bundles of the fasciculi to the index and middle fingers. The ulnar nerve near he elbow gives rise to a branch which enters the volar surface of the muscle near the junction f the proximal and middle thirds of that portion of the belly, giving tendons to the ring and ittle fingers. There is some variation in the extent of the innervations by the branches of the lnar and those of the median nerve. To a greater or less extent through anastomosis their erritories overlap. The nerve fibers arise from the seventh and eighth cervical and first horacic nerves.

Action.—To flex the terminal phalanx of each finger on the second and the second on the irst, while that of the superficial flexor is to flex the second phalanx on the first. The ction of the two flexors on the first phalanx is somewhat more limited. The interosseous nuscles, aided by the lumbricals, are the chief flexors of the first row of phalanges. The flexor rofundus acts, though not powerfully, as a flexor of the wrist.

Relations.—The flexor profundus muscle lies beneath the flexor sublimis and the flexor carpi lnaris muscles, the median nerve, and the ulnar vessels and nerve. Under the muscle lie the lna the interosseous membrane, and the pronator quadratus muscle. Under the transverse

FIG. 404.—INSERTIONS OF THE TENDONS OF THE MUSCLES WHICH ACT ON THE FINGER. (After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)



pal (anterior annular) ligament the tendons lie beneath those of the flexor sublimis in the ie synovial sac. In the palm the tendons with the associated lumbrical muscles lie upon the erosseous muscles, the adductor of the thumb, and the deep palmar arch, and beneath flexor sublimis tendons. For the relations to the synovial bursæ see p. 436.

Variations.—There is considerable variation in the extent of the radial origin and in the ent of the independence and fusion of the different fasciculi. In the prosimians a common don extends as far as the hand. The division in the higher forms is associated with refine- nt of movements of the fingers. One or more special fasciculi not infrequently join the scle from the flexor sublimis, the flexor pollicis longus, the medial epicondyle, or the ulna. e **accessorius ad flexorem digitorum profundum** is a fasciculus which arises from the coro- d process of the ulna and sends a tendon to join the tendon of one of the fingers, most fre- ntly the middle or index. It is found in 20 per cent. of bodies.

The flexor pollicis longus (fig. 403).—*Origin.*—The attachment extends along the oblique e and the ventral border of the radius from slightly below the bicipital tuberosity to within m. of the wrist. Medially it is continued into the interosseous membrane. Proximally the don frequently extends to the distal radial margin of the coronoid process of the ulna and es rise to fiber-bundles connected with the muscle, as well as to a fasciculus of the flexor fundus.

Structure and insertion.—The fiber-bundles descend obliquely to be inserted in a penni- m manner on a tendon which begins high up on the volar surface near the ulnar border the muscle, and descends as a broad band which near the wrist becomes cylindroid. The ertion of fibers continues nearly to the point where the tendon passes under the transverse pal ligament. Here the tendon enters the carpal canal radial to the tendons of the flexor fundus, and passes beneath the superficial head of the short flexor of the thumb, then between thumb sesamoids into the osteofibrous canal of the thumb, in which it is continued to the e of the terminal phalanx.

Nerve-supply.—Usually from two branches of the volar interosseous ramus of the median ve. These enter the proximal half of the ulnar margin of the muscle. The nerve fibers e from the sixth, seventh (and eighth) cervical nerves.

Action.—It is a strong flexor of the second phalanx on the first and has less powerful action the metacarpophalangeal joint and on the wrist. It adducts and flexes at the carpometa- pal joint.

Relations.—It lies beneath the flexor sublimis, the flexor carpi radialis and brachioradialis scles, and the radial artery. Near the wrist it crosses over the insertion of the pronator adratus. In the hand the tendon runs beneath the opponens pollicis and the superficial head the flexor brevis, and across the deep head of the latter.

Variations.—It may be fused or united by fasciculi with the flexor profundus, the flexor sublimis, or the pronator teres. It may be partially doubled, giving rise to an accessory tendon which extends to the index finger. The origin may extend to the medial epicondyle of the humerus (epitrochlear bundle).

d. Fourth Layer

This layer consists of a single quadrilateral muscle which passes transversely across the lower part of the forearm from the ulna to the radius. In the leg there is no corresponding muscle.

The pronator quadratus (fig. 408).—*Origin.*—Medial side of the volar surface of the lower fourth of the ulna.

Structure and insertion.—From the ulna a strong aponeurosis extends a third of the way across the volar surface of the muscle. From this membrane and from the bone fiber-bundles extend transversely to be inserted on the distal quarter of the volar surface of the radius and on the triangular area above the ulnar notch. The deeper fiber-bundles which arise directly from the ulna are inserted into the radius by means of an aponeurosis. The superficial and deep portions of the muscle are often separated. The muscle is thicker distally than proximally.

Nerve-supply.—The volar interosseous nerve descends along the interosseous membrane, passes behind the middle of the proximal margin of the muscle, and sends branches into its deep surface. The nerve fibers arise from the (sixth), seventh and eighth cervical and first thoracic nerves.

Action.—To pronate the forearm.

Relations.—The muscle lies immediately beneath the muscles of the third layer and upon the radius and ulna, the interosseous membrane, and radioulnar joint. The radial artery and ulnar nerve pass in front of it, the volar interosseous artery behind it.

Variations.—It may be missing or may extend further up the forearm than usual or down upon the carpus. It may be triangular or divided into parts the fiber-bundles of which take different directions. It may send fasciculi to the carpus or metacarpus or be fused with the flexor carpi radialis brevis (see below).

Abnormal Muscles of the Volar Side of the Forearm and Wrist

The epitrochleo-olecranonis (anconeus internus).—A muscle fasciculus, distinct from the distal margin of the triceps, which runs from the medial epicondyle to the olecranon over the groove for the ulnar nerve, by a branch of which it is supplied. It takes the place of the fibrous arch normally extending between the epicondylar and ulnar heads of the flexor carpi ulnaris. It occurs in about 25 per cent. of bodies (Testut), and represents an adductor of the olecranon of the lower mammals. Occasionally the medial head of the triceps may descend over the ulnar groove, but this forms another type of muscle variation.

The flexor carpi ulnaris brevis (ulnocarpeus).—An abnormal muscle which arises from the distal quarter of the volar surface of the ulna and is inserted in the hamatum (unciform) the pisiform, the abductor of the little finger, or the superior extremity of the fifth metacarpal.

The uncipisiformis.—A short, thick band of muscle which runs from the pisiform to the tip of the hamulus of the os hamatum (unciform) parallel with the pisohamate (pisounciform) ligament. It is innervated by the ulnar nerve.

The flexor carpi radialis brevis (radiocarpeus). An abnormal muscle found in about 5 per cent. of bodies (Le Double). It arises from the lateral or the volar surface of the distal half of the radius Some of the fiber-bundles may spring from the pronator quadratus, the fasciæ of the forearm, or the ulna. It is inserted into the carpus or metacarpus, and occasionally even into the first phalanx of the index finger, etc. It is supplied by a branch of the volar interosseous nerve. It serves to flex the wrist. It is said to represent the tibialis posterior of the leg.

Bursæ

B. m. flexoris carpi ulnaris.—Between the tendon of this muscle and the pisiform bone.

B. m. flexoris carpi radialis.—Between the tendon of this muscle and the tubercle of the navicular bone.

A bursa is often found between the tendon of the deep flexor of the index finger and the carpus. This bursa is frequently in communication with the radial and ulnar tendon-sheaths.

A bursa is also often found between the deep and superficial tendons of the index finger.

Synovial Tendon Sheaths
(Figs. 397 and 405)

Vagina tendinis m. flexoris carpi radialis.—About the tendon as it passes beneath the transverse carpal ligament.

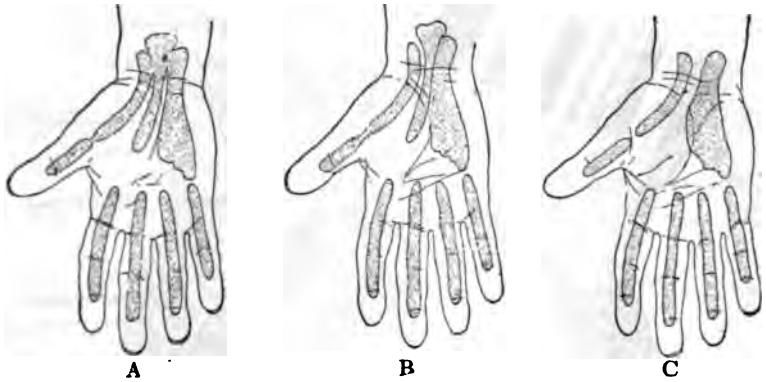
Vaginæ tendinum mm. flexorum digitorum.—The osteofibrous canals of the digits are lined by a synovial membrane which is reflected by means of a fold (cul-de-sac) to the tendons at each end and over the vincula tendinum, in which blood-vessels and nerves for the tendons are contained. The synovial cavity of the first and usually that of the fifth digit communicate with those of the palm.

In the wrist and palm two large synovial sacs may usually be recognized, although the number may be raised to five or reduced to one.

The radial sac, vagina tendinis m. flexoris pollicis longi, surrounds the long flexor tendon of the thumb in the wrist and palm and usually communicates with that of the thumb. In the palm a well-marked mesotendon usually extends to the deep ulnar side of the tendon from the parietal layer of the sheath.

The ulnar sac, **vagina tendinum mm. flexorum communium,** surrounds the tendons of the long flexors of the fingers. It begins proximal to the transverse carpal ligaments and extends nearly or quite to the synovial sheath of the little finger on the ulnar side and on the radial side to the center of the palm.

FIG. 405.—SYNOVIAL SHEATHS OF THE TENDONS OF THE LONG FLEXORS OF THE FINGERS. A. Frequent type; B. normal type; C. fetal type. (After Poirier and Charpy.)



3. MUSCULATURE OF THE HAND
(Figs. 397, 399, 406–410)

The intrinsic muscles of the hand are taken up in the following groups:—

a The subcutaneous muscle of the palm.
b The muscles of the little finger.
c The muscles of the thumb.
d The lumbrical muscles.
e The interosseous muscles.

The ulnar nerve supplies the muscles of the little finger, the interossei, the medial lumbrical muscles, and two of the muscles of the thumb; the median nerve supplies most of the muscles of the thenar region and the lateral lumbrical muscles.

(*a*) *Subcutaneous Muscle*
(Fig. 406)

The **palmaris brevis** is a small, trapezoid sheet situated between the hypothenar fascia and the skin. It arises at the lateral edge of the palmar aponeurosis from tendinous slips which may be traced through the aponeurosis to the navicular and greater multangular. It is composed of nearly parallel fiber-bundles, and extends into the deep surface of the skin along the ulnar border of the palm. It is generally taken to be a subcutaneous muscle like the superficial muscles of the head and neck. It has, however, been suggested that it represents the remnants of a short flexor of the digits corresponding with the flexor digitorum brevis of the foot.

Nerve supply.—The superficial branch of the palmar division of the ulnar nerve gives rise to a twig which enters the deep surface of the muscle. The fibers come from the (seventh and) eighth cervical and first thoracic nerves.

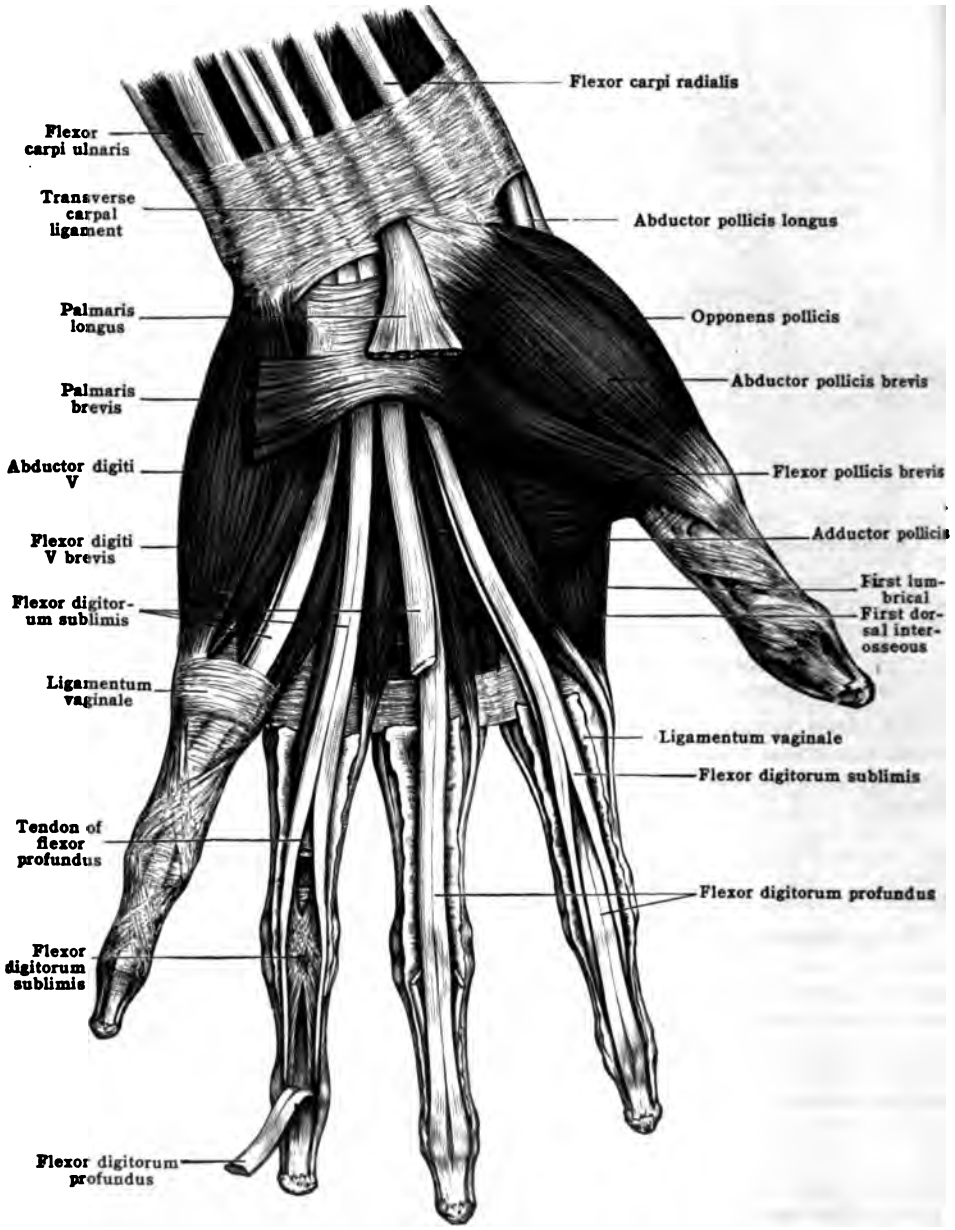
Action.—The action of the muscle is to draw the skin of the ulnar side of the hand toward the center of the palm. It is said that it thus helps to from a cup-shaped hollow when the hand conveys fluid to the mouth The contraction of the muscle by raising a ridge over the ulnar nerve and artery when an object is grasped hard serves, according to Henle, to protect these structures.

Variations.—It varies in size. In about 2 per cent. of bodies it is absent (Le Double). It may send tendinous slips to the pisiform bone. (For a thenar subcutaneous muscle, see variations of the abductor pollicis brevis.)

(*b*) *Muscles of the Little Finger*
(Figs. 406–408)

In the hypothenar eminence are three muscles, the abductor, the flexor brevis, and the opponens digiti quinti. The **abductor digiti quinti** is a flat, fusiform muscle which arises from the pisiform and is inserted into the ulnar border of the first phalanx and into the dorsal aponeurosis through which it helps to flex the

FIG. 406.—THE SUPERFICIAL MUSCLES OF THE PALM OF THE HAND.



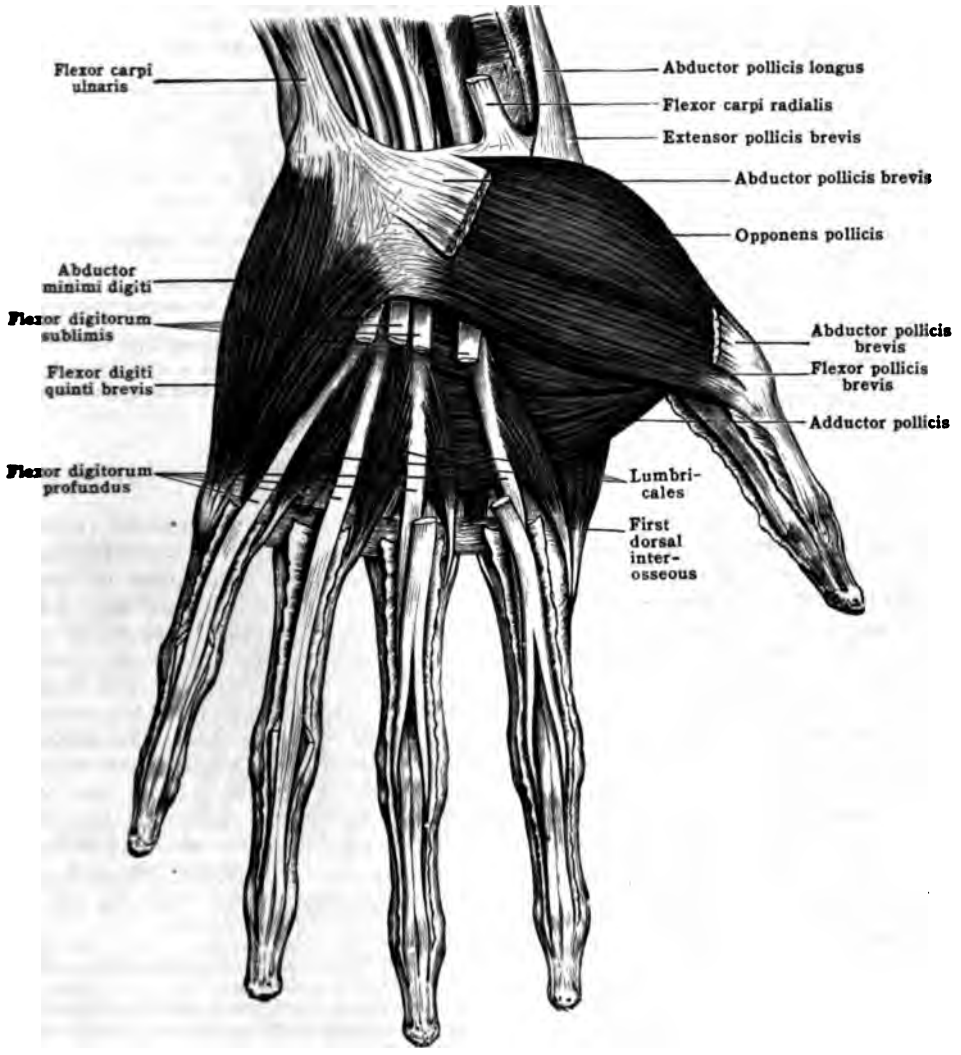
first and extend the second and third phalanges of the little finger. **The fusiform flexor brevis** arises from the hamatum (unciform) and adjacent part of the transverse carpal (anterior annular) ligament and is inserted into the ulnar side of the base of the first phalanx. The triangular **opponens** likewise arises from the hamatum (unciform) and the transverse (anterior annular) ligament. It is inserted into the ulnar border and the head of the fifth metacarpal.

The abductor of the little finger corresponds with that of the little toe. A part of the opponens beneath the ulnar nerve corresponds with that of the little toe, while the more superficial portion is unrepresented in the foot. The flexor brevis of the little toe corresponds with a part of the deep portion of the opponens of the little finger. The flexor brevis of the little finger is unrepresented in the foot. (Cunningham.)

The abductor digiti quinti (figs. 406, 407).—*Origin.*—From the distal half of the pisiform, the ligaments between this and the hamatum, the tendon of the flexor carpi ulnaris, and often from the transverse carpal (anterior annular) ligament.

Structure and insertion.—The fiber-bundles descend vertically, at first increasing in number and then concentrated, toward two short tendons one of which is inserted into the ulnar border of the first phalanx of the little finger and the other into the aponeurosis of the extensor tendon of the little finger.

FIG. 407.—THE DEEPER MUSCLES OF THE PALM OF THE HAND.



Nerve-supply.—From the deep palmar division of the ulnar nerve before it passes through the opponens, or from the superficial palmar branch, arise one or more twigs which enter the radial side of the muscle on its deep surface in the proximal third. The nerve fibers arise from the (seventh and) eighth cervical and first thoracic nerves.

Action.—To abduct the little finger, flex the first phalanx, and extend the last two.

Relations.—It overlies the opponens and flexor brevis. Superficially it is covered by fascia and the palmaris brevis muscle. Along the proximal part of its radial margin run the deep palmar branches of the ulnar artery and nerve.

Variations.—It may be missing or doubled. It may be fused with the short flexor or receive fasciculi from the palmaris longus, the ulnar flexor, the fascia of the forearm, etc.

The flexor digiti quinti brevis (figs. 407, 408).—*Origin.*—By a short tendon from the hook of the hamatum (unciform) and from the adjacent parts of the transverse carpal (anterior annular) ligament.

Structure and insertion.—The fiber-bundles take a nearly parallel course and are inserted by a short tendon which is fused with that of the abductor and is inserted into the ulnar side of the base of the first phalanx of the little finger. A sesamoid bone may lie in the tendon.

Nerve-supply.—A branch from the superficial or deep palmar division of the ulnar nerve enters the deep surface of the muscle in its proximal half. The nerves to the abductor and flexor may arise in common from the ulnar. The nerve fibers arise from the (seventh and) eighth cervical and first thoracic nerves.

Action.—To flex the first phalanx of the little finger. When it sends a tendon slip to the aponeurosis of the extensor of the finger it helps to extend the two terminal phalanges.

Relations.—The muscle closely adjoins and is partly covered by the abductor. The palmaris brevis and the lateral volar digital artery to the fifth finger lie superficial to it. Under it lies the opponens.

Variations.—The muscle may be wanting or may be closely fused with the abductor or the opponens. It may receive an accessory slip from the forearm fascia. It may give a tendon slip to the extensor aponeurosis or to the head of the fifth metacarpal.

The opponens digiti quinti (fig. 408).—*Origin.*—Partly tendinous, from the distal ulnar border of the hook of the hamatum (unciform) and from the adjacent transverse carpal (anterior annular) ligament.

Structure and insertion.—The fiber-bundles diverge, the proximal short and horizontal, the distal long and oblique, and are inserted on the whole of the ulnar border and on a part of the head of the fifth metacarpal. Often the muscle is divisible into two portions between which the ulnar nerve runs.

Nerve-supply.—Before the deep palmar branch passes through the muscle it gives rise to a twig which enters its volar surface in the middle third near the ulnar margin. The nerve fibers arise from the (seventh and) eighth cervical and first thoracic nerves.

Action.—To flex, adduct, and slightly rotate the fifth metacarpal; as, for example, in 'cupping' the hand to drink from it.

Relations.—The opponens lies beneath the abductor and flexor brevis muscles. The deep branches of the ulnar nerve and artery pass through the opponens near its carpal origin and then under it extend into the palm.

Variations.—It may be fused with neighboring muscles or receive accessory slips.

The **tensor capsularis articulationis metacarpophalangei digiti quinti** is a slender muscle which arises from the ligaments which unite the pisiform to the hamatum, and is inserted into the volar surface of the metacarpophalangeal joint of the little finger.

(c) *Muscles of the Thumb*
(Figs. 406–408)

In the thenar region there are four muscles. Of these, the **abductor pollicis brevis** is the most superficial. Then come the **opponens pollicis** and the **short flexor**, and beneath the last the **adductor pollicis**. All are **triangular in form.** The **abductor pollicis brevis** arises from the radial side of the **volar surface** of the carpus and is inserted into the radial side of the base of the **first phalanx** of the thumb. The **opponens** is a thick muscle extending from the **transverse carpal** (anterior annular) ligament to the radial side of the first **metacarpal.** The **flexor pollicis brevis** arises by two heads, a deep and a superficial, from the carpus and is inserted into the radial side of the base of the first phalanx. The **adductor pollicis** arises from the carpus and the second and third metacarpals and is inserted into the ulnar side of the first phalanx of the thumb. From the tendons of insertion of the abductor and flexor brevis slips are continued into the dorsal aponeurosis of the thumb so that they aid in extending the second phalanx.

In the foot an opponens hallucis occurs as an abnormal muscle. The abductor, flexor brevis and adductor of the thumb are represented by the corresponding muscles of the big toe, although the last two muscles are not perfectly homologous in the hand and foot.

The abductor pollicis brevis (fig. 406).—*Origin.*—From the volar surface of the transverse carpal (anterior annular) ligament, and from the greater multangular bone (trapezium). Also often from the navicular bone and from a tendon slip of the long abductor.

Structure and insertion.—The fiber-bundles converge upon a flat tendon with two lamellæ, the deeper of which is inserted into the radial side of the base of the first phalanx of the thumb and the superficial into the aponeurosis of the extensor pollicis longus.

Nerve-supply.—By a branch of the first volar digital ramus of the median nerve. This branch passes over or through the flexor brevis and enters the muscle on the volar surface in the middle third near its ulnar border.

Action.—To abduct the thumb, flex the first phalanx, and extend the terminal phalanx.

Relations.—It lies beneath the thenar fascia lateral to the superficial head of the flexor brevis and over the opponens. The superficial volar artery usually perforates the muscle.

Variations.—It may be wanting or may be divided into two divisions. The origin may extend to the fascia of the forearm or styloid process of the radius. It may receive an accessory slip from the long radial extensor, the opponens, or the short extensor of the thumb. A *thenar subcutaneous muscle* is occasionally present. It is narrow, is closely associated with the short abductor of the thumb, and extends from the radial side of the base of the first metacarpal into the skin of the thenar eminence.

The opponens pollicis (fig. 408).—*Origin.*—From the volar surface of the transverse carpal (anterior annular) ligament and from the tubercle of the greater multangular bone (trapezium).

Structure and insertion.—The fiber-bundles extend obliquely in a nearly parallel direction to their insertion along the whole lateral border of the volar surface of the shaft and the head of the first metacarpal.

Nerve-supply.—By a branch of the first volar digital ramus of the median nerve. This branch passes over or through the superficial division of the flexor brevis near the origin of the muscle. One or two twigs enter the deep surface of the proximal third of the oppponens near its ulnar border. The nerve fibers arise from the sixth and seventh cervical nerves.

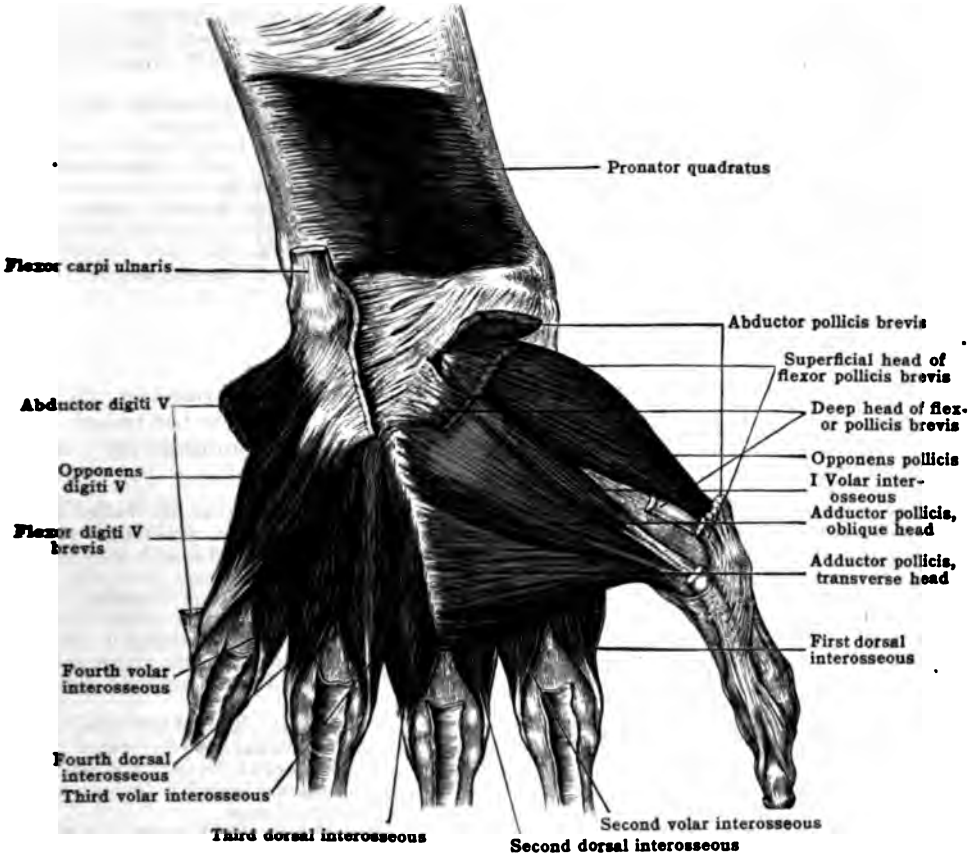
Action.—To flex, adduct, and rotate medialward the first metacarpal bone. The volar surface of the thumb is thus brought to face the volar surface of the other digits.

Relations.—It lies beneath the thenar fascia and the abductor brevis. The flexor brevis overlies its ulnar border.

Variations.—It may be absent or it may be divided into two heads. It is usually more or less fused with the short flexor.

The flexor pollicis brevis (figs. 407, 408).—The muscle is divided by the tendon of the long flexor into a superficial and a deep portion. The **superficial head** arises from the greater

FIG. 408.—THE PRONATOR QUADRATUS AND DEEP MUSCLES OF THE PALM.



multangular bone (trapezium), the adjacent part of the transverse carpal (anterior annular) ligament, and the tendon sheath of the flexor carpi radialis. The fiber-bundles descend closely applied to the opponens, and terminate by a tendon which is attached to the lateral side of the front of the base of the first phalanx. Over the joint a sesamoid bone lies in the tendon. The **deep head** has a tendinous origin from the os multangulum minus (trapezoid) and the os capitatum (magnum). The fiber-bundles take an oblique course, to be inserted into the tendon of the superficial part. A muscle fasciculus which arises from the ulnar side of the base of the first metacarpal and the neighboring carpal ligaments and is inserted on the ulnar side of the base of the first phalanx, is sometimes considered to be the deep head of the flexor brevis. It is closely bound up with the carpal head of the adductor pollicis and they have a common tendon. Some fibers of the medial division of the tendon may be traced into the aponeurosis of the extensor tendon. It is probable that this portion of the muscle represents a first volar interosseous, and it is so described later with the interosseous muscles. There is much dispute as to what fasciculi should be included in the flexor brevis.

Nerve-supply.—The muscle is usually supplied by twigs derived from a branch from the first volar digital ramus of the median nerve as this branch passes through its substance, and by twigs from the deep branch of the ulnar. Brookes found this supply in 19 out of 29 instances, in 5 by the median alone, and in 5 by the ulnar alone. The nerve fibers come from the sixth and seventh cervical nerves.

Action.—To flex, adduct, and rotate medialward the metacarpal of the thumb; flex the first phalanx; and extend the second phalanx.

Relations.—Proximally the short flexor is grooved for the tendon of the long flexor, beneath which more distally the deep head of the muscle passes laterally. The superficial portion of the muscle lies beneath the skin. The ulnar border of the deep head is fused proximally with the adductor.

Variations.—The deep head may be absent. Either or both heads may be double. The superficial head may be fused with the abductor brevis, and is usually more or less fused with the opponens.

The adductor pollicis (fig. 408).—*Origin.*—By two heads. The **carpal or oblique head** arises from the deep carpal ligaments, the capitatum and the bases of the second and third metacarpals; the **metacarpal or transverse head,** from the crest of the third metacarpal, from the suprametacarpal fascia of the third interspace, and sometimes also from that of the fourth interspace and from the capsules of the second, third, and fourth metacarpo-phalangeal articulations.

Structure and insertion.—The fiber-bundles converge toward a tendon which is inserted into the ulnar side of the front of the base of the first phalanx of the thumb. A sesamoid bone lies in the tendon over the joint.

Nerve-supply.—One or more twigs from the deep palmar branch of the ulnar enter the middle third of the muscle on its deep surface. There may also be an anastomosing branch from the median nerve. The nerve fibers come from the sixth, seventh and eighth cervical and first thoracic nerves.

Action.—To adduct and flex the first metacarpal and flex the first phalanx of the thumb. When the thumb is in an extreme position of apposition, it acts as an abductor.

Relations.—Superficial to the muscle lie some of the tendons of the deep flexor of the fingers and the first two lumbrical muscles. It extends over the two more lateral intermetacarpal spaces, and is in part subcutaneous on the dorsal surface. The deep volar arch extends between the two heads and beneath the oblique head. The oblique head of the muscle is closely united to the first volar interosseous, so that the latter by some is considered a part of the adductor.

Variations.—The extent of the attachments of origin of the muscle vary considerably. The two heads of the muscle may be more or less completely separated from one another. Each may be divided into separate fasciculi.

(*d*) *Lumbrical Muscles*

From the deep flexor tendons in the palm of the hand arise the lumbrical muscles, four in number, which are attached by small tendons to the radial side of the extensor tendons (figs. 404, 407, 408). These lumbrical muscles have homologues in the sole of the foot.

The lumbricales (figs 406, 407).—*Origin.*—The two lateral arise from the radial side of the volar aspect of the first and second tendons of the flexor digitorum profundus; the two medial arise from the adjacent sides of the second and third andthird and fourth tendons.

Structure and insertion.—The fiber-bundles of each muscle arise directly from the flexor tendons near the distal border of the transverse carpal (anterior annular) ligament. They converge as far as the metacarpophalangeal joint, upon a small tendon which begins about the middle of the muscle. The tendon passes out between the palmar aponeurosis and the transverse capitular ligament, winds about the metacarpophalangeal joint, expands, and is attached along the side of the first phalanx to the radial border of the tendon of the extensor digitorum communis.

Nerve-supply.—Branches from the median nerve enter the middle third of the radial border of the first two or three lumbrical muscles. The last one or two are supplied by branches from the deep volar branch of the ulnar nerve, which enter the middle third of the deep surface. The third lumbrical and sometimes one or more of the others may receive a branch from both nerves. The nerve fibers come from the eighth cervical and first thoracic nerves.

Action.—Together with the interosseous muscles they flex the basal phalanges on the metacarpal bones and extend the terminal and middle phalanges. They also adduct the fingers toward the thumb.

Relations.—The muscles run between the tendons of the flexor profundus and beneath the palmar aponeurosis. They lie upon the fascia covering the interosseous muscles, the capitular ligaments, and the septum over the adductor and deep head of the flexor pollicis brevis.

Variations.—These are very frequent, especially in case of the third and fourth. Each may be doubled or missing. They may arise from the tendons of the flexor sublimis or from the belly of the deep flexor. The first lumbrical may come from the tendon of the long flexor, from the opponens, or the metacarpal of the thumb. The tendon of insertion may go to the ulnar side of the base of the digit opposite that to which the tendon is usually attached, or the tendon may divide and go to the adjacent sides of two fingers. Kopsch has found that in 110 bodies all four lumbricals were inserted on the radial side of their respective digits in 39 per cent. In 35 per cent. the first, second, and fourth were so inserted, while the third sent slips to the adjacent sides of the middle and ring fingers. An accessory fasciculus has been found to arise from the tendon of the flexor pollicis longus and go to the base of the index finger.

(*e*) *Interosseous Muscles* (figs. 408–410)

These muscles lie between the metacarpal bones and are covered dorsally and ventrally by fasciæ attached to the metacarpals. In each interspace are two mus-

a dorsal and a volar (palmar). The volar interossei are inserted into all the rs except the middle finger, and are adductors toward an axis passing through middle finger; the dorsal interossei are inserted into both sides of the middle r and into the radial side of the second and the ulnar side of the fourth finger, are abductors. All also serve as flexors of the first row of phalanges and sors of the second and third. In the foot the axis to and from which the osseous muscles adduct and abduct the toes passes through the second toe.

FIG. 409.—THE VOLAR INTEROSSEI.

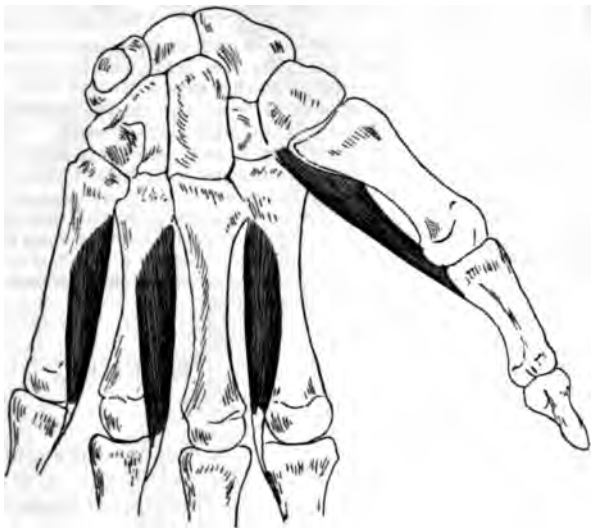


FIG. 410.—THE DORSAL INTEROSSEI.

e **interossei volares** arise from the sides toward the middle finger and the front of the of the first, second, fourth, and fifth metacarpals. The first arises from near the base, the from three-fourths of the shaft. The fiber-bundles of each muscle converge in a penni- manner upon a tendon which is inserted into the aponeurosis of the digital extensor tendon e base of the first phalanx on the middle finger side of the corresponding digit (see fig. 404) rst volar interosseous is often described as a division of the flexor pollicis brevis or of the tor pollicis.

The interossei dorsales arise from the adjacent sides of the metacarpal bones in each interspace. On the sides nearest the middle finger they cover three-fourths of the bone, on the opposite sides much less. The fiber-bundles converge in a bipenniform manner upon a tendon which begins high in the muscle and is inserted into the aponeurosis of the extensor muscle and the base of the first phalanx on each side of the middle finger, on the thumb side of the index finger, and the ulnar side of the ring finger. The interosseous muscle in the first interspace is thick and strong and forms with the adductor pollicis the fleshy web between the base of the thumb and the palm.

Nerve-supply.—By branches of the deep volar division of the ulnar nerve. As a rule, a branch to each volar interosseous enters the proximal third of the muscle. To each dorsal interosseous a branch is given which enters between the two heads. These branches may be variously combined before entering the interosseous muscles. The nerve fibers arise from the eighth cervical and first thoracic nerves.

Action.—To move the fingers toward the radial and ulnar sides, to flex the first phalanx and extend the second and third. The volar interossei move the fingers toward the median axis of the middle finger in repose, the dorsal from this axis.

Relations.—The volar interossei lie volarward from the dorsal interossei. The two sets of muscles are bound in place by the dorsal and volar metacarpal fasciæ. The tendons pass out on the dorsal side of the transverse capitular ligament and are closely applied to the metacarpophalangeal joints. The muscles of the first two interspaces lie immediately dorsal to the adductor of the thumb; the others dorsal to the flexor tendons.

Variations.—The tendon-slip from an interosseous muscle to the base of the first phalanx of a digit may be missing. This is more frequent in case of the volar than in that of the dorsal interossei, and in the medial than the lateral muscles. Either a volar or a dorsal interosseous muscle may be double or missing. Rarely the insertions of the interosseous muscles characteristic of the foot (see p. 531) may be found in the hand.

III. SPINAL MUSCULATURE

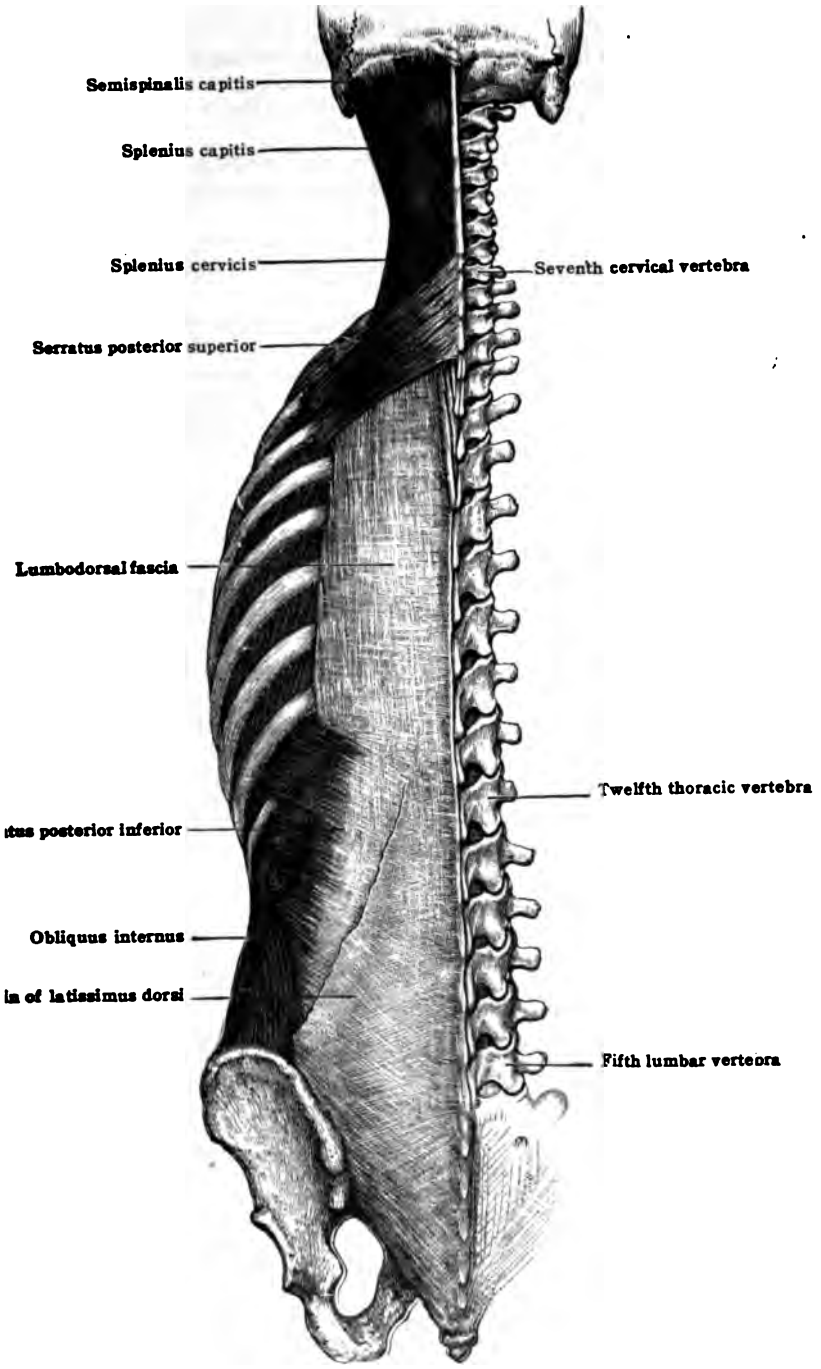
(Figs. 411–414)

The spinal (vertebral) column is of special interest as the segmented longitudinal axial support of the body which has given rise to the term 'vertebrates' as applied to the group of animals of which man is the highest form. The segmentation in fishes permits the lateral movements of the body which are their chief means of propulsion. In the land-vertebrates, with the exception of snakes, the limbs are developed as the chief organs of propulsion but flexibility of the column is retained for the sake of freedom of movement. In man the spinal column, with the exception of the sacral region, may be readily extended (bent backward) and flexed (bent forward), abducted (bent to the side) and rotated. Freedom of movement is greatest in the cervical and lumbar region and is restricted by the thorax in the thoracic region. The cervical region allows considerable flexion, extension and rotation, but a more limited abduction. In the thoracic region rotation and abduction are freer than flexion and extension. The lumbar region is that in which the chief flexion and extension of the trunk takes place, but abduction and rotation are limited, especially the latter. In the isolated articulated spinal column freedom of movement of the various parts depends chiefly upon the thickness and elasticity of the intervertebral disks, upon the conformation of the articular processes, and upon the elasticity or arrangement of the various ligaments uniting the vertebræ. In the living body freedom of movement is further restricted by the musculature and skeletal apparatus attached to the column. There is much individual variation in the flexibility of the vertebral column.

The various movements of the column are produced partly by muscles which act directly on it and partly by muscles which act on it through the head, thorax or pelvis. Most of the muscles which act on it directly belong to the intrinsic dorsal musculature; that is, to musculature which is derived from the dorsal divisions of the myotomes and is innervated by the dorsal divisions of the spinal nerves. This musculature extends from the sacrum to the skull and is closely applied on each side of the middorsal line of the body to the backs of the vertebræ and the back of the thorax (fig. 412). Its chief function is to extend the spinal column and head, hence the old term applied to the superficial portion of this musculature 'erector spinæ.' During the development of the body, muscles belonging to the ventrolateral thoracic musculature and to the upper extremity come to overlie in part the intrinsic dorsal musculature. The trapezius and rhomboid muscles which cover it in the cervical and thoracic regions, and the latissimus dorsi which covers it in the thoracic and lumbar regions belong to the shoulder girdle and arm and have already been described, p. 382. The serratus posterior superior, which overlaps it in the upper thoracic region, and the serra-

erior inferior, which overlaps it at the junction of the thoracic and lumbar are derived from the intercostal musculature which is described later, p. 411). All of these muscles are innervated by the ventrolateral divisions pinal nerves. The levatores costarum (fig. 414), which extend from the

FIG. 411.—THE THIRD AND FOURTH LAYERS OF THE MUSCLES OF THE BACK. (INTRINSIC DORSAL MUSCULATURE)



se process of the thoracic vertebræ to the ribs, and which, in spite of their ct chiefly on the spinal column, are derived from the external intercostal ture and are innervated by the intercostal nerves.

Ventral to the spinal column and closely applied to it there are a few muscles the chief function of which is to flex the column. All are supplied by branches from the ventrolateral divisions of the spinal nerves. Of these the *longissimus colli* and *longissimus capitis* and *scalene* muscles have been described in connection with the muscles of the neck, p. 388. In the thoracic region there are no muscles of this type. In the lumbar region there are four muscles on each side, the pillars of the *diaphragm*, the *psoas minor*, the *psoas major* and the *quadratus lumborum* (figs. 422, 437). All of these muscles are flexors of the spine, except the quadratus, which is an extensor. The psoas major muscle is also a flexor of the thigh. Even more powerful flexors of the column than those above mentioned are some of those which work indirectly upon it through the leverage o ered by the skull (sterno-cleidomastoid described above, p. 382), and the thorax (the ventrolateral abdominal musculature).

Abduction and rotation of the spine are produced by contraction of muscles on one side while the corresponding muscles on the other side are relaxed. See Table, p. 536.

In the present section we shall confine our attention to the intrinsic dorsal musculature, leaving for consideration elsewhere the other musculature which acts on the vertebral column.

The **intrinsic dorsal musculature** is attached to the sacrum, to the ilium, to the spines, transverse, and articular processes and laminæ of the lumbar, thoracic, and cervical vertebræ, to the backs of the ribs and to the base of the skull. Two great longitudinal subdivisions may be recognized, a **lateral,** supplied by lateral branches of the posterior divisions of the spinal nerves, and a **medial,** supplied by medial branches. The lateral portion is further divisible into a **superficial division,** including the splenius and sacrospinalis, consisting chiefly of systems of muscles extending laterally from the spines of the vertebræ upward toward the transverse processes of the vertebræ, the ribs, and the mastoid process of the skull; and a **deep division,** the dorsal intertransverse muscles, extending between successive transverse processes. The medial portion likewise consists of two parts: a **superficial medial** (spinalis dorsi and cervicis) composed of fasciculi extending from inferior to superior spines, best developed in the dorsal region; and a **deep portion** (semispinalis capitis, transversospinal and interspinal), consisting mainly of muscle fasciculi which pass from the transverse processes upward toward the spines of vertebræ situated more cranially. In the neck the more superficial extend to the base of the skull.

Between the base of the skull and the first two vertebræ there are several specialized muscles. There is also frequently present the rudimentary *sacrococcygeus posterior* described on p. 481, which represents an extension into the caudal region of the intrinsic dorsal musculature.

The primitive condition of the dorsal musculature is one of metameric segmentation. This is characteristic of fishes, many amphibia, and of the embryos of all higher vertebrates. In the tailless amphibia, however, a partial differentiation of the dorsal musculature takes place during embryonic development, and in all higher forms a differentiation takes place which corresponds in many ways to that described above for man. According to Favaro, the splenius is differentiated from the medial dorsal system, but its innervation should place it with the lateral system. In the human embryo the dorsal segmental musculature extends into the tail region, but afterward here undergoes retrograde metamorphosis.

The **fasciæ** and the general relations of the muscles of the back may be followed in the cross-sections shown in figs. 378, 382, 388, 415, and 438.

The **tela subcutanea** of the upper dorsal region has been described in connection with the muscles of the shoulder girdle (p. 382). It is thick, fibrous, and adherent. In the lower dorsal region it is somewhat less compact, but is thicker and contains more fat. It is usually divisible into two layers, of which the deeper is adherent to the lumbodorsal fascia.

The splenius (fig. 411) is enveloped in a thin, adherent fascial covering. The sacrospinalis is covered by a fascia, the **fascia lumbodorsalis** (fig. 411), which inferiorly is attached to the iliac crest, the distal and lateral margins of the sacrum, and the sacral spines. In the lumbar and thoracic regions it is attached medially to the vertebral spines. Laterally, in the lumbar region, it is reflected around the muscle to its ventral surface, where a 'ventral' or 'deep' layer forms an intermuscular septum (fig. 415) between the quadratus lumborum and the sacrospinalis. This ventral layer (fig. 414) extends from the twelfth rib to the iliac crest and the iliolumbar ligament, and is attached medially to the transverse processes of the lumbar vertebræ, from which fiber-bands extend laterally into it. It is strengthened above by fiber-bundles which pass from the first and second lumbar vertebræ to the twelfth rib (lumbocostal ligament). (For the relation of the abdominal muscles to this fascia see p. 459.)

In the thoracic region (fig. 415) the lumbodorsal fascia is attached to the ribs lateral to

the iliocostal muscle. In the cervical region (fig. 382) the fascia is continued into the intermuscular septa which surround the muscles of this group in the neck.

The *transversospinal muscles* are covered throughout their extent by a fascial membrane which serves to separate them from the longissimus in the sacral, lumbar, and thoracic regions.

In the dorsal region of the neck (figs. 378, 382, 388) the muscles are covered on each surface by adherent fascial sheets, **fascia nuchæ**, and are arranged in several concentric layers, each of which is separated from its neighbors by dense fatty areolar tissue. The deepest of the layers is formed by the muscles of the transversospinal group. This is covered by a dense membrane, and is separated from the semispinalis capitis (complexus) by a thick layer of areolar tissue containing the chief blood-vessels and nerves of the neck. The semispinalis capitis (complexus) is covered on each surface by a more delicate adherent membrane, and is separated from the splenius by loose tissue. The splenius has a somewhat denser adherent fascial covering into which the fascia of the levator scapulæ is continued. Separated from this by areolar tissue lies the trapezius. The cervical and thoracic portions of the semispinalis are separated by delicate membranous septa from the semispinalis capitis (complexus), the levator scapulæ, and the splenius. The muscles of each side are separated in the dorsal median plane by the dense ligamentum **nuchæ**, into which the various cervical septa and fasciæ extend. The suboccipital muscles are covered by fascial sheaths which are so fused as to constitute a special fascia for these muscles. Distally this is continued into the fascia of the transversospinal muscles.

MUSCLES

A. Superficial Lateral Dorsal System

The splenius (fig. 411).—The two parts of which this muscle is composed may be separately considered.

The splenius cervicis.—*Origin.*—By a narrow aponeurotic band from the spinous processes and the supraspinous ligament of the third to the sixth thoracic vertebræ.

Structure and insertion.—The fiber-bundles extend upward and laterally and give rise to a flat muscle sheet from which fasciculi arise that are inserted by short tendinous processes on the posterior tubercles of the transverse processes of the first two or three cervical vertebræ. The processes are often united with those of the levator scapulæ and the longissimus cervicis.

The splenius capitis.—*Origin.*—From the ligamentum nuchæ in the region of the third to the seventh cervical vertebræ and from the spinous processes and the supraspinous ligament of the first two to five thoracic vertebræ.

Structure and insertion.—The fiber-bundles form a sheet which continues cranialward that of the splenius cervicis. The fiber-bundles converge somewhat and are inserted by a short, broad, thick tendon into—(1) the back, the side, and the tip of the mastoid process below the sternocleidomastoid muscle, and (2) into the neighboring part of the occipital bone.

Relations.—The splenius lies dorsal to the semispinalis capitis (complexus) and to the cervical (transversalis cervicis) and the cranial (trachelomastoid) portions of the longissimus and the cervical portion (cervicalis ascendens) of the iliocostalis and to the levator scapulæ, and is partly covered by the trapezius, sternocleidomastoid, serratus posterior superior, and the rhomboids. In the triangle bounded by the trapezius, sternocleidomastoid, and the levator scapulæ it is subcutaneous.

Nerve-supply.—The lateral branches of the posterior divisions of the second, third and fourth (sometimes also of the first, the fifth and the sixth) cervical nerves give off rami which enter the deep surface of the muscle.

Action.—To incline and rotate the head and neck toward the side on which the muscle is placed. When both muscles act, the head and neck are extended.

Variations.—The extent of separation and of fusion of the two muscles varies. Absence of either muscle is rare. The splenius capitis may be divided into mastoid and occipital portions. The attachment of the muscle also varies somewhat. Occasionally the spinal origin of the splenius may extend to the cranial end of the ligamentum nuchæ. The origin may extend laterally over the fascia covering the deeper dorsal muscles. An accessory slip, the **splenius cervicis accessorius**, separated from the main muscle by the tendon of the serratus posterior superior, is frequently (8 per cent. of instances, Le Double) found to run from the lower cervical or upper thoracic vertebræ to the transverse process of the atlas.

The sacrospinalis (erector spinæ), (figs. 412, 413).—*Origin.*—(1) From a strong aponeurosis attached to the spines of the lumbar, and the sacral vertebræ, to the ligament passing from the sacrum to the coccyx, to the lateral sacral crest, the sacrotuberous ligament, the long posterior sacroiliac ligament, and to the dorsal fifth of the iliac crest; (2) directly from the iliac crest in front of and lateral to the attachment of the aponeurosis; and (3) from the short posterior sacroiliac ligaments. The aponeurosis covers the muscles of the sacral region and is there united to the overlying fascia by more or less dense areolar tissue. Opposite the iliac crest fiber-bundles begin to take origin from the lateral margin of the dorsal surface as well as from the deep or ventral surface of the aponeurosis of origin, and gradually the line of dorsal attachment extends medially until, in the lower thoracic region, the tendon becomes completely embedded in the muscle-fasciculi which take their origin from it. The aponeurosis, which is the strongest in the lower lumbar region, is composed chiefly of fibers which take a direction upward and somewhat lateralward.

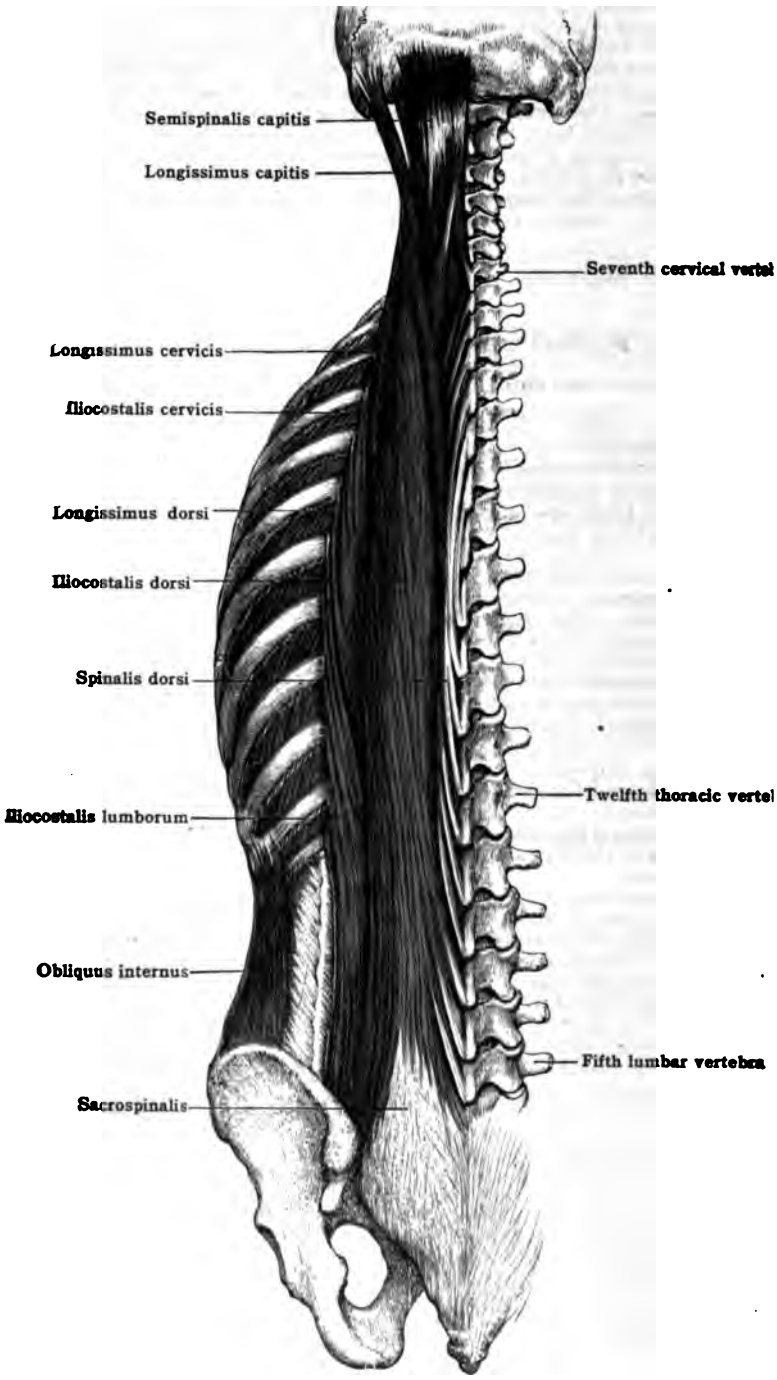
In the lower lumbar region the sacrospinalis (erector spinæ) muscle begins to show a distinct division into its two chief component parts, the iliocostalis and the longissimus. The parts of which the iliocostalis and longissimus are composed will be taken up separately.

The iliocostalis lumborum (figs. 412, 413).—*Origin.*—(1) Chiefly from the back of the sacrospinal aponeurosis, medial to and cranialward from the iliac crest, and (2) from the iliac

crest directly. The deep medial surface of the muscle is closely united in the lumb to the longissimus.

Structure and insertion.—From the mass of fiber-bundles which compose the m ciculi are given off which are attached chiefly by tendinous slips to—(1) the tips of the processes of the lumbar vertebræ; (2) the fibrous processes which extend lateralward

FIG. 412.—THE FIFTH LAYER OF THE MUSCLES OF THE BACK.



tips of the transverse processes of the upper lumbar vertebræ into the anterior l lumbodorsal fascia; (3) the inferior margin of the last six or seven ribs near the angle sertions into the lumbodorsal fascia and the twelfth rib are usually fleshy. The tached to the lumbar vertebræ are by some considered to belong to the longissim

Relations.—The muscle lies on the lateral margin of the longissimus and upon t

the external intercostal and levatores costarum muscles, and under the axioappendicular muscles described above.

The iliocostalis dorsi (accessorius).—*Origin.*—By fleshy fasciculi from the superior borders of the lower seven ribs medial to the angles.

Structure and insertion.—The slips of origin lie beneath the preceding portion of the muscle, pass medial to and partly fuse with it, and give rise to a belly from which tendinous slips extend to be inserted into the upper seven ribs near their angles and to the transverse process of the seventh cervical vertebra.

Relations.—The muscle lies upon the ribs and the external intercostal muscles lateral to the longissimus.

The iliocostalis cervicis (cervicalis ascendens).—*Origin.*—By fleshy slips from the upper borders near the angles of the seventh to the third (sometimes to the second or first) ribs.

Structure and insertion.—The slips of origin are covered by the slips of insertion of the dorsal portion (accessorius). They emerge medial to them and give rise to a fleshy belly from which tendons pass to the backs of the transverse processes of the sixth to the fourth cervical vertebræ.

Relations.—The scalenus posterior lies in front, the levator scapulæ at the side, and the splenius and longissimus (transversalis) cervicis medial to this muscle.

A *bursa* is frequently found between the muscle and the tubercle of the first rib.

The longissimus dorsi (figs. 412, 413).—*Origin.*—(1) From the deep surface of the sacrospinal aponeurosis; (2) from the short posterior sacroiliac ligaments; and (3) through accessory slips which arise from the transverse processes of the first two lumbar and the last five or six thoracic vertebræ. In the lumbar region it is fused dorso-laterally with the iliocostalis.

Structure and insertion.—From the muscle mass arise fasciculi which are inserted partly directly, partly by means of tendons, into—(1) the lower border of the back of the transverse processes of the lumbar vertebræ and the inferior margins of the ribs lateral to the tubercles; and (2) the accessory tubercles of the lumbar and the tips and inferior margins of the transverse processes of the thoracic vertebræ. The attachment to the first rib is usually wanting. The attachment to the first five ribs may fail. The medial attachments seldom extend to the first vertebra.

Relations.—The lateral margin of the muscle is covered by the iliocostalis. Medially it overlies the transversospinal muscles. The lateral branches of the dorsal veins, arteries, and nerves pass mainly in the fibrous tissue which separates the longissimus from the iliocostalis, the medial branches chiefly between the longissimus and the transversospinal muscles. The relations to the axioappendicular muscles and to the dorsal fascia have been pointed out above. Ventrally it lies upon the intertransverse muscles, the external intercostals, and the levatores costarum.

The longissimus cervicis (transversalis cervicis).—*Origin.*—By tendinous slips from the transverse processes of the first four to six thoracic vertebræ.

Structure and insertion.—The fasciculi which arise from these slips give rise to a muscle belly from which tendons of insertion extend to the posterior tubercles of the transverse processes of the mid-cervical (second to sixth) vertebræ.

Relations.—This muscle lies between the longissimus dorsi and capitis with which it is to some extent fused and the iliocostalis dorsi (accessorius) and cervicis (cervicalis ascendens) muscles.

The longissimus capitis (trachelomastoid).—*Origin.*—By tendinous slips from the transverse processes of the first three or four thoracic vertebræ and the articular processes of the last four cervical.

Structure and insertion.—The muscle fasciculi arising from these tendons form a belly which is united to the mastoid process by a short tendon. A tendinous inscription often crosses the muscle.

Relations.—It lies ventral to the splenius capitis, lateral to the semispinalis capitis (complexus) and medial to the longissimus cervicis (cervicalis ascendens).

Nerve-supply of the sacrospinalis.—From the lateral branches of the posterior divisions of the spinal nerves. The exact distribution of these branches is too complex to be treated here. The nerves for the iliocostalis arise from the eighth cervical to the first lumbar, those for the longissimus from the first cervical to the fifth lumbar.

Action of the sacrospinalis.—The sacrospinalis serves, when acting on one side, to bend the spinal column toward that side, and when acting on both sides, to extend the spinal column. The cranial portions of this musculature incline the head and neck and rotate them toward the side on which they lie, and when both muscles act they extend the head and neck. The iliocostalis muscle has the greatest power for producing lateral inclination. The iliocostalis lumborum depresses the ribs, while the iliocostalis cervicis (cervicalis ascendens) may aid in elevating them. The spinalis muscle serves merely as an extensor.

Variations of the sacrospinalis.—The slips of origin and insertion of the various parts of this muscle and the extent of fusion of the various parts vary greatly. Statistical data from which the most frequent conditions might be determined are wanting. Tendinous inscriptions may extend across the longissimus cervicis and other parts of the sacrospinalis.

B. Deep Lateral Dorsal System

The intertransversarii (figs. 383, 414).—These are vertical bands composed of short bundles which pass between the transverse processes of the cervical, lumbar, and the lower thoracic vertebræ.

(a) *Cervical* (fig. 383).—Ventral, lateral and dorsal muscles are found in the cervical region. The ventral and lateral muscles run between the ventral tubercles and tips of the transverse processes of the vertebræ, are homologous with the intercostal muscles, are supplied by branches from the anterior divisions of the corresponding spinal nerves, and have been described above (p. 390). The dorsal muscles run between the dorsal tubercles and belong to the intrinsic

dorsal musculature. They are supplied by the lateral branches of the posterior divisions of the cervical nerves. (According to Lickley, both sets of cervical intertransverse muscles are supplied by the anterior divisions of the spinal nerves.) The three sets of muscles are, however, more or less fused. The first pair of muscles extends between the atlas and axis, the lowest passes to the transverse process of the first thoracic vertebra, or to the first rib close to this. The *obliquus capitis superior* (described later) belongs, however, to the posterior set of muscles, the *rectus capitis lateralis* (p. 391) to the lateral set. The vertebral artery runs vertically between each pair of muscles above the sixth, and the anterior division of each cervical nerve passes laterally between the artery and the dorsal muscle in each space, and then out between the ventral and lateral muscles. The posterior division of each cervical nerve passes medial to each dorsal muscle.

(b) *Thoracic.*—Small muscle fasciculi may extend between the transverse processes of the thoracic vertebræ and between the last thoracic and first lumbar. They are most frequent in the upper and lower thoracic regions. Often they are replaced by tendinous bands. In the second interspace the insertion may extend to the rib near the transverse process. The innervation is from the lateral branches of the posterior divisions of the spinal nerves.

(c) *Lumbar* (fig. 414).—In the lumbar region there is a lateral set of muscles connecting the adjacent margins of the transverse processes and a medial connecting the mammary tubercle of one vertebra to the mammary or the accessory tubercle of the vertebra next above. They extend between each two of the five lumbar vertebræ and sometimes also to the first sacral. They lie between the sacrospinalis and psoas muscles. The medial muscles are supplied by the lateral branches of the posterior divisions of the spinal nerves. The lateral muscles are supplied by branches from the junction between the two divisions of the corresponding spinal nerves. These branches probably belong to the anterior divisions.

Action.—The intertransverse muscles bend the vertebral column laterally, and when acting on both sides, make it rigid.

Variations.—The number of intertransverse spaces occupied by the muscles varies, especially in the thoracic region. They may be doubled or extend over more than one interspace.

C. Superficial Medial Dorsal System

The spinalis dorsi (fig. 412).—*Origin.*—By tendinous bands from the tips of the two upper lumbar and the last two thoracic spines.

Structure and insertion.—From the deep surface of the tendinous bands there arises a long slender muscle belly which is fused laterally with the longissimus dorsi. It is inserted by tendinous processes to the spines of the upper thoracic vertebræ, usually the second or third to the ninth.

Nerve-supply.—From the medial divisions of the sixth to ninth thoracic nerves.

The spinalis cervicis.—A muscle of inconstant development which arises from the spines of the two upper thoracic and two lower cervical vertebræ and extends to the spines of the second to the fourth cervical vertebræ. The nerve supply is from the dorsal divisions of the lower cervical nerves.

Action.—To extend the vertebral column.

Variation.—There is great variation in the development of the spinalis muscles. Similar fasciculi are sometimes found in the lumbar region and in the cervical region sometimes extend to the skull.

D. Deep Medial Dorsal System

1. *Vertebro-occipital Muscle*

The semispinalis capitis (complexus) (fig. 412).—This muscle is usually separated from the semispinalis muscles of the back and neck by a well-marked septum and has a distinctive structure.

Origin.—(1) By long tendinous fasciculi from the tips of the transverse processes of the upper five or six thoracic vertebræ and of the seventh cervical vertebra; (2) by short fleshy processes from the articular processes and bases of the transverse processes of the third to the sixth cervical vertebræ; and (3) by delicate fleshy fasciculi from the spinous processes of the upper thoracic vertebræ.

Structure and insertion.—The slightly diverging fiber-bundles form a long, flat belly which is inserted, partly by means of an aponeurosis which covers the muscle laterally, into the lower surface of the squamous portion of the occipital, between the superior and inferior nuchal lines. There is often a transverse tendinous inscription across the muscle opposite the sixth cervical vertebra, and less frequently one between the upper and middle thirds of the muscle. These are best marked in the medial portion of the muscle, which comes from the thoracic vertebræ and is sometimes separately designated as the *spinalis capitis* (*biventer cervicis*).

Nerve-supply.—It is supplied chiefly by the medial branches of the posterior divisions of the first four or five cervical nerves. The muscle also gets some twigs from the lateral branches.

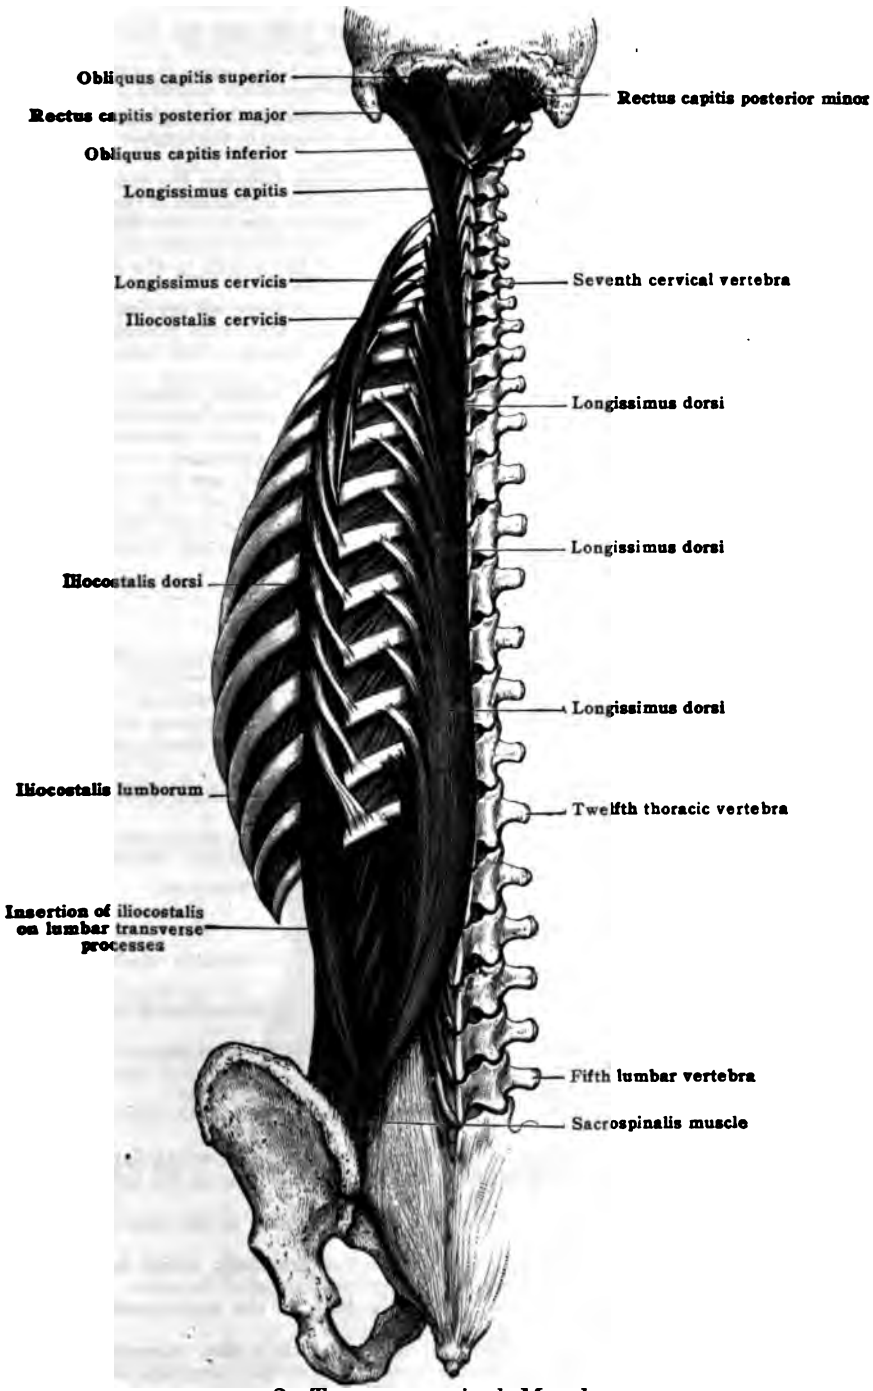
Relations.—It lies dorsolateral to the suboccipital muscles and to the semispinalis cervicis. From this latter it is separated by a septum containing the descending branch of the occipital artery, the deep cervical artery, and the medial dorsal branches of the cervical nerves. It is covered laterally by the longissimus capitis (trachelomastoid), and dorsally by the splenius, and above the upper margin of the splenius by the trapezius.

Action.—To extend the head and to incline it slightly toward the same side.

Variations.—The origin of the muscle may extend to the eighth thoracic vertebra or merely to the first thoracic. It may be fused with the longissimus (transversalis) cervicis. A special

fasciculus may run beneath the muscle from the upper thoracic vertebræ to the head. The origin from the spinous processes of the thoracic vertebræ is not constant. The part of the muscle arising from this origin may be looked upon as a spinalis capitis.

FIG. 413.—THE FIFTH LAYER OF THE MUSCLES OF THE BACK, AFTER SEPARATING THE LONGISSIMUS AND ILIOCOSTALIS DIVISIONS.



2. *Transversospinal Muscles*

The semispinalis dorsi et cervicis (fig. 414).—This superficial transversospinal muscle sheet extends from the twelfth thoracic to the second cervical vertebra. The fasciculi which compose it arise by short tendons from the backs of the transverse processes, and are inserted by short tendons into the spines.

The semispinalis dorsi.—*Origin.*—From the sixth to the tenth or twelfth thoracic vertebræ.

Insertion.—The upper four to six thoracic and the last two cervical vertebræ. The fasciculi extend over four to six vertebræ.

Nerve-supply.—Third to sixth thoracic.

The semispinalis cervicis.—*Origin.*—From the upper five or six thoracic vertebræ.

Insertion.—Into the fifth to the second cervical vertebræ. The fasciculi extend over four to five vertebræ.

Nerve-supply.—Third to sixth cervical.

Relations.—This muscle lies beneath the longissimus dorsi and the semispinalis capitis (complexus) and over the following musculature.

Variations.—A semispinalis lumborum is a muscle rarely found extending from the lumbar to the lower thoracic vertebræ.

The multifidus (fig. 414).—This second layer of transversospinal musculature extends from the sacrum to the second cervical vertebra. It is best developed in the lumbar region and least so in the thoracic.

Origin.—(1) From the groove on the back of the sacrum between the spines and the articular elevations, from the dorsal sacroiliac ligaments, from the dorsal end of the iliac crest, and from the deep surface of the aponeurosis of the sacrospinal muscle; (2) from the mammary and accessory processes of the lumbar vertebræ; (3) from the backs of the transverse processes of the thoracic vertebræ; and (4) from the articular processes of the fourth to the seventh cervical vertebræ and the back of the transverse process of the seventh.

Insertion.—Spinous processes of the lumbar, thoracic, and lower six cervical vertebræ.

Structure.—The more superficial fasciculi arise by short tendinous processes, the deeper ones directly. The more superficial fasciculi extend to the fourth or fifth vertebra above, the middle to the third, and the deepest to the second above.

The rotatores.—These, the third layer of transversospinal muscles, extend from the sacrum to the second cervical vertebræ. They are composed of short fleshy fasciculi which extend to the second vertebra above (*rotatores longi*) and to the first above (*rotatores breves*). The fasciculi arise from the back and upper borders of the transverse processes or their homologues, and are inserted into the laminæ of the preceding vertebræ. They are best developed in the thoracic region. Some authors consider the rotatores breves confined to the thoracic region. In the cervical region the fasciculi usually run from articular processes to the bases of the spines, in the lumbar region from the mammary processes to the caudal margin of the laminæ of the arches.

3. *The Interspinal Muscles*

The **interspinales** consist of short fasciculi which extend from the upper surface of the spine of each vertebra near its tip to the lower surface of the spine of the vertebra above. In the neck the muscles lie in pairs between the bifid extremities of the vertebræ. In the lumbar region they form broad bands attached to the whole length of the spinous processes and are separated by the interspinous ligaments. In the thoracic region they usually are undeveloped.

NERVE SUPPLY AND ACTION OF MEDIAL DORSAL MUSCLES

These muscles are all supplied by the medial branches of the posterior divisions of the spinal nerves. They extend the vertebral column when acting on both sides. When acting on one side, they produce a movement of rotation toward the opposite side.

E. Suboccipital Muscles
(Figs. 413, 414)

The rectus capitis posterior major.—*Origin.*—From the upper surface of the spine of the epistropheus.

Structure and insertion.—The muscle-fibers diverge to form a broad triangular band which is inserted into the lateral half of the inferior nuchal line of the occipital bone and the area below it. Its insertion is immediately below that of the obliquus superior.

The rectus capitis posterior minor.—*Origin.*—From the upper part of the side of the posterior tubercle of the atlas.

Structure and insertion.—The fiber-bundles diverge to form a flat, triangular sheet inserted below the medial third of the inferior nuchal line of the occipital bone on the inferior surface of the squama occipitalis.

The obliquus capitis inferior.—*Origin.*—From the upper part of the side of the spine of the epistropheus (axis).

Structure and insertion.—The fiber-bundles form a fusiform belly which is inserted by a short tendon into the lower part of the tip of the transverse process of the atlas.

The obliquus capitis superior.—*Origin.*—From the back of the upper part of the transverse process of the atlas.

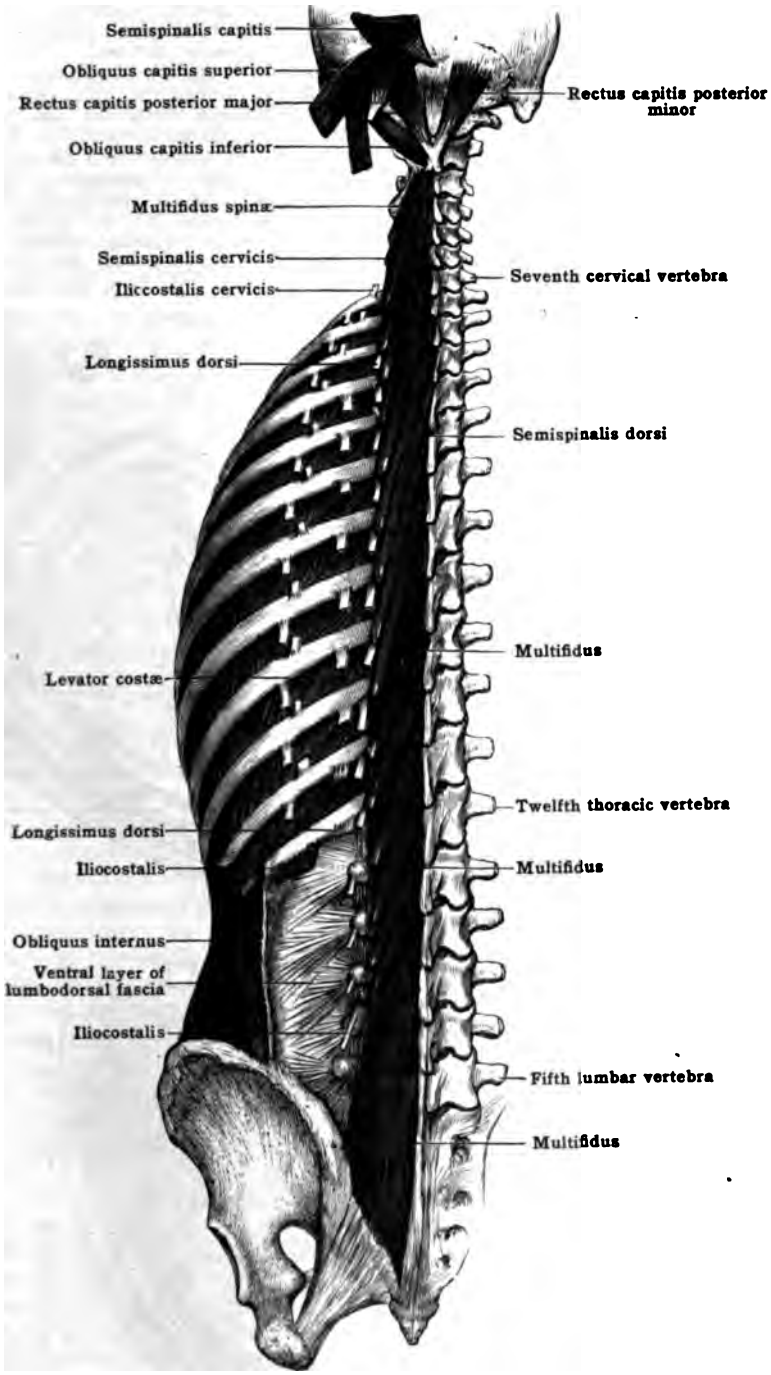
Structure and insertion.—The fiber-bundles diverge to form a flat, triangular muscle, inserted into the lateral third of the inferior nuchal line of the occipital bone, and above the lateral part of the insertion of the rectus capitis posterior major.

Nerve-supply.—These muscles are all supplied by the posterior branch of the suboccipital (first cervical) nerve. The branch to the two rectus muscles passes across the dorsal surface of the major rectus and supplies branches to the middle of the dorsal surface of each muscle. The branch to the superior oblique muscle enters the middle of the medial margin, that to the inferior oblique about the middle of its superior margin. The inferior oblique and major

rectus muscles usually, the other muscles occasionally, receive branches from the second cervical nerve.

Relations.—The two oblique muscles with the rectus major serve to bound a small triangular space, the suboccipital triangle, through which pass the dorsal division of the suboccipital nerve and the vertebral artery. The two minor recti lie on the atlanto-occipital

FIG. 414.—THE TRANSVERSOSPINAL MUSCLES.



membrane in the upper part of the space bounded by the major recti. The muscles are covered medially by the semispinalis capitis (complexus), laterally by the longissimus and splenius capitis. In front of the two oblique muscles and the major rectus runs the vertebral artery. The great occipital nerve runs between the semispinalis capitis (complexus) and the inferior oblique and the two recti in a dense fatty connective tissue containing the extensive suboccipital venous plexus.

FIG. 415, A and B.—SECTIONS THROUGH THE LEFT SIDE OF THE TRUNK IN THE REGIONS SHOWN IN THE DIAGRAM.

The muscles of the body wall have been slightly pulled apart in order to reveal the relations of muscles, fasciæ, and aponeuroses. *a* and *b* in the diagram indicate sections A and B, fig. 382; a^1 and b^1, sections A and B, fig. 388; a^2 and b^2, sections A and B, fig. 438.

Vert. thoracalis X.

Action.—The rectus muscles and the superior oblique draw the head backward. The ctus major and the inferior oblique, when acting on one side, rotate the face toward that side.
Variations.—Each of these muscles may be doubled by longitudinal division. Accessory ps may connect the two recti with the semispinalis capitis. The **atlantomastoid** is a small uscle frequently found. It passes from the transverse process of the atlas to the mastoid ocess.

IV. THE THORACOABDOMINAL MUSCULATURE

The thoracic and abdominal viscera are contained within cavities, the ventro- teral walls of which may be contracted and expanded by muscular action. The eletal support for the intrinsic musculature of these walls consists of the ribs, e sternum and the vertebral column and the pelvis. The intrinsic musculature the thoracic walls is situated chiefly between the ribs (*intercostal muscles*, figs. 6, 417) while in the region of the abdomen it extends in broad sheets from the wer part of the thorax to the pelvis (the *quadratus lumborum* and the *external* id *internal oblique*, *transverse*, and *rectus* muscles, figs. 418, 420, 421, 437). Be- ween the two cavities, attached to the lower part of the thorax and to the lumbar rtebræ lies the dome-shaped diaphragm (fig. 422). The thoracic cavity ex- nds on each side slightly above the first rib. The abominal cavity extends ownward and backward into the pelvis, as the pelvic cavity.

The function of the intercostal muscles is to expand and contract the thoracic vity for the sake of respiration. The shape of the ribs and their articulations ith the vertebræ are such that a slight rotation of the neck of each rib will cause e shaft to swing outward and upward or in the reverse direction. The costal rtilages are elastic enough to permit this movement, and at the same time are rong enough to make the thorax an effective skeletal apparatus. Ninety joints e called into play in the movements of the thorax (24 between the heads of e ribs and the vertebræ, 20 between the tuberosities and the transverse pro- sses of the vertebræ, 24 between the ribs and costal cartilages, 14 between the stal cartilages and the sternum, 6 between the costal cartilages and 2 intraster- al). When the shafts of ribs are swung outward and upward the thorax is en- rged in the anteroposterior and transverse axes. In the adult when standing ie sternum may be raised nearly 3 cm., and protruded 1 cm. The cartilages the lower ribs may be raised 4 to 5 cm. The sides of the thorax at the level the second rib may be protruded 3 cm., and at the level of the eighth rib nearly far. This extent of movement, however, is found only in forced respiration. n ordinary quiet respiration it is far less, the sternum being raised merely 3 or mm., and protruded 2 mm., and the thorax is enlarged at the sides merely 5 mm. R. Fick). The chief muscles used in quiet inspiration are the external intercostals nd the intercartilaginous parts of the internal intercostals.

During inspiration the diaphragm contracts so that the thoracic cavity is rther enlarged perpendicularly. The extent of movement of the upper part f the diaphragm is estimated by R. Fick at from $1\frac{1}{2}$—3 cm.

The ventrolateral abdominal muscles contract the thoracic cavity by depress- ig the thorax and by pushing the diaphragm upward. They directly contract ie abdominal cavity. Contraction of the abdominal cavity is of aid in defe- ation and parturition. The abdominal muscles are also of value in flexion, bduction, and rotation of the vertebral column and pelvis.

The thorax, with its intrinsic musculature, is in large part covered by the uusculature which extends from the trunk to the shoulder girdle and arm; orsally by the trapezius and rhomboids, ventrally by the pectoral muscles, and terally by the serratus anterior and the latissimus dorsi, as well as by the sca- ula and the muscles which pass from it to the humerus. The upper extremity n each side is largely supported from the spine by the trapezius, rhomboid and vator scapulæ muscles but it none the less exerts some pressure on the thorax nd interferes to some extent with respiration. If the girdle and arm are fixed raised the muscles which pass from them to the thorax are an aid in forced in- piration. Advantage of this is taken when in artificial respiration the arms are ised so as to lift the ribs through traction by the latissimus dorsi, the pectoralis uscles and the subclavius. Some of the muscles of the neck, especially the scalene uscles and the sternocleidomastoid, are likewise of value in forced inspiration.

Expiration is produced not only by the part of the internal intercostals

which lie between the bony ribs, and by the abdominal muscles, but also by the lumbar iliocostales and by the quadratus lumborum.

The intrinsic muscles of the thorax and abdomen are derived from the twelve thoracic myotomes and the first one or two lumbar and are innervated by the corresponding nerves, while the musculature of the shoulder girdle and arm which covers the intrinsic muscles of the thorax is of cervical origin and is innervated by cervical nerves. The diaphragm is likewise of cervical origin and is innervated by the phrenic nerve from the cervical plexus.

The intrinsic muscles of the back extend over the thoracic musculature (external intercostals and levators of the ribs, fig. 414) and in turn are in part covered by muscles which extend dorsally from the thoracic region (posterior serrate muscles, fig. 411).

The intrinsic thoracoabdominal muscles are composed laterally of three layers of sheet-like muscles.

In the **external layer** the fiber-bundles run downward and ventralward. This layer is represented in the thoracic region by the external intercostal muscles, the levators of the ribs and the posterior serrate muscles. The fiber-bundles of the **external intercostals** (fig. 416), extend between each pair of ribs but between the costal cartilages are replaced by fibrous tissue, the *external intercostal ligaments*. The **levatores costarum** (fig. 414), extend from the transverse process of one vertebra to the rib which articulates with the next vertebra below and in some instances the fiber-bundles are continued to the second rib below.

The **serratus posterior superior and inferior** (fig. 411), are derivatives of the external oblique which during development wander in part over the intrinsic dorsal musculature. The *superior serrate* arises from the spines of the last two cervical and first two thoracic vertebræ and is inserted into the second to the fifth ribs. The *inferior serrate* muscle arises from the spines of the last two thoracic and first two lumbar spines and is inserted into the last four ribs. The fiber-bundles of this muscle therefore take a direction opposite to that of the other muscles of the group. These muscles aid in inspiration. In the abdominal region the external layer is represented by the **external oblique** muscle (fig. 418). This arises by digitations from the last seven ribs and is inserted into the crest of the ilium and by means of a broad flat aponeurosis into the linea alba in the midventral line and into the inguinal ligament below. The external intercostal, levatores costarum, and posterior serrate muscles are innervated from branches which arise near the tubercles of the ribs. The external oblique muscles are innervated by branches which in large part arise in conjunction with or from the lateral branches of the anterior divisions of the last seven thoracic nerves and frequently also by branches from the iliohypogastric.

The **middle layer** of the lateral thoracoabdominal musculature is composed of fiber-bundles which run downward and backward obliquely across the fiber-bundles of the external layer. In the thoracic region it is represented by the internal intercostal and subcostal muscles. The **internal intercostal** (fig. 416) muscles lie between the costal caritlages and between the ribs as far dorsalward as the angles, beyond which they are replaced by membranous tissue and by the **subcostal muscles.** The latter, instead of extending from one rib to the next rib below, extend to the second or third rib below. They are best developed in the lower part of the thoracic cavity. In the abdominal region the middle layer is represented by the **internal oblique muscle** (fig. 419). This arises from the lumbodorsal fascia, the crest of the ilium and the inguinal ligament and is inserted into the sheath of the rectus abdominis muscle and into the inferior margins of the ventral extremities of the three lower ribs. The aponeurosis, which helps to form the sheath of the rectus, divides in the upper abdominal region into two layers, one of which passes in front and the other of which passes behind the rectus to be inserted into the linea alba in the midventral line. In the lower third of the ventral abdominal wall both layers pass in front of the rectus. The fiber-bundles which compose the internal oblique muscles do not all follow the usual course of the fiber-bundles of this layer. At the level of the iliac crest they pass nearly transversely across the body and below here they slant downward and forward. Just above the inguinal ligament and medial to its center the internal oblique muscle is continuous with the thin **cremaster muscle** (fig. 420), which is prolonged over the spermatic cord and the tunica vaginalis of the testis and epididymis in the male and over the ligamentum teres in the female. The cremaster muscle is attached laterally

the inguinal ligament, medially to the outer layer of the sheath of the rectus ar the insertion of the latter.

The **inner layer** of the thoracoabdominal musculature is composed of fiber-ndles which take a course transversely across the body. In the thoracic region is represented by the **transversus thoracis** (fig. 417), a slightly developed muscle hich arises from the costal cartilages of the third to sixth ribs and is inserted into he lower part of the sternum and into the xiphoid process. In the upper portion f the muscle the fiber-bundles extend obliquely downward and forward instead of transversely. In the abdomen this layer is represented by the **transversus abdominis** (fig. 421) which arises from the cartilages of the lower seven ribs, from the lumbodorsal fascia, the iliac crest and lateral part of the inguinal ligament and is inserted into the linea alba by means of an aponeurosis which lies behind the rectus in the upper two-thirds of the ventral wall of the abdomen and in front in the lower third. It is intimately fused with the aponeurosis of the internal oblique.

The main trunks of the anterior divisions of the last five or six thoracic nerves give rise to branches which supply the muscles both of the middle and inner layers f the lateral thoracoabdominal musculature. In the abdominal region these runks run in the main between the two layers. Some muscular branches are sually also supplied from the iliohypogastric and ilioinguinal nerves. In the oracic region the intercostal nerves run external to the subcostal muscles, rough the substance of the costal part of the internal intercostal muscles, and ternal to the parts of the internal intercostals which lie between the costal rtilages. Eisler includes the subcostal muscles and that part of the internal tercostals which lies internal to the nerve trunk, with the inner rather than with e middle layer of the thoracic musculature.

The ventral part of the muscular thoracoabdominal wall is represented by a gle muscle on each side, the rectus abdominis muscle, except just above the mphysis pubis where the rudimentary pyramidalis is usually found. The **rectus dominis muscle** (fig. 419), is a band-like muscle which arises from the ventral rfaces of the fifth to the seventh costal cartilages and from the xiphoid process d is inserted into the superior ramus of the pubis. It is ensheathed by the oneuroses of the lateral abdominal musculature described above. The compo-nt fiber-bundles run nearly parallel with the midsagittal line. Transverse scriptions partially divide the muscles into segments. It is innervated by the t six or seven thoracic nerves. The **pyramidalis** (fig. 419) is a small muscle hich arises from the superior pubic ramus and is inserted into the linea alba for out a third of the distance to the umbilicus.

The lateral intertransverse muscles of the lumbar region described on p. 449 obably belong to the ventrolateral musculature of the trunk. The nerves pplying them come from the junction between the posterior and anterior visions of the spinal nerves.

The inguinal (Poupart's) ligament and the **inguinal canal** (fig. 420), described detail below, are of considerable practical interest because of the frequency of rnias in this region. In the quadrupeds the pressure of the weight of the ab-minal viscera centers toward the umbilicus while in man it centers toward the ntral part of the line of attachment of the abdominal wall to the pelvis. The wer margin of the aponeurosis of the external oblique muscle is here strength-ed to form the inguinal (Poupart's) ligament which extends from the anterior-perior iliac spine to the pubic tubercle. Near the latter it is reflected (curves edialward) to the pubic crest forming the triangular **lacunar ligament** (Gimber-t's). The medial half of the inguinal ligament helps to bound a slit-like space, **guinal canal,** through which in the male the spermatic cord passes to the scrotum, d in the female, the round ligament passes to the labium majus. This canal gins on the inner side at the (internal) abdominal ring, which is situated above d medial to the center of the inguinal ligament. The canal, which is about 4 n. long, extends medialward and downward to the subcutaneous (external dominal) ring, a slit-like opening in the aponeurosis of the external oblique just ove the inguinal ligament. The canal is bounded ventrally by the aponeurosis the external oblique and the cremaster muscle, below by the reflected portion the inguinal ligament, dorsally by the transversalis fascia and above by the ansversus, internal oblique, and cremaster muscles.

The **quadratus lumborum** (fig. 437), which extends from the twelfth rib to the ilium and iliolumbar ligament, is supplied by direct branches of the lumbar nerves in series with the nerves supplying the musculature of the abdominal wall. It will, therefore, be taken up with the intrinsic thoracoabdominal muscles. It depresses the thorax and abducts and extends the spine. The **psoas muscle**, on the other hand, which also lies at the back of the abdominal cavity, represents an extension of the intrinsic musculature of the limb to the spinal column (see p. 487).

The **diaphragm** (fig. 422), a dome-shaped muscle which is attached to the lower margin of the thorax and to the upper lumbar vertebræ, and separates the thoracic and abdominal cavities, arises in the embryo in the region of the neck, and maintains cervical relations through its innervation by the phrenic nerves, which spring one on each side usually from the third to fifth cervical nerves. It does not belong morphologically with the other muscles considered in this section, but is here included because of its physiological and anatomical relations and the convenience of treating it in connection with the intrinsic thoracoabdominal muscles. A diaphragm completely separating the thoracic from the abdominal cavities is found only in the mammals. The central portion of the diaphragm is an aponeurosis or central tendon with a convex ventral and concave dorsal margin. Into this tendon is inserted the musculature which arises on each side from the xiphoid cartilage, the cartilages and tips of the last six or seven ribs and by means of three crura from the sides of the first four lumbar vertebræ.

In fishes and tailed amphibians the musculature of the body wall is composed of metamerically segmented musculature. In all higher vertebrates it is likewise at an early embryonic stage segmental, being composed of the ventrolateral portions of the myotomes. The ventral ends of the myotomes give rise to a ventral longitudinal muscle which runs on each side of the body next the midline in front, and retains more or less of the primitive segmentation. The rectus abdominis and the infrahyoid muscles represent this system in man. Very frequently traces of the system may also be seen on the upper thoracic wall in the form of slender muscular and aponeurotic slips. The rectus muscle in man is usually developed from the last seven thoracic myotomes. The pyramidalis becomes split off from its lower end. The lateral part of the ventrolateral portions of the thoracic myotomes usually gives rise to several strata of muscles which vary somewhat in different vertebrates, although quite similar among the mammals. In man the twelve thoracic and first two lumbar myotomes give rise to the lateral musculature of the thoracoabdominal wall.

The quadratus lumborum represents the ventrolateral portions of the lumbar myotomes with the exception of that portion of the first two which enter into the lateral abdominal musculature and of the fifth, which probably undergoes retrograde metamorphosis.

It will be noted that the abdominal wall is composed of musculature which has an origin chiefly from the thoracic myotomes. At an early stage of embryonic development both the thoracic and the abdominal viscera are covered by a non-muscular membrane. The myotomes extend into this from the thoracic region, and as the musculature is differentiated, it approaches the median line in front and extends distally to the pelvis. Owing to the rotation of the limbs the abdominal musculature is stretched ventrally over an area corresponding to the lumbar and sacral regions dorsally. The last part of the thoracoabdominal wall to be furnished with musculature is that about the umbilicus. Occasionally the process fails to be completed in this region.

Each spinal nerve supplies primarily the musculature derived from the myotome which lay caudal to it, and at first the musculature lies wholly superficial to the nerves. With subsequent differentiation the metamerism is somewhat obscured by anastomosis of nerves and fusion of myotomes; and a part of the internal oblique layer and all the transverse layer of the lateral musculature comes to lie on the inner side of the main nerve-trunks.

The **fasciæ** and the topographical relations of the thoracoabdominal muscles may be followed in the sections shown in figs. 388, 415, and 438.

FASCIÆ

Tela subcutanea.—As mentioned above, most of the intrinsic thoracic musculature is covered by other muscles, while the superficial layer of the abdominal musculature is subcutaneous. A panniculus adiposus, **Camper's fascia**, in which much fat may be deposited is usually easily distinguishable, especially in the lower part of the ventral wall of the abdomen, from a membranous fascial sheet which is loosely attached to the underlying fascial envelopment of the muscles. To this membrane has been applied the term **Scarpa's fascia**. Near the groin it is separated from the panniculus adiposus by blood-vessels and lymphatic glands. It is closely bound to the linea alba between the two rectus muscles, to the fibrous structures in front of the pubic bone, to the fascia lata below the inguinal ligament, and to the crest of the ilium.

Over the scrotum of the male and vulva of the female both layers of the tela subcutanea are continued. In the male the fat of the more superficial layer disappears and the two layers blend with the fundiform (suspensory) ligament and fascia of the penis and the dartos and septum of the scrotum.

scle fasciæ and sheaths.—The posterior serrate muscles (fig. 411) are enveloped by two
nt layers of an aponeurotic sheet that extends as a single membrane between them and is
ed lateralward to the ribs and medialward to the spines of the thoracic vertebræ. The
rane between the muscles may represent the rudiment of a primitive continuous muscle
s is found in some lower vertebrates. This membrane may usually be easily separated
he aponeurosis of the latissimus dorsi on its superficial surface and the lumbodorsal fascia

part attached to the ribs and in part are fused to form a membrane which becomes ad-
to the deep surface of the latissimus dorsi in the thoracic region and to the lumbodorsal
in the lumbar region.

e internal oblique muscle and the transversus abdominis have similar membranous
ngs which are fused to the aponeuroses of origin and insertion of these muscles. The
ranes on the muscles are, however, much more delicate than that of the external oblique.
or less fusion between the two muscles with disappearance of the membranes covering
posing surfaces takes place, especially in the lower part of the abdominal wall. The super-
nuscle fasciæ of the external oblique and the fasciæ of the internal oblique are continued
ie thin *cremasteric fascia* which covers the cremasteric muscle, spermatic cord and testis.

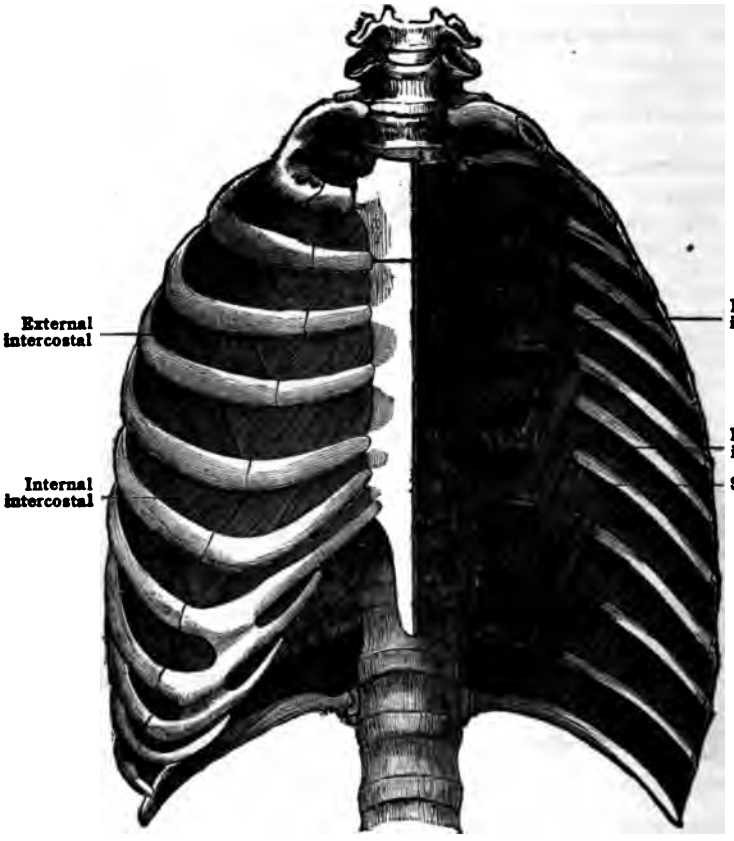
e diaphragm is covered on each surface by a more or less well-marked adherent membrane.

e **transversalis fascia** is a thin membrane which lies external to the peritoneum of the ab-
al wall. It covers the peritoneal surface of the transversus muscle and its aponeurosis.
ally it is continued across the median line internal to the rectus abdominis. In the lum-
gion the fascia divides at the lateral margin of the quadratus lumborum (fig. 415), one
of it passing dorsal to this muscle to be attached to the lumbodorsal fascia. The other
extends over the ventral surface of the quadratus and becomes fused with the psoas

Proximally the transversalis fascia becomes fused with the fascial membrane adherent
diaphragm. In the region of the iliac fossa the transversalis fascia is reflected from the
ersus muscle to the iliopsoas fascia, with which it usually becomes fused. Sometimes,
er, it may be traced as a very delicate membrane over the iliac artery and vein. As
essels pass below the inguinal ligament a process from the transversalis fascia is usually
ed into their sheath.

The sheath of the rectus (figs. 415, 438) is formed externally in the upper portion of its extent by the aponeurosis of the external oblique which fuses below the costal margin with the external layer of the aponeurosis of the internal oblique. In the lower portion of the abdomen this fusion takes place nearer the linea alba than in the upper portion. In the lower third of its extent the rectus is covered ventrally by the fused aponeuroses of the two oblique muscles conjoined with that of the transversus. Internally the rectus is covered in the upper two-thirds of the abdomen by the inner layer of the aponeurosis of the internal oblique conjoined with that of the transversus and by the transversalis fascia. In the lower third of the abdomen the aponeurosis of the internal oblique, together with that of the transversus, passes in front of the rectus, leaving the rectus in this portion of its abdominal surface covered merely by the transversalis fascia and the peritoneum. The line which marks the lower limit of the dorsal ensheathment of the rectus by the aponeurosis of the transversus muscle is called the linea semicircu-

FIG. 417.—THE MUSCLES ATTACHED TO THE BACK OF THE STERNUM.



laris, or fold of Douglas. Between the transversalis fascia and the rectus just above the pubis there is a space filled with loose connective tissue or with fat.

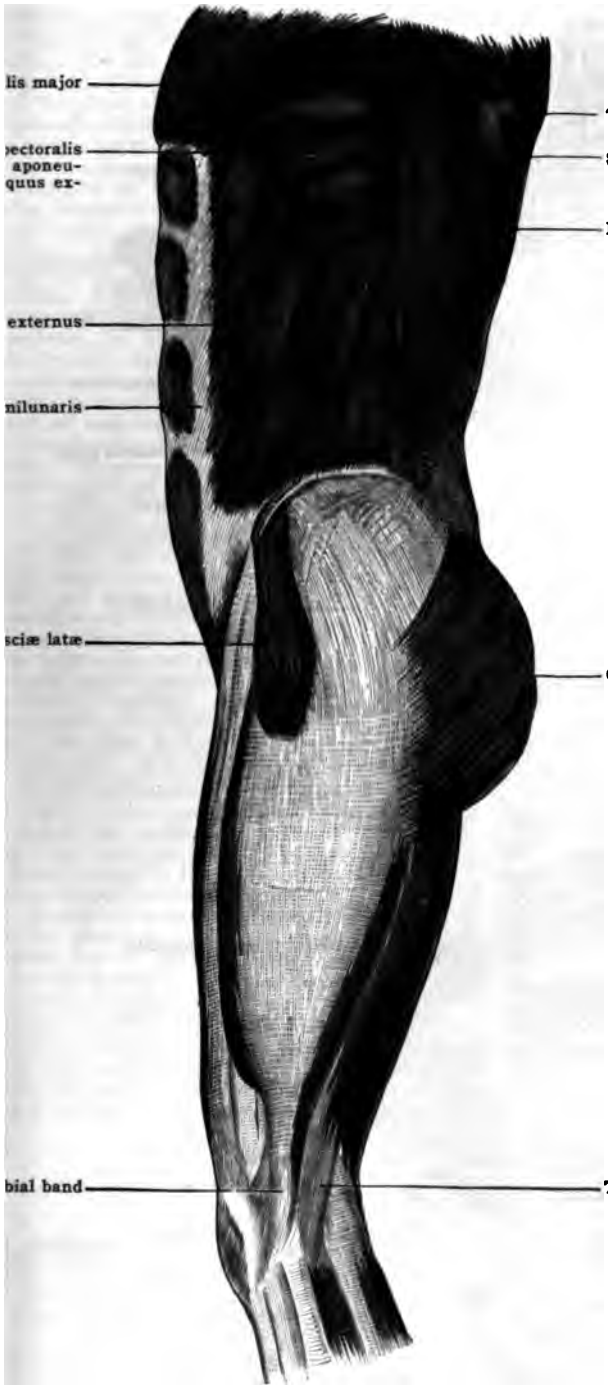
The pyramidalis lies beneath the ventral layer of the sheath of the rectus. From the latter it is sometimes separated by a distinct fascial layer.

Between the rectus muscles of each side the investing aponeuroses are firmly united into a dense tendinous band, the linea alba (figs. 415B, 420). This is broadest opposite the umbilicus. Above this it gradually grows narrower toward the xiphoid process to the ventral surface of which it is attached. Hagenton has shown that the linea alba varies much in width. It is relatively wide in fat people and in fetuses. From the tip of the xiphoid process it is often separated by a bursa. Toward the symphysis pubis it extends as a narrow line. Just above the symphysis it divides to be attached on each side to the tubercle (spine) of the pubis. Behind it broadens into the *adminiculum lineæ albæ* which is attached on each side to the pubis. The linea alba is composed mainly of the interlacing of the fibers which pass into it from the aponeurotic sheaths of the rectus abdominis. From it and Scarpa's fascia, a few centimeters above the symphysis, there arises a broad elastic band, the *fundiform ligament* (superficial suspensory ligament) of the penis, which sends a fasciculus on each side of the penis. Below the penis these fasciculi unite. At the umbilicus there is a circular opening encircled by dense fibrous tissue and filled with a thick connective tissue, extending from the tela subcutanea to the subserosa.

The *ventral layer of the lumbodorsal fascia* and its relations to the abdominal muscles also merit attention. This lies between the intrinsic dorsal musculature and the quadratus lumborum muscle and extends from the twelfth rib to the iliolumbar ligament. It is strengthened by the lumbocostal ligament, which extends between the transverse processes of the first and

ar vertebræ and the twelfth rib, and by fibrous processes which extend into it sverse processes of the lumbar vertebræ to which it is attached. With the lateral s ventral layer the dorsal layer of the lumbodorsal fascia is fused. The dorsal f the transversus muscle is united to the lumbodorsal fascia at the line of junction l and dorsal layers. The internal oblique muscle, covered externally by a fascia

FIG. 418.—SUPERFICIAL MUSCULATURE OF ABDOMEN AND THIGH.

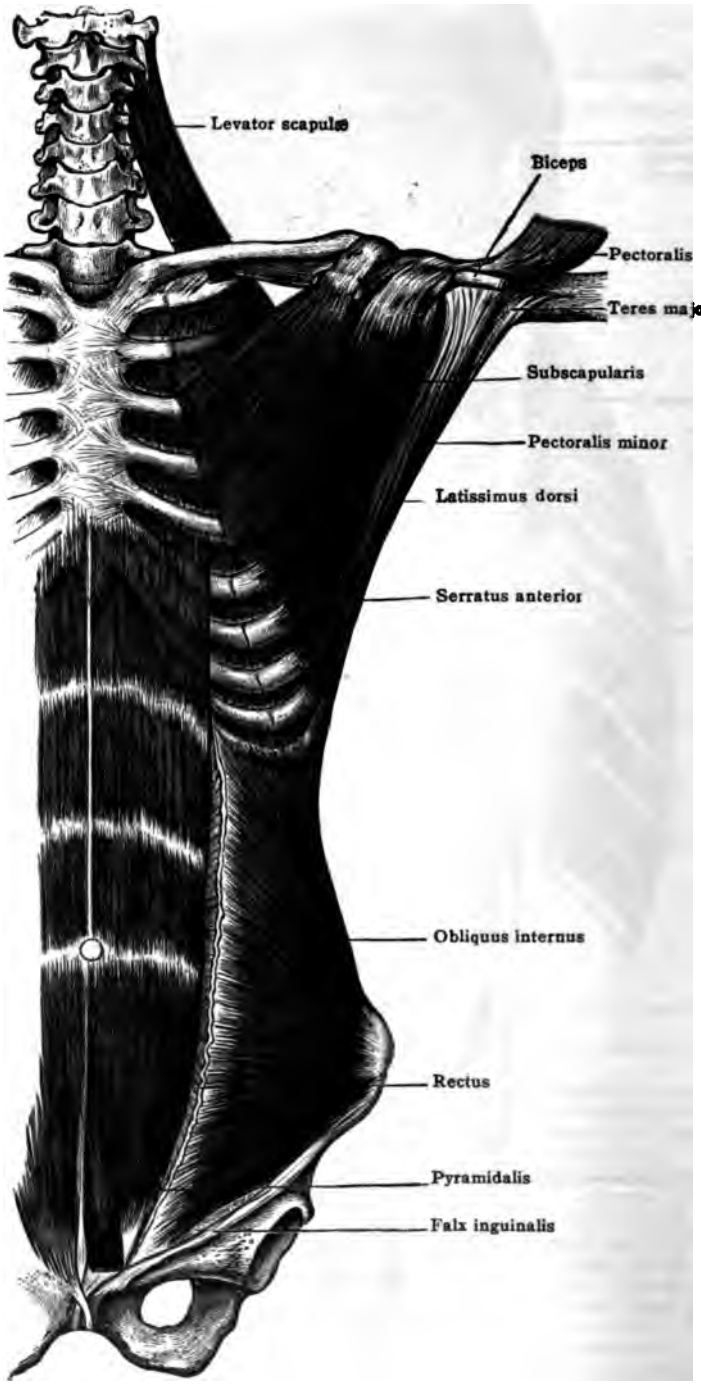


sally from the external oblique, arises in part from the dorsal layer of the lumbo-
ear the junction of the two layers.

al ligament (Poupart's ligament) (figs. 418, 420, 421, 1109) is a strong band which the lower margin of the aponeurosis of the external oblique from the anterior-spine to *the pubic tubercle.* *Internally* the iliac fascia is fused to it. Distally

the fascia lata of the thigh is attached to it. The deeper lateral abdominal muscles in part arise from it. Medially near the attachment of the ligament to the pubic tubercle (spine) diverging fibers are given off which pass inward and upward to the pecten (crest) of the pubis and give rise to the triangular **lacunar ligament** (Gimbernat's ligament). This is fused with the

FIG. 419.—THE PECTORALIS MINOR, OBLIQUUS INTERNUS, PYRAMIDALIS, AND RECTUS ABDOMINIS.



fascia of the pectineus muscle and bounds the femoral ring. Above **the inguinal ligament near** its medial extremity lies the external opening of the inguinal canal, **the subcutaneous (external) inguinal ring** [annulus inguinalis subcutaneus]. This opening **is formed by the diverging of the** lower medial fibers which compose the aponeurosis of the **external oblique muscle. The** upper fibers form the upper boundary, superior crus, of the ring **and pass to the front of the**

s pubis. The inferior fibers form the inferior boundary, *inferior crus*, of the ring and
e pubic tubercle (spine). Between these two fiber-bands *intercrural* (intercolumnar)
about the lateral boundary of the ring and serve to strengthen the anterior and infe-
of the inguinal canal. Some of the fibers of the superior crus, intermingled with other
s to the opposite side of the body and are inserted into the tubercle (spine) and
he pubis and into the superior crus of the opposite side. The structure thus formed
he **reflected inguinal ligament** (Colles's ligament, or triangular fascia).

al canal [canalis inguinalis].—This term is applied to the slit in the lower margin of
minal wall through which, in the male, the spermatic cord passes, and in the female, the
m teres. It is not a true canal. The inner end begins at the (internal) **abdominal**
ulus inguinalis abdominalis] (fig. 1108). This is situated just above and slightly medial
ddle of the inguinal (Poupart's) ligament. Below the ligament in this region lies the
anal through which the femoral vessels pass into the thigh. The (internal) abdominal
vered by the peritoneum and the transversalis fascia. The latter here sends a shallow
e extension outward to be attached to the spermatic cord. The base of this funnel-
ession toward the inguinal (Poupart's) ligament is formed by a thickened band of
e *tractus iliopubicus*. Medially and laterally the bundles of fibrous tissue which con-
is tract spread out fan-like, medially over the sheath of the rectus and toward the
terally over the transversus muscle and toward the crest of the ilium. The trans-
lominal muscle arises from the inguinal ligament nearly as far as the lateral margin of
minal ring. The fiber-bundles of this portion of the muscle course ventralward above
of the funnel mentioned above and are inserted by tendons forming a more or less
aponeurosis, the 'conjoined tendon' [falx inguinalis], common to it and the internal
nto the ventral sheath of the rectus abdominis muscle, into the tubercle, crest and
the pubis and sometimes into the pectineal fascia or the lacunar (Gimbernat's)
. Tendinous bands from the transversalis muscle curve downward medial to the
abdominal ring and help to strengthen the transversalis fascia here. These bands
e the *interfoveolar ligament* [ligamentum interfoveolare, Hesselbachi]. The fibrous
nstituting this ligament are attached to the lacunar ligament and the pectineal fascia.
the abdominal ring the spermatic cord (or in the female the ligamentum teres) passes
d and foward in a space (inguinal canal) about 4 cm. long and then through the sub-
s (external abdominal) ring which has been described in connection with the inguinal
. The ventral wall of the inguinal canal is composed of the aponeurosis of the external
the intercrural fibers, and the cremaster muscle. Laterally it is also covered by the
ortions of the internal oblique and transversus muscles. The caudal wall or floor of
is formed chiefly by the lacunar (Gimbernat's) ligament and laterally also by the ilio-
ct. Cranialward the lateral part of the space is covered by the transversus and internal
nuscles, the medial part by the cremaster muscle. The dorsal (internal) wall is formed
y the transversalis fascia. Medially the lacunar (Gimbernat's) ligament and the con-
endon (falx inguinalis), when this is well developed, help to form the dorsal wall.
o these structures the dorsal wall is thinner but may be strengthened by a well developed
tract. Near the (internal) abdominal ring it is strengthened by the interfoveolar
, and sometimes by muscle slips (interfoveolar muscle).

minal fossæ in the inguinal region (cf. fig. 923).—The hernias so frequent in this region
special study of the inner surface of the abdominal wall of considerable practical im-
. Medial to the abdominal (internal) inguinal ring the inferior internal epigastric
ive rise to a slight fold (*plica epigastrica*) which slants medialward and upward toward
is muscle. From the lateral margin of the tendon of insertion of the rectus muscle
oward the umbilicus over the obliterated umbilical artery there extends a better marked
plica umbilicalis lateralis. Lateral to the plica epigastrica lies the **fovea inguinalis**
with the abdominal inguinal ring. Between the plica epigastrica and the plica
lis lateralis lies the **fovea inguinalis medialis**. In the latter region the fascia trans-
which here forms the inner wall of the inguinal canal is strengthened by two longitudinal
ands belonging to the aponeurosis of the transversalis muscle and described above, the
olar ligament at the medial side of the (internal) abdominal ring, and the falx inguina-
oined tendon) lateral to the rectus muscle. These bands vary in width. When they are
he part of the internal wall of the inguinal canal covered merely by the thin transversa-
and the peritoneum is relatively large and, since this region lies behind the subcuta-
xternal abdominal) ring, opportunity is offered for direct inguinal hernia.

MUSCLES

A. Ventral Division

rectus abdominis (fig. 419).—*Origin.*—Ventral surface of the fifth to seventh costal
s, the xiphoid process, and the costoxiphoid ligament.

tion.—The upper border of the body of the pubis and the ventral surface of the
sis. (The origin and insertion are often described as reversed.)

ture.—The muscle is long, flat, and somewhat triangular in form. Cranialward it is
nd thin; caudalward it becomes thicker as it converges toward the insertion. The
ndles of the muscle have a longitudinal course. It is crossed by several incomplete,
transverse tendinous bands, **inscriptiones tendineæ**, better developed on the ventral
the dorsal surface of the muscle and intimately united to the ventral sheath of the rectus.
hese, corresponding segmentally to the tenth rib, is usually situated opposite the um-
Another, corresponding to the ninth rib, is situated midway between this and the lower
of the thoracic wall, and one corresponding to the seventh rib is found at the level of the
process. Between *this and the one corresponding* to the ninth rib an additional inscrip-

tion is frequently found. Below the umbilicus an inscription corresponding with the eleventh rib is often found (30 per cent.). In these inscriptions many of the fiber-bundles have their origin and insertion. The thoracic attachments take place by means of band-like fasciculi which extend upward from the highest inscription, the fiber-bundles of these fasciculi being inserted by short tendinous bands. The pubic attachment of the muscle takes place by a short, thick tendon, usually divisible into two portions, of which the broader, lateral portion is inserted into a rough area extending from the pubic tubercle (spine) to the symphysis, while the more slender medial portion is attached to the fasciæ in front of the symphysis pubis, where its fibers interdigitate with those of the opposite side. In addition to the attachments mentioned, some of the fiber-bundles are attached to the sheath of the rectus and many, after interdigitating, terminate in the intramuscular framework.

Nerve-supply.—The anterior branches of the six or seven lowermost intercostal nerves enter the deep surface of the muscle near its lateral edge. The cutaneous branches pass obliquely through its substance, while the muscular branches give rise to an intramuscular plexus. As a rule, the chief ventral branch of the tenth thoracic nerve enters the substance of the muscle slightly below the umbilical transverse inscription. The branches of the eleventh and twelfth nerves enter at a lower level. The main branch of the ninth nerve enters slightly below the preumbilical inscription; the eighth nerve, between this and the lower margin of the thorax. Either the sixth or seventh nerve may supply the fasciculi of origin. In addition to the main branches other smaller branches of the nerves of the abdominal wall are also usually distributed to the muscle. Each segment, either directly or through intramuscular plexuses, has a supply from more than one spinal nerve.

Action.—To depress the thorax and flex the spinal column. When the thorax is fixed the rectus serves to flex the pelvis upon the trunk.

Relations.—It lies between the transversalis fascia and the tela subcutanea and is ensheathed by the aponeuroses of the lateral abdominal muscles, as above described. The epigastric artery runs on its deep surface.

Variations.—The rectus muscle varies in the number of its tendinous inscriptions and in the extent of its thoracic attachment. It may extend farther than usual on the thorax. Frequently aponeurotic slips or slips of muscle on the upper part of the thorax indicate a more primitive condition in which the muscle extended to the neck. Absence of a part or the whole of the muscle has been noted. The muscles of the two sides may be separated by a considerable interval in the neighborhood of the umbilicus. The muscle is relatively thicker in men than in women.

The pyramidalis (fig. 419).—*Origin.*—Upper border of the body of the pubis.

Structure and insertion.—The fiber-bundles extend toward and are inserted into the linea alba for about a third of the distance to the umbilicus, and give rise to a flat, triangular belly.

Nerve-supply.—Usually through a branch of the twelfth thoracic, which may extend into the muscle through the rectus abdominis. Not infrequently a special branch extends into the muscle from the iliohypogastric or ilioinguinal, or rarely from the genitofemoral.

Action.—To draw down the linea alba in the median line.

Relations.—It lies between two laminæ of the anterior layer of the sheath of the rectus.

Variations.—It is missing in about 16 per cent. of instances (Le Double). Dwight has found it absent in 81 out of 450 males and in 60 out of 223 females dissected at the Harvard Medical School. It may extend upward to the umbilicus or be but very slightly developed. It may be double. In many of the mammals it is missing. It is well developed in the marsupials and monotremes.

B. Lateral Division

1. *Serratus Group* (fig. 411)

The serratus posterior superior.—*Origin.*—By a broad, thin aponeurosis from the ligamentum nuchæ and the spines of the last one or two cervical and the first two or three thoracic vertebræ.

Structure and insertion.—The fiber-bundles take a nearly parallel course downward and lateralward and give rise to a flat belly which ends by four fasciculi on the upper margin of the second to the fifth ribs, lateral to the iliocostalis.

Nerve-supply.—Through branches from the first four intercostal nerves. These nerves give rise to a plexus which passes across the deep surface of the muscle in the middle third between the tendons of origin and insertion.

Action.—To elevate the ribs to which the muscle is attached, and through them to enlarge the thorax.

Relations.—It lies upon the wall of the thorax and the intrinsic dorsal musculature and beneath the levator scapulæ, rhomboids, serratus anterior, and trapezius. Its fasciculi extend on the ribs to those of the serratus anterior (magnus).

The serratus posterior inferior.—*Origin.*—Through an aponeurosis, fused medially and inferiorly with the lumbodorsal fascia, from the last two or three thoracic and first two or three lumbar spines.

Structure and insertion.—From the aponeurosis arise four flat bands which are successively attached to the inferior margins of the last four ribs, lateral to the iliocostalis.

Nerve-supply.—From the ninth to eleventh intercostal nerves arise branches which form a plexus that extends across the deep surface of the muscle in the middle third between the tendons of origin and insertion.

Action.—To draw outward the four lower ribs and through them to enlarge the thorax. Together with the serratus posterior superior and the connecting aponeurotic fascia it aids in keeping the intrinsic dorsal muscles in place.

Relations.—It lies upon the intrinsic dorsal musculature, the lower dorsal part of the thorax and the lumbodorsal fascia, and beneath the latissimus dorsi, the trapezius, and their aponeuroses.

Variations.—The fasciculi of both muscles vary in number and may be replaced by aponeurotic slips. Aberrant muscle fasciculi, **supracostales posteriores**, may be found in the fascia which connects the two muscles. In several of the lower mammals the two muscles are normally continuous.

2. *External Oblique Group*

The intercostales externi (fig. 416).—These muscles extend in the intercostal spaces from the tubercles of the ribs to the costal cartilages. The intermediate muscles do not, however, often quite reach the cartilages. The first intercostal muscle may extend to the sternum. The others are continued through the intercostal region by thin aponeuroses, the **external intercostal ligaments**, the fibers of which have a direction corresponding to that of the muscle fiber-bundles. Dorsally the muscles are fused with the levatores, and ventrally the lower seven muscles are more or less fused with the corresponding fasciculi of the external oblique.

Origin.—From the lower margin of each rib external to the costal sulcus.

Structure and insertion.—The fiber-bundles take a parallel course obliquely forward and downward to the upper margin of the next rib. The proximal fiber-bundles are more oblique than the distal, and the muscles are best developed in the dorsal part of the intercostal spaces.

Nerve-supply.—By several branches from the corresponding intercostal nerves.

Action.—To elevate the ribs and enlarge the thorax. Acting on one side, they abduct toward that side and rotate toward the opposite side.

Relations.—They are covered externally by the pectoral muscles, the serratus anterior, and serrati posteriores, the levatores costarum, the sacrospinalis (erector spinæ), and the external oblique muscles. Internally they are separated by a slight amount of loose tissue from the internal intercostals, the membranes which continue these muscles medially, and from the subcostal muscles.

Variations.—When the twelfth rib is very small or is lacking, the eleventh intercostal muscle may be missing. When there is a supernumerary cervical or thirteenth thoracic rib, there may be an extra external intercostal muscle. Next to the first intercostal, the fourth most frequently reaches the sternum.

The levatores costarum (fig. 414).—These consist of a series of flat, triangular muscles, each of which *arises* from the tip and inferior margin of a transverse process and extends laterally with diverging fiber-bundles to be *inserted* into the dorsal surface of the rib below, from the tubercle to the angle. The first extends from the transverse process of the seventh cervical vertebra to the first rib. They increase successively in size from this to the last, which is attached to the twelfth rib. Those arising from the transverse processes of the eighth to the eleventh thoracic vertebræ send their more medial fiber-bundles across the rib below to join the lateral margin of the succeeding muscle (levatores longi). The levatores costarum are closely united to the external intercostals and are innervated by the intercostal nerves of the corresponding intercostal spaces. The first muscle is innervated by the eighth cervical nerve.

Action.—To bend laterally and extend the spinal column, and to rotate it toward the opposite side.

Relations.—They are covered dorsally by the longissimus dorsi and the iliocostalis.

Variations.—The first levator may be continued into the scalenus posterior. When greatly developed, the series of levators forms a serrate muscle.

The obliquus abdominis externus (fig. 418).—*Origin.*—By eight fleshy digitations from the external surface of the lower eight ribs immediately lateral to where they join the cartilages. The first five slips interdigitate with the serratus anterior (magnus), the last three with the latissimus dorsi.

Insertion.—(1) By a strong aponeurosis which extends over the rectus to the linea alba, where the more superficial fibers interdigitate across the median line, and to the inguinal (Poupart's) ligament; and (2) directly into the outer lip of the crest of the ilium. The aponeurosis over the rectus is usually partly fused with the aponeurosis of the internal oblique.

Structure.—The fiber-bundles which compose the flat fasciculi of origin diverge slightly as they pass forward and downward, and by fusion of their edges give rise to a flat sheet of muscle. The fasciculus taking origin from the fifth rib passes nearly directly ventrally, but the succeeding fasciculi incline somewhat downward, those from the seventh to the ninth ribs showing the greatest downward inclination. The lower margin of the fasciculus which arises from the seventh rib terminates opposite the umbilicus, that from the ninth rib extends toward the anterior superior spine of the ilium, and those from the last three ribs descend to the iliac crest. The first two fasciculi extend over the lateral margin of the rectus, the next two to its lateral edge. The fourth and fifth usually terminate along a line extending ventrally from the anterior superior iliac spine toward the rectus.

Nerve-supply.—The external oblique is supplied by rami from the lateral branches of the lower seven intercostal nerves and usually from the iliohypogastric as well. The rami of the first two or three nerves usually extend on the external surface of the muscle, while the others extend on the deep surface of the muscle as the cutaneous branches are passing through it toward the skin. The nerves of the external oblique take a more transverse direction than the fasciculi of the muscle. Thus the branch from the tenth intercostal nerve extends toward the umbilicus and that of the twelfth toward a point midway between the umbilicus and the symphysis pubis. The nerves have a segmental distribution corresponding with the primitive segmental condition of the muscle.

Action.—(1) To compress the abdomen; (2) to depress the thorax; (3) to flex the spinal column; and (4) to rotate the column toward the opposite side. With the thorax fixed it serves to flex and rotate the pelvis.

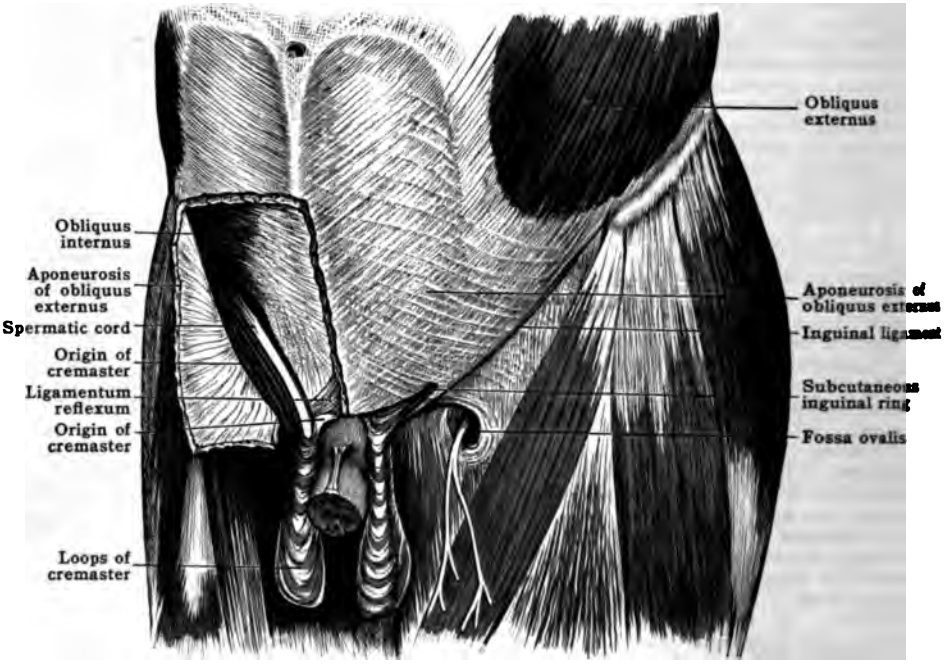
Relations.—It lies superficial to the lower ventrolateral margin of the thorax and the internal oblique muscles. It is partly covered by the latissimus dorsi muscle behind. Otherwise it is subcutaneous.

Variations.—It may have a more or less extensive origin from the ribs. Broad fasciculi not infrequently are separated by loose tissue from the main belly of the muscle either on its deep or superficial surface. Occasionally tendinous inscriptions are found. These transverse inscriptions are constant in many of the smaller mammals. The **supracostalis anterior** is a rare fasciculus sometimes found on the upper portion of the thoracic wall. It is usually supplied by branches of the upper thoracic nerves and seems to be a continuation upward of the external oblique muscle. In some prosimians the external oblique extends normally to the first or second rib.

3. *Internal Oblique Group*

The intercostales interni (figs. 416, 417, 419).—These extend in the intercostal spaces from the angles of the ribs to the sternal ends of the spaces. The upper and lower muscles are usually continued dorsally slightly beyond the angles of the ribs, while the intermediate muscles frequently do not quite reach them. Dorsomedially the internal intercostals are continued in the form of thin fascial sheets across the inner surface of the external intercostals and become fused with the subcostals.

FIG. 420.—STRUCTURES OF INGUINAL REGION.



Origin.—Near the angles of the ribs they arise from the internal lip of the costal sulcus. More ventrally they arise mainly from the external lip of the sulcus, but also in part from the internal lip.

Structure and insertion.—The fiber-bundles take a parallel course downward and dorsalward to the upper margin of the rib below. They are less obliquely placed than those of the external intercostals. The muscles are thicker in front and grow thinner dorsally. They contain less fibrous tissue than the external intercostals.

Nerve-supply.—From numerous branches of the corresponding intercostal nerves.

Actions.—Investigators disagree as to the functions. It is probable that the portions of the muscles between the ribs contract, those between the costal cartilages expand, the thorax.

Relations.—Between the ribs they are covered by the external intercostal muscles and between the costal cartilages by the external intercostal ligaments. Between the internal and external muscles there is some loose areolar tissue. Proximally, for a short distance, the intercostal nerve in each interspace runs between the external and internal intercostal muscles, but more distally it runs first in the substance of and then on the internal surface of the internal intercostal. Eisler distinguishes that portion of the internal intercostal muscle which lies external to the nerve as the intercostalis intermedius, that which lies internal as the true internal intercostal. The terminal branches of the first six nerves, however, pass through the muscle on their way to the skin, while the last six pass beneath the inferior margin of the thorax. Internal to the internal intercostal muscle lie the transversus (triangularis sterni) and subcostal muscles, the diaphragm, and the pleural membranes. The more distal internal intercostal muscles are continuous with the internal oblique and the subcostal muscles.

Variations.—The tenth and eleventh internal intercostal muscles normally are but slightly developed and often may be wanting. The internal intercostals of the first three spaces may extend to the vertebræ.

The subcostales (figs. 416).—These muscles are due to an extension over two or more intercostal spaces of those fiber-bundles of the internal intercostal muscles which lie in the proximal part of the interspaces. They arise near the angles of the ribs, and are usually well developed only in the lower part of the thorax. The component fiber-bundles keep the general direction of the internal intercostals, but they converge toward the tendons of insertion, which are attached in each case to the second or third rib below, between the angle and the neck.

Nerve-supply.—The main nerve of supply for each muscle comes from the intercostal nerve running below the rib from which the muscle takes origin.

Action.—To depress the ribs and contract the thorax.

Relations.—They lie on the inner side of the internal and external intercostals and the ribs, and are covered by the pleural membranes.

Variations.—They vary much in development. Next to the lower fasciculi, the fasciculi in the cranial part of the thorax are those usually best developed.

The obliquus abdominis internus (fig. 419).—*Origin.*—From the lumbodorsal fascia the intermediate lip of the ventral two-thirds of the iliac crest, and the lateral half of the inguinal ligament.

Structure and insertion.—From the origin the fiber-bundles radiate forward in a flat sheet. The most dorsal extend to the lower three ribs, where they become continuous with the internal intercostals. The rest extend toward the lateral margin of the rectus, the upper ones toward the xiphoid process, the intermediate toward the umbilicus, the lower ones somewhat obliquely downward across the lower part of the abdomen. The fiber-bundles which extend toward the rectus terminate in an aponeurosis which in its upper two-thirds divides into two layers, one of which passes in front of and the other behind the rectus muscle to the linea alba. In the lower third the aponeurosis passes as a single membrane in front of the rectus. In the neighborhood of the subcutaneous inguinal (external abdominal) ring the muscle is continued into the cremaster. Medial to the ring some fasciculi are attached to the tubercle of the pubis and to the symphysis.

Nerve-supply.—From branches of the last three intercostal and the iliohypogastric, ilioinguinal and genitofemoral (?) nerves as these pass between this muscle and the transversus.

Action.—To depress the thorax, flex the vertebral column, and bend and rotate it toward the side on which the muscle is placed. When the thorax is fixed, the muscle serves to flex and rotate the pelvis.

Relations.—It lies between the external oblique and the transversus. The **trigonum lumbale** (triangle of Petit) is an area, variable in size, between the posterior margin of the external oblique, the lateral margin of the latissimus dorsi, and the crest of the ilium. In this area the internal oblique is subcutaneous.

Variations.—The attachments and the extent of development of the fleshy part of the muscle vary considerably. Occasionally tendinous inscriptions are found in the muscle which indicate a primitive segmental condition.

The cremaster (fig. 420).—The cremaster muscle is found well developed only in the male. It represents an extension of the lower border of the internal oblique muscle and possibly also of the transverse over the testis and spermatic cord.

Origin.—(1) Lateral, thick and fleshy, from about the middle of the upper border of the inguinal ligament, and (2) medial, thin and tendinous, from the sheath of the rectus muscle and the tubercle (spine) of the pubis.

Structure.—The lateral head is applied to the lateral side, the medial head to the medial side, of the spermatic cord. Both pass with this through the subcutaneous (external abdominal) ring of the inguinal canal and become spread in loops over the testis. Ensheathing the muscle and between the somewhat scattered fiber-bundles which compose it, there extends a thin membranous layer of connective tissue, the **cremasteric (Cowper's) fascia.**

Nerve-supply.—The genital nerve (external spermatic), usually joined by a ramus from the ilioinguinal nerve, gives rise to branches which spread over the muscle.

Action.—To lift the testis toward the subcutaneous inguinal (external abdominal) ring.

Relations.—It is covered by the aponeurosis of the external oblique, the cremasteric fascia, the dartos, and the skin. It covers the spermatic cord and the testis.

Variations.—In the female the muscle is represented by a few fasciculi on the round ligament. It may arise wholly from the transversalis fascia or be somewhat fused with the transversus muscle. The latter condition is especially frequent in muscular individuals.

4. *Transversus Group*

The transversus thoracis (triangularis sterni) (fig. 416).—*Origin.*—By aponeurotic bands from the dorsal surface of the lower half of the body of the sternum and the xiphoid process.

Structure and insertion.—The muscle is composed of several flat, thin fasciculi, partly fibrous, more or less isolated, which are inserted by aponeurotic bands into the dorsal surface of the cartilages of the second or third to the sixth ribs, and occasionally also into the tips of the bony portions of the ribs. The lower fasciculus is closely related to the cranial margin of the transversus abdominis.

Nerve-supply.—By rami from the ventral portions of the second to the sixth intercostal nerves. These nerves give rise to a longitudinal plexus across the deep surface of the muscle near the middle of the constituent fasciculi.

Action.—To depress the ribs in expiration.

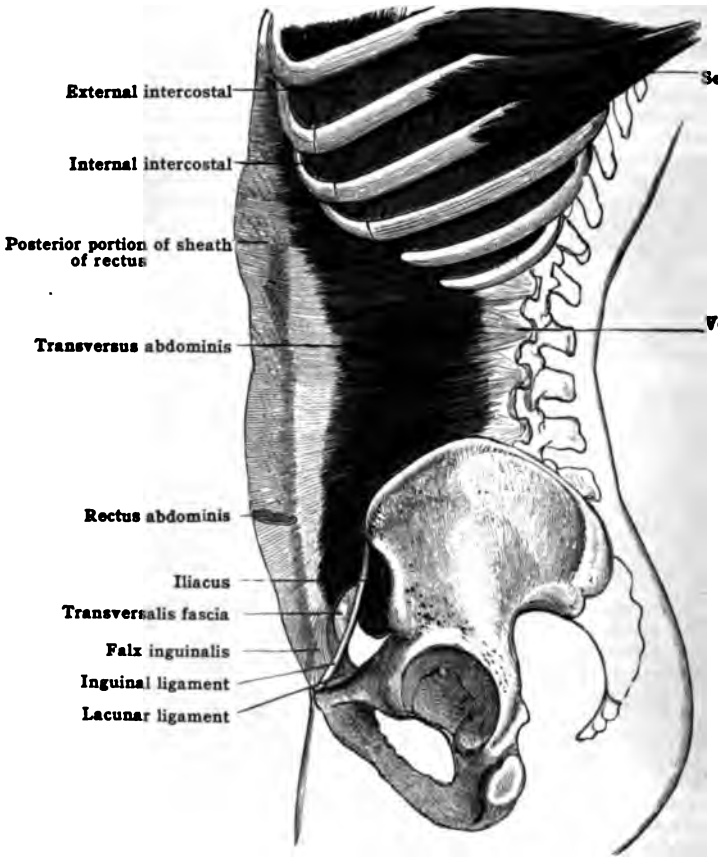
Relations.—The sternum, the costal cartilages, internal intercostal muscles, and the internal mammary vessels lie in front and the pleura and pericardium behind the muscle.

Variations.—It is an exceedingly variaole muscle, both in the extent of its attachment and in the development of the individual fasciculi. The fasciculi vary in number from one to six. With this muscle Eisler would class the subcostal muscles and those portions of the internal intercostal muscles which lie internal to the intercostal nerves.

The transversus abdominis (figs. 417, 421).—*Origin.*—Directly from—(1) the inner side of the cartilages of the lower six ribs by dentations which interdigitate with the attachments of the diaphragm; (2) the internal lip of the iliac crest and lateral half of the inguinal ligament; and (3) through an aponeurosis from the lumbodorsal fascia.

Structure and insertion.—The fiber-bundles give rise to a broad, thin belly and take a nearly transverse course across the inner side of the abdominal wall. The lowermost fibers, however, are inclined obliquely toward the pubis. The fleshy portion of the muscle terminates in a strong aponeurosis along a curved line, which extends above well under the rectus and emerges lateral to the rectus opposite the umbilicus, whence it extends toward the middle of the inguinal ligament. In the upper two-thirds of the abdomen the aponeurosis extends behind the rectus

FIG. 421.—TRANSVERSUS ABDOMINIS AND SHEATH OF RECTUS.



to the linea alba and fuses with the inner lamina of that of the internal oblique. In the lower third of the abdomen it extends in front of the rectus to the linea alba, and is here also fused with the aponeurosis of the internal oblique. Some of the fibers are continued into the aponeurosis of the muscle of the opposite side. The lower attachment of the muscle is somewhat more complex. The fiber-bundles here bend around the spermatic cord, on the medial side of which they are spread out to be attached to the lacunar (Gimbernat's) ligament and pectineal fascia, the pubis, and the sheath of the rectus. The attachment to the lacunar ligament and pectineal fascia takes place by means of an aponeurotic band, the more lateral fibers of which are dense and curve below the spermatic cord to the lacunar ligament and the pectineal fascia below this. This band is called the interfoveolar ligament. It is composed partly of bundles of fibers prolonged from the aponeurosis of the opposite transversus, and bounds the abdominal ring medially and below. Medially the transversus is united to the upper part of the os pubis, and to the sheath of the rectus by an aponeurotic band, the falx inguinalis (conjoined tendon). Between the interfoveolar ligament and the falx inguinalis the transversalis fascia forms the posterior wall of the inguinal canal. In this area a detached band of muscle-fibers is sometimes found. This is called the musculus interfoveolaris.

Nerve-supply.—The transversus is supplied with nerves by the last five or six thoracic and the iliohypogastric, ilioinguinal and genitofemoral nerves as these course forward between this muscle and the internal oblique.

Action.—The chief function is to compress the abdominal viscera. Through the portions extending between the lower margins of the thorax on each side it serves to contract the thorax and so may aid in expiration.

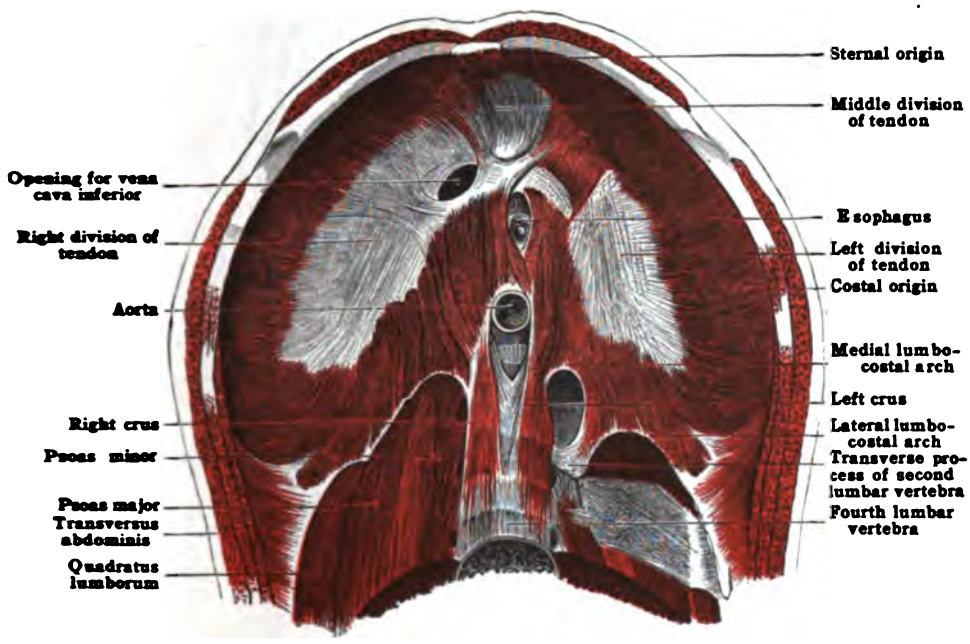
Relations.—It lies on the inner side of the lower ribs, the internal oblique and rectus muscles, and is covered on the deep surface by the transversalis fascia.

Variations.—It is very rarely absent. It shows considerable variation in the extent of its development. The **pubotransversalis** is a small muscle which may extend from the superior ramus of the pubis to the transversalis fascia near the abdominal inguinal ring. The **puboperitonealis** is a similar muscle which may pass from the pubic crest to the transversus near the umbilicus. The **tensor laminæ posterioris vaginæ musculi recti abdominis**, essentially like the preceding, may extend from the inguinal ligament to the rectus sheath on the deep surface of the rectus muscle near the umbilicus. The **tensor laminæ posterioris vaginæ musculi recti et fasciæ transversalis abdominis** likewise extends from the transversalis fascia near the abdominal inguinal ring to the fold of Douglas.

C. Lumbar Muscle

The quadratus lumborum (fig. 437).—*Origin.*—From—(1) the internal lip of the iliac crest near the junction of the middle and dorsal thirds, and the iliolumbar ligament; (2) the transverse processes of the three or four lower lumbar vertebræ; and (3) the lumbodorsal fascia.

Fig. 422.—Diaphragm.



Structure and insertion.—From the origins there arises a complex quadrangular muscle belly from which spring the fasciculi of termination. These extend to—(1) the transverse processes of the upper three or four lumbar vertebræ; (2) to the fiber-bands which extend out laterally in the lumbar fascia from the transverse processes; and (3) to the medial part of the lower border of the twelfth rib.

Nerve-supply.—Through direct branches from the first three or four lumbar nerves.

Action.—It serves primarily to produce lateral flexion of the spinal column. When both muscles act together, they produce extension of the column. The muscle also serves to depress and fix the twelfth rib.

Relations.—It rests posteriorly on the lumbodorsal fascia and the transverse processes of the lumbar vertebræ. Its medial edge is partly covered by the psoas. In front of it also lie the kidney, the intestines, and the lumbar arteries and nerves. It is ensheathed by membranes continued over each surface from the transversalis fascia. Of these, the anterior is the better marked and is called the **lumbar fascia.**

Variations.—There is much individual variation in the internal structure of the muscle and in its attachments. Its insertion may extend to the eleventh rib.

The **psoas major** and **minor** belong essentially to the musculature of the lower limb and are there described (p. 487).

D. The Diaphragm

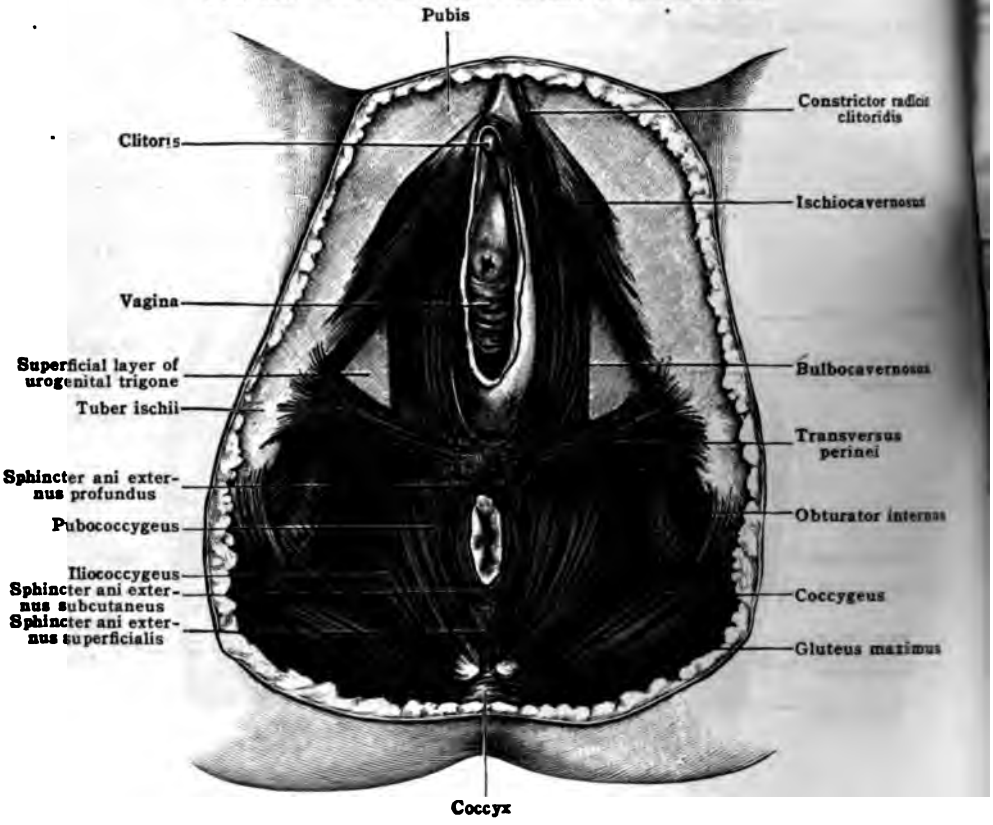
The diaphragm (figs. 417, 422).—This dome-shaped musculomembranous sheet has, when seen from above, something of the outline of a kidney. It consists of a pair of muscles which arise one on each side from the thoracic wall and are inserted into a central tendon. Lateral

to the tendon the diaphragm projects higher into the thoracic cavity than in the central area. On the right, in moderate expiration, it extends in adults to the height of the medial extremity of the fifth rib, and on the left to the fifth interspace.

Origin.—On each side from—(1) the lower border and back of the xiphoid process and the adjacent aponeurosis of the transversus abdominis or from the tendinous arch extending from the tip of the xiphoid process to the cartilages of the fifth and sixth ribs, (*sternal portion*); (2) the lower border and inner surfaces of the cartilages of the seventh and eighth ribs, the cartilages and osseous extremity of the ninth rib and the osseous extremities of the last three ribs (*costal portion*); and (3) from the lumbar vertebræ (*lumbar portion*). The lumbar portion is divided somewhat irregularly into three crura, between which pass blood-vessels and nerves.

The **lateral crus** arises from the lateral surface of the bodies of the first two lumbar vertebræ and from fibrous thickenings of the fascia over the psoas and quadratus lumborum muscles. Of these, one, the **medial lumbocostal arch** (internal arcuate ligament), extends from the body of the second lumbar vertebra to the transverse process of the same vertebra; the other, the

FIG. 423.—THE PERINEAL MUSCLES IN THE FEMALE.



lateral lumbocostal arch (external arcuate ligament), extends from the tip of the transverse process of the second lumbar vertebra to the twelfth rib. The lateral crus is only inconstantly attached to this. The **intermediate crus** arises from the ventrolateral surface of the body of the second lumbar vertebra from the sides of the bodies of the first two lumbar vertebræ and from the intervening disks. The **medial crus** arises from the front of the bodies of the third and the fourth lumbar vertebræ. On the left side it usually extends only to the third vertebra, and it does not always extend to the fourth on the right. The extremity and medial margin of this crus are tendinous, the lateral portion fleshy. On the second, third, and fourth, and the lower part of the first lumbar vertebræ the medial crus of each side is separated from its fellow by the **hiatus aorticus** (for the aorta and thoracic duct). Over the first lumbar vertebra they are fused by a process which extends from the right crus into the lower ventral surface of the left. Above here the right crus may be divided into two parts, one of which, fused with the left crus, passes on the left of the **hiatus esophageus**, while the other passes on the right. Sometimes the hiatus esophageus lies between the right and left crura. Frequently the left crus gives off a slip which passes to the ventral surface of the right below the **hiatus**.

The **costal portion** arises by a series of dentations which do not correspond perfectly in number with the ribs. Some costal cartilages have two dentations attached to them. It interdigitates with the transversus abdominis but in part arises from tendinous arches which bridge the origin of the transversus in the last three interspaces.

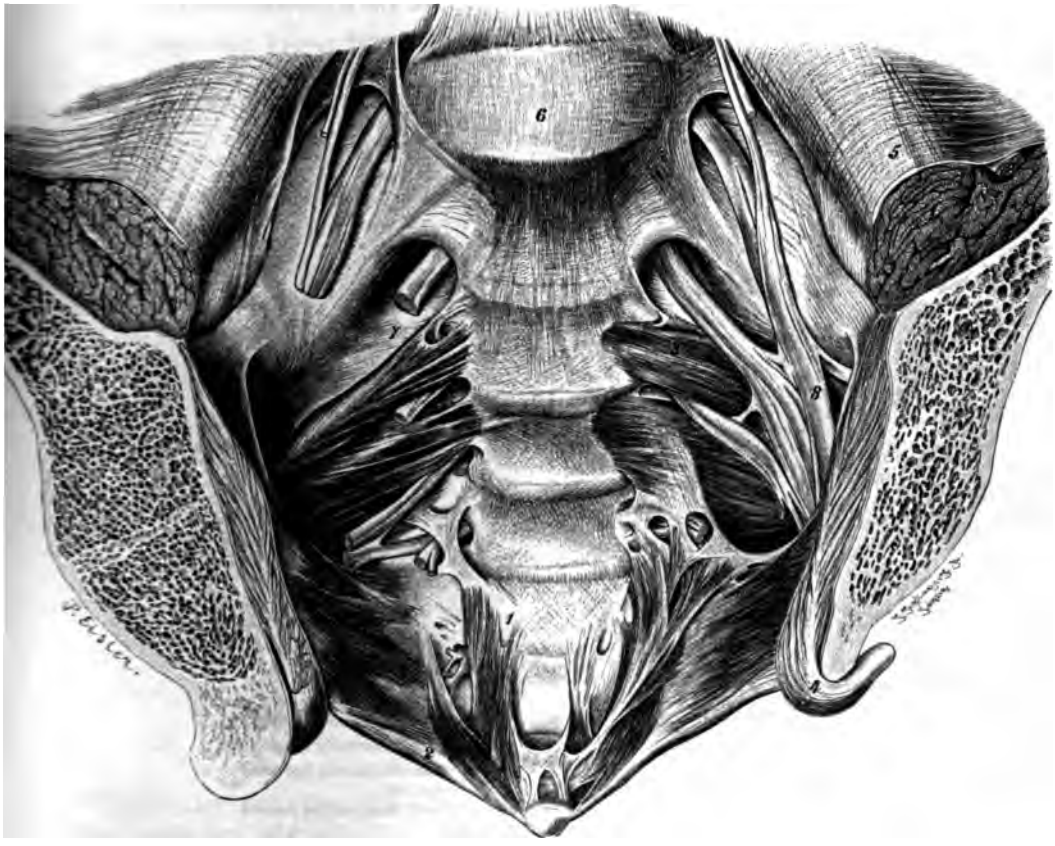
Structure and insertion.—The central tendon has somewhat the shape of a trifoliate leaf, the place of the stem being taken by the region occupied by the vertebral column, one leaflet lying on each side of this and one in front. The ventral part is usually placed somewhat to the

left and is more or less completely fused with the left leaflet. Between the ventral and the right leaflets there is a large opening through which passes the inferior vena cava, the **foramen venæ cavæ**. The leaflets are fused in front and behind this.

The fleshy portion of the muscle is composed of fiber-bundles which pass at first nearly vertically upward and then arch over to be attached to the margins of the central tendon. The sternal portion of the muscle is the shortest. It is often separated from the costal portion by a small space through which the superior epigastric vessels pass.

Nerve-supply.—From the phrenic nerves, one of which arises on each side from the third to the fifth cervical nerves. Each nerve penetrates the diaphragm lateral to the central tendon and breaks up into an extensive plexus on the inferior surface of the muscle. Some of the lower intercostal nerves also contribute to the sensory innervation of the margin of the muscle and possibly also slightly to the motor innervation. The sympathetic nerves furnish fibers for the blood-vessels.

FIG. 424.—VENTRAL COCCYGEAL MUSCLES (After Eisler.)—1. M. sacrococcygeus anterior. 2. M. coccygeus. 3. M. piriformis. 4. M. obturator internus. 5. Fascia iliaca, above the iliopsoas. 6. Fibrocartilago intervertebralis lumbosacralis. 7. Ventral trunk of first sacral nerve. 8. Sacral plexus.



Action.—To enlarge the thoracic cavity and thus cause inspiration. According to R. Fick, however, the diaphragm plays a less important part in inspiration than is usually assumed for it. The middle part of the central tendon is united to the pericardium and through this to the cervical fascia, and is, therefore, not very moveable. In the contraction of the muscle it is the dorsal and lateral portions which in the main are flattened. The diaphragm aids in defecation, parturition and vomiting, by the pressure it exerts on the abdominal viscera. It also acts as a constrictor of the esophagus.

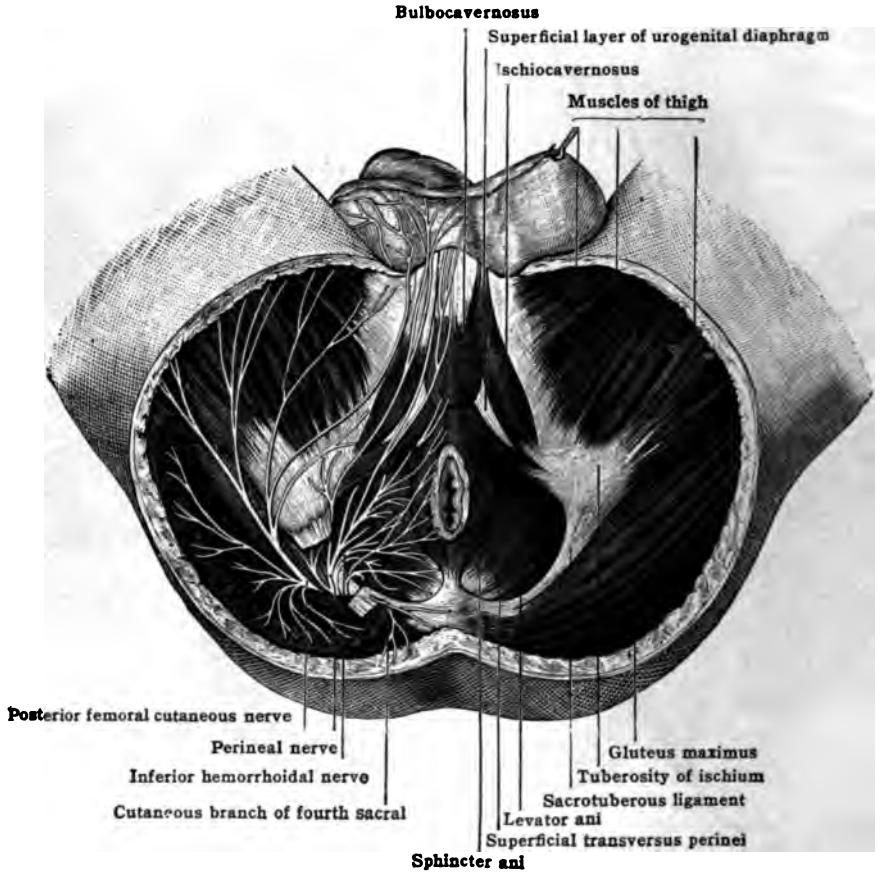
Relations.—Above lie the heart and the lungs; below lie the liver, stomach, duodenum, pancreas, spleen, kidneys, and suprarenal bodies.

Variations.—The sternal portion of the muscle is frequently absent. Infrequently the diaphragm is incompletely developed dorsally on the left side. This condition is rarer on the right side. The extent of the various insertions of the diaphragm shows considerable individual differences. The vertebral portion of the muscle may be slightly fused with the psoas or with the quadratus lumborum. Some fusion of the ventral portion of the muscle with the transversus thoracis has also been seen. Small fasciculi may pass to neighboring structures: the esophagus, stomach, liver, mesentery, etc. Muscle fasciculi are frequently found in the central tendon.

V. MUSCULATURE OF THE PELVIC OUTLET

In order to understand the musculature of the pelvic outlet it is necessary first to consider briefly the structure of the pelvis minor. It is bounded laterally and in front by the ilium below the terminal (iliopectineal) line, the ischium and the pubis, and by the obturator membrane and the sacrospinous (small sciatic), sacrotuberous (great sciatic) and the interpubic ligaments. The pubis, ischium and the obturator membrane are covered by the obturator internus muscle (figs. 423, 432) which here takes its origin and which converges toward and passes through the lesser sciatic notch on its way to its insertion on the great trochanter of the femur. The piriformis muscle (figs. 424, 427), which arises from the sides of the pelvic surface of the sacrum, from the posterior border of the great sciatic

FIG. 425.—THE MALE PERINEUM. (Modified from Hirschfeld and Leveillé.)



notch and the neighboring part of the sacrotuberous (great sciatic) ligament nearly fills up the great sciatic notch on its way to its insertion on the great trochanter. The walls of the pelvis are thus padded by muscles which belong to the limb. The muscles are covered by fascia best developed over the obturator internus muscle as the obturator fascia. The gluteus maximus muscle (figs. 418, 425, 431, 432), which arises from the back of the ilium, the sacrum, and the coccyx, and is inserted into the femur and the fascia of the thigh overlaps to some extent the sacrotuberous ligament, and in the standing position the tuberosity of the ischium so that its lower margin forms an accessory boundary to the pelvic outlet.

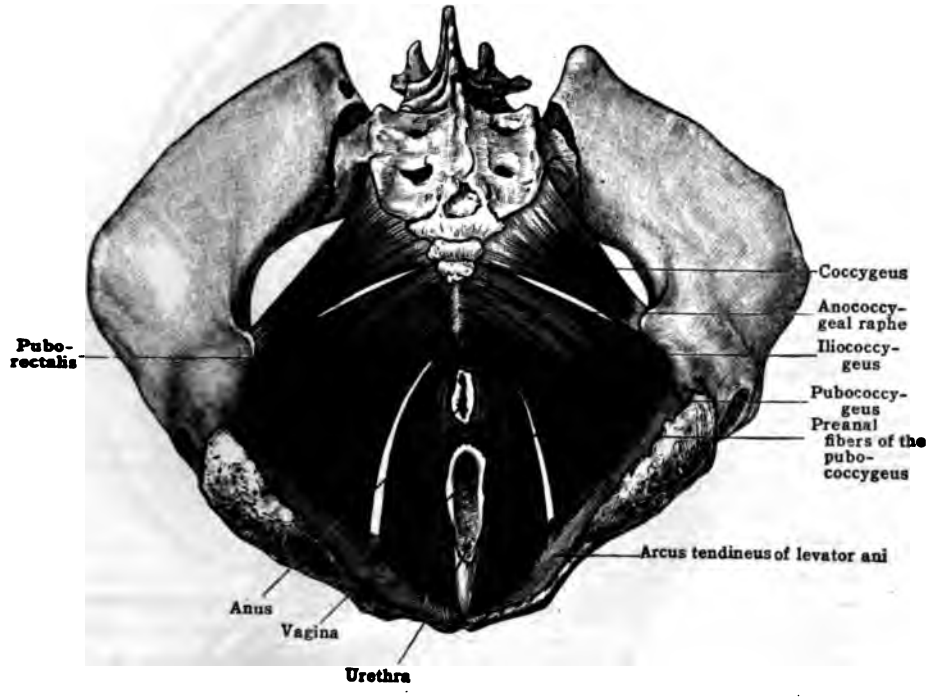
The outlet of the pelvis thus bounded by bone, ligaments and by muscles belonging to the lower extremity presents two triangles (figs. 423, 425), an anterior or urogenital triangle, with the base between the two ischial tuberosities and the apex below the symphysis pubis, and a posterior or rectal with the base between the ischial tuberosities and the apex at the coccyx. The outlet is closed by a

cial musculature forming the pelvic floor and divisible into three groups of mus- and fascia; those of the pelvic diaphragm and anus, those of the urogenital phragm, and those of the external genitalia.

The *pelvic diaphragm* [diaphragma pelvis] extends from the upper part of the vic surface of the pubis and ischium to the rectum which passes through it to be rounded by the external sphincter. The urogenital trigone or *urogenital dia-agm* [diaphragma urogenitale] lies between the ischiopubic rami superficial to pelvic diaphragm and surrounds the membranous urethra and in the female o the vagina. The *external genital* muscles lie superficial to the trigone.

The muscles of the **pelvic diaphragm** are two in number on each side, the coccy-us, and the levator ani (figs. 426–428). The **coccygeus** arises from the ischial pine and is inserted into the lateral margin of the lower sacral and the upper coccygeal vertebræ. It is closely applied to the pelvic surface of the sacro-spinous (small sciatic) ligament. In so far as it is active it flexes and abducts the coccyx.

FIG. 426.—THE PELVIC DIAPHRAGM IN THE FEMALE, FROM BELOW AND BEHIND.

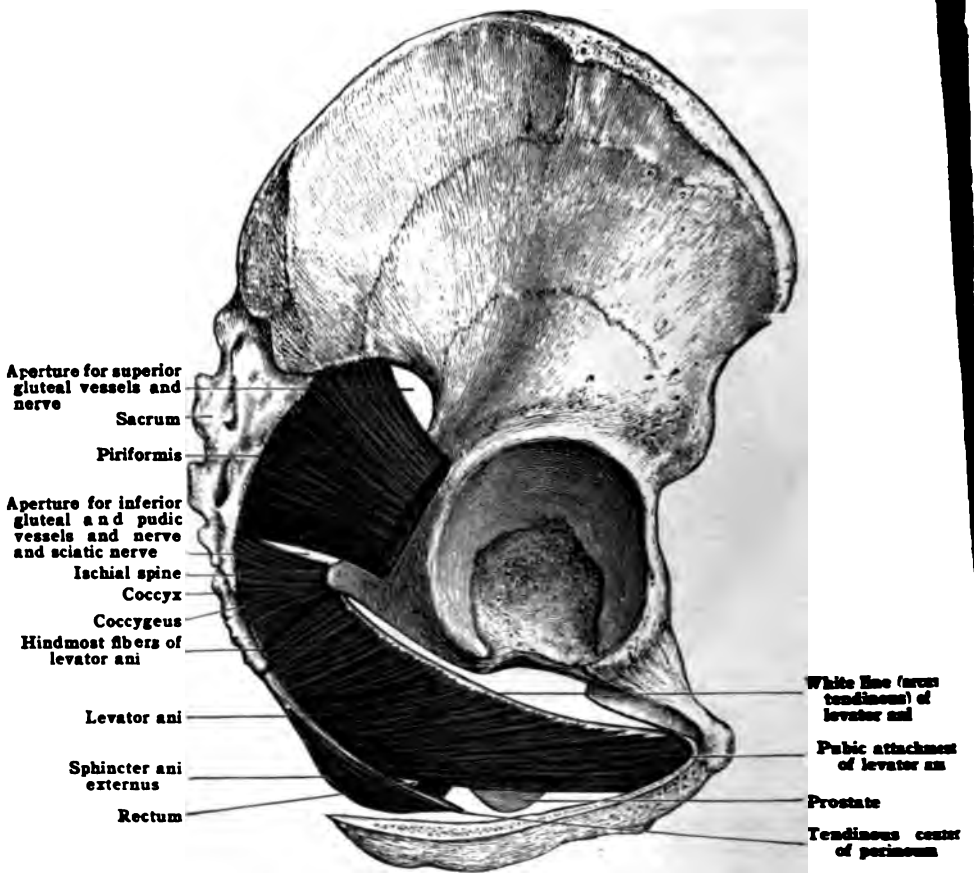


The **levator ani** (figs. 426-428) arises from the inner side of the pubis, along a line extending laterally from the inferior margin of the symphysis to the obturator canal, and from the obturator fascia along a line, the *arcus tendineus*, extending from the pubis to the spine of the ischium. The levator ani is inserted into the median raphé back of the anus, the anococcygeal raphé, into the tip and sides of the coccyx and into an aponeurosis, which is attached to the anterior sacrococcygeal ligament. It is divisible into three portions, a *pubococcygeal*, an *iliococcygeal*, and a *puborectal*. The levator ani muscles of the two sides are separated by a slit which extends from the rectum to the symphysis pubis and in which in the male lie the lower part of the prostate, and the membranous urethra (fig. 427), and in the female the vagina and urethra (fig. 426). Back of the rectum some of the fiber-bundles from the muscles of the two sides interdigitate, while others terminate in the anococcygeal raphé. A few fiber-bundles also interdigitate across the median line, in front of the rectum (pubococcygeal, fig. 426) and some are inserted into the walls of the rectum. The levator ani and coccygeal muscles of the two sides form a funnel-shaped muscular support for the pelvic viscera (fig. 430). When the abdominothoracic diaphragm contracts, as during inspiration, the pressure on the viscera is transmitted to the pelvic diaphragm

which resists the pressure and elevates the viscera when the abdominothoracic diaphragm relaxes. The levator ani muscle also constricts the rectum and pulls it forward and in the female constricts the vagina from side to side.

As it passes through the pelvic diaphragm, the rectum for about two and a half centimeters is surrounded by a special **external sphincter** muscle (figs. 424, 425, 428), divisible into three concentric layers as described below. This muscle, especially differentiated from the primitive sphincter of the cloaca, serves to close the rectum. It is supplemented by a sphincter of smooth muscle which lies immediately beneath the mucous membrane of the anus. It is attached behind to the coccygeus, and in front to the central tendon of the perineum described below.

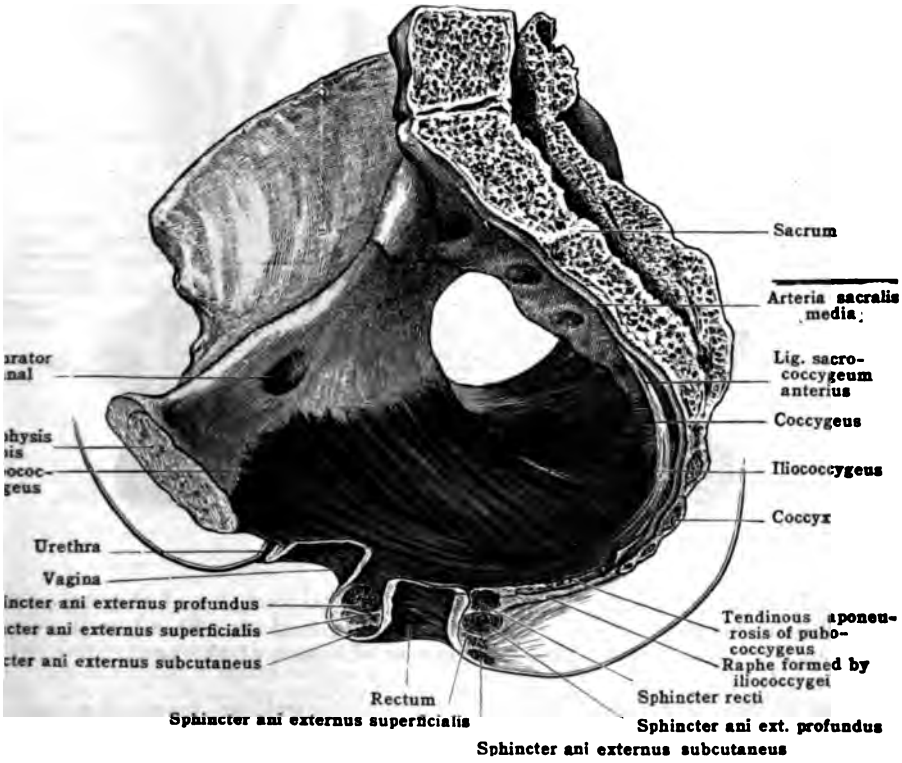
FIG. 427.—LATERAL VIEW OF MUSCLES OF THE FLOOR OF THE PELVIS.
(A portion of the ischial and pubic bones sawn away.)



The lateral origin of the levator ani, as above described and as shown in figs. 427, 428, 430, is considerably above the osseous and muscular margin of the pelvic outlet. The muscles of each side converge toward the postanal region so that a space is left between the lateral wall of the pelvis, and the levator ani and external sphincter (fig. 430). This space, the **ischiorectal fossa**, is filled with fat (figs. 431, 433, 1101). It is deepened laterally by the lower margin of the gluteus maximus muscle (fig. 431). In the fascial canal (Alcock's canal) in the lateral wall of the fossa run the internal pudic (pudendal) vessels and nerves (fig. 432). Above the pelvic diaphragm in the median part of the pelvic cavity are found the bladder, the ampulla of the rectum, and the prostate gland (in the male) or the vagina and uterus (in the female). Laterally on each side there is a subperitoneal space, filled with connective tissue and containing blood-vessels and nerves (fig. 433). Fasciæ invest each surface of the pelvic diaphragm (*diaphragmatic fascia*) and extend about the viscera (*endopelvic fascia*).

he muscular apparatus of the anterior or urogenital triangle of the pelvic it is much more complicated than that of the posterior or rectal triangle just ribed. We have seen that between the levator ani muscles of each side in t of the rectum there is a slit which extends to the symphysis pubis and that gh it, the lower part of the prostate and the urethra extend in the male, the ra and the vagina in the female. Between the ischiopubic rami there is ched a triangular muscular and fibrous membrane, which likewise surrounds urogenital ducts and which serves to strengthen the pelvic wall in this n. This structure is known as the **urogenital diaphragm** (**trigone**) ('triangular ient') (figs. 429, 431, 434). The musculature within it includes two muscles 429), the sphincter urogenitalis (urethræ) and the deep transverse perineal le. The *sphincter* embraces the urethra and associated structures. The onent fiber-bundles arise chiefly from the fibrous tissue in the angle beneath ymphysis pubis, but partly also from the descending pubic rami. They pass

28.—Sagittal Section of the Pelvis to Show the Pelvic Diaphragm and External Sphincter Ani.



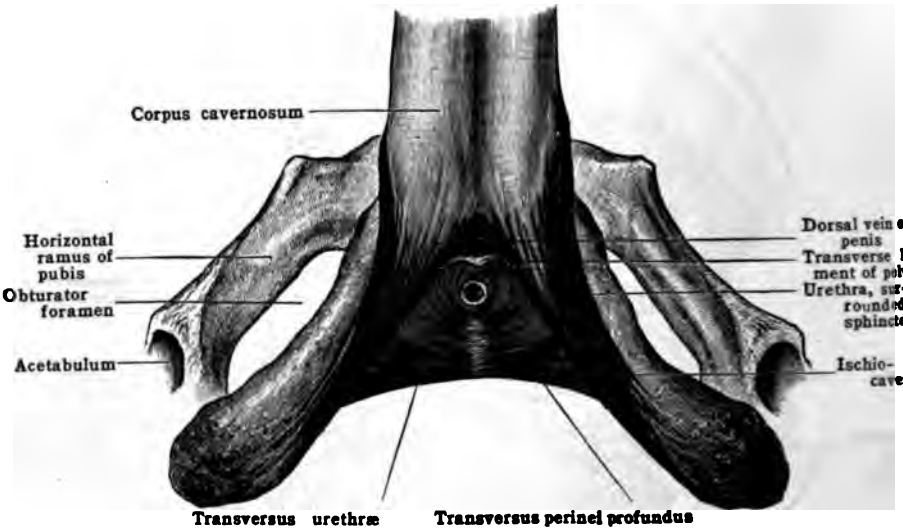
ard and medialward on each side of the urethra and then partly interdigitate the median line, partly terminate in a median raphe. Some fiber-bundles ce in the male the lower part of the prostate and Cowper's gland. In male the fiber-bundles of the sphincter partly terminate in the wall of the a. Some of them are continued downward on each side of the vagina and ligitate with fiber-bundles from the deep transverse perineal muscle. The *ransverse perineal* muscle (fig. 429) arises on each side from the ischiopubic s. It constitutes a flat band of muscle, the fiber-bundles of which in part ligitate across the median line, and in part are inserted into a median raphe. ne musculature of the urogenital diaphragm is enclosed between two well ed **fascial layers** (**fig.** 431, 434), the deep (superior) and superficial (inferior) of the urogenital diaphragm. The anterior margins of the two fascial are fused to form the transverse ligament of the pelvis which extends be- the inferior pubic rami, beneath the dorsal nerves and veins of the penis ris). At the anal margin of the musculature these two layers are also fused

with one another. The deep layer of the urogenital diaphragm forms the floor of the anterior recess of the ischiorectal fossa (fig. 431).

Superficial to the urogenital diaphragm lie the external genitalia (figs. 424, 425). Voluntary muscle is here found in connection with the crura of the penis (clitoris) and the bulb of the penis (vestibule). Although the musculature in the two sexes is fundamentally similar, nevertheless, owing to the differences in the structure of the genitalia in the two sexes, it is convenient to take up first the external genital musculature in the male and then that in the female.

In the male the crus penis, the posterior part of the corpus cavernosum, is relatively large. It lies in the groove between the ischiopubic ramus and the urogenital diaphragm (fig. 429), to the former of which it is firmly united. It is enwrapped on its free medial surface by the **ischiocavernosus** muscle (erector penis) (figs. 429, 433). The fiber-bundles of this muscle arise from the ischial tuberosity and from the ischiopubic ramus on each side of the attachment of the

FIG. 429.—MUSCLES OF THE UROGENITAL DIAPHRAGM (MALE).



crus. It is inserted into the medial and ventral surfaces of the crus near the attachment of the suspensory ligament. Some of the fiber-bundles may frequently be traced to the dorsal surface of the root of the penis (levator penis muscle).

The corpus spongiosum [corpus cavernosum urethræ terminates posteriorly in the bulb which lies on the urogenital diaphragm between the two crura (figs. 425, 433). It is united to the superficial layer of the trigone (fig. 433). It is enveloped by the **bulbocavernosus** muscle, composed of right and left halves united by a median raphe on the superficial surface of the bulb (fig. 425). Each half consists of several superimposed layers of fiber-bundles described below. The component fiber-bundles arise from the superficial layer of the urogenital diaphragm, from fibrous tissue on the dorsum of the bulb in the angle between the two crura, from the lateral surface of the corpus cavernosum penis in front of the ischiocavernosus and from the dorsal surface of the penis. It is inserted into a tendinous structure situated in front of the anus, the central tendon of the perineum, and into the median raphe on the free surface of the bulb. By its contraction the bulbocavernosus forces semen or urine from the bulbous part of the uretha.

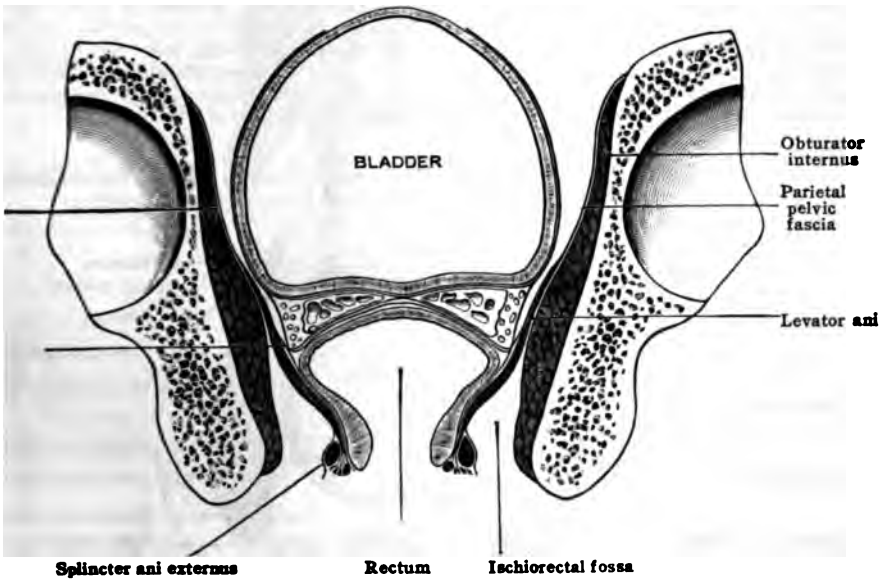
The **superficial transverse muscle** of the perineum (figs. 423, 425) arises on each side from the ascending ramus of the ischium and is inserted into the central tendon of the perineum. It is frequently weakly developed. It acts with the deep transverse perineal muscle in fixing the perineum and thus offering support for the action of other muscles.

he female (fig. 423) the *ischiocavernosus* does not differ markedly from that male although usually smaller. The superficial transverse muscles are, other hand, usually relatively better developed. The central tendon of ineum is likewise usually better developed in women and is more elastic, a teristic of value in childbirth.

e chief difference in the musculature in the two sexes is found in the *vernosus* (fig. 433). This, in the female, arises from the back of the clitoris, pus cavernosum and the trigone. It covers the outer side of the bulb of tibule and the gland of Bartholin. It is inserted into the central tendon of ineum. The chief function of the pair of muscles is to constrict the vagina.

e external genital muscles are covered by a deep layer of the tela subcutanea, fascia, which is firmly fused with the urogenital diaphragm at the anal l of the latter.

430.—Diagram to show the Fasciæ of the Pelvis in Section. (After Holl.)



MORPHOLOGICAL REMARKS

e the shoulder-girdle and the muscles which extend from this and from the trunk to the ıtremity are superficially placed with respect to the trunk, and do not interrupt the ıusculature the reverse is true of the hip-girdle and the musculature of the lower ex-

The hip-girdle is firmly united to the spinal column at the sacrum. The muscles ise from the trunk and are attached to the lower limbs are few in number compared with the upper extremity and, unlike the latter, are deeply placed. Thus the psoas major fig. 437) arises on each side of the lumbar region of the spinal column at the back of the al cavity and is inserted into the femur and the piriformis (fig. 437) arises from the front crum at the back of the pelvic cavity and is inserted into the great trochanter of the

The skeleton and musculature of the lower extremity, furthermore, markedly inter- the continuity of the trunk musculature which in the lower vertebrates and in the hu- bryo may be followed continuously to the caudal end. The interruption is much less behind than in front. The intrinsic dorsal spinal musculature extends well down over of the sacrum, but on the back of the lower end of the sacrum and on the back of the here is found merely the inconstant sacrococcygeus posterior. Of the ventrolateral ture the musculature of the abdominal wall, as is indicated by its innervation, is de- m the lower thoracic and the first one or two lumbar myotomes; the quadratus lum- at the back of the abdominal cavity (fig. 437), from the first three or four lumbar es. Beyond here there is an interruption until we come to the musculature of the tlet which, in part, may be looked upon as modified trunk musculature belonging to the e sacral myotomes. The intervening region is 'cut out' for the reception of the base of r extremity.

of interest to note that more and more of the ventrolateral wall of the trunk is 'cut the midventral line is approached. Thus while the quadratus lumborum behind ts spinal segments as far caudal as the third or fourth lumbar, the rectus abdominis represents segments merely as far caudal as the twelfth thoracic. Similarly while the s at the back part of the pelvic outlet represents the third and fourth sacral segments, or ani at the front represents chiefly the fourth.

The musculature which in the tailed mammals is used to move the tail as well as to wall the pelvic cavity and close rectal and urogenital openings, in man is modified wholly for latter functions. It constitutes the pelvic diaphragm.

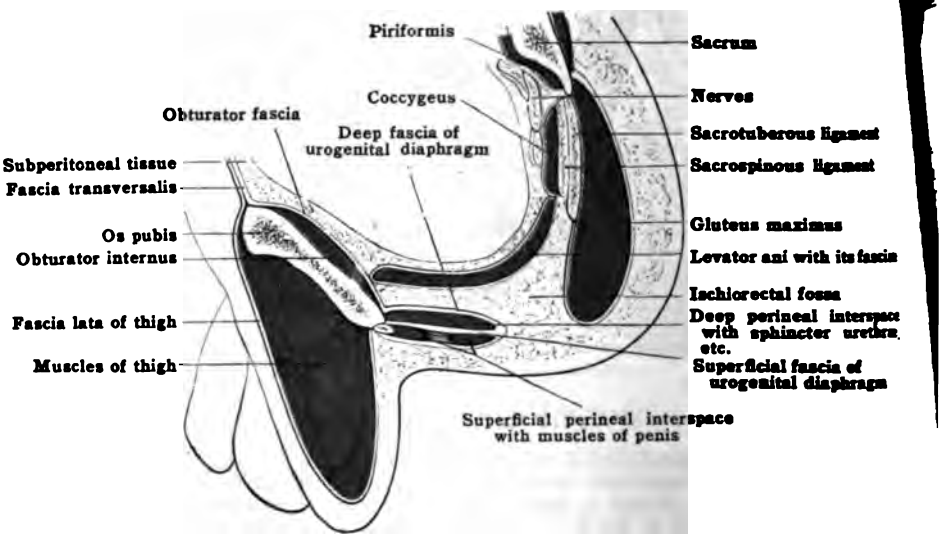
The musculature of the urogenital diaphragm of the external genitalia and anus in ma differentiated from the primitive sphincter of the cloaca.

FASCIÆ

The **tela subcutanea** in the male perineal region contains many bundles of smooth muscle fibers continuous with and similar to the dartos of the scrotum (corrugator cutis ani). At the sides where it passes over the lower margin of the gluteus maximus it contains a large amount of fat, but in the dorsal region over the coccyx and sacrum, as in the midperineal region, the fat is limited in amount. In the labia majora of the female perineum there is much fat in the tela subcutanea.

The **ischiorectal fossa** (figs. 431, 432, and 433) is bounded laterally by the obturator internus muscle and fascia, the tuberosity of the ischium and the ischiopubic ramus, medially by the levator ani and coccygeus muscles and fasciæ, ventrally by the dorsal aspect of the urogenital diaphragm and dorsally by the gluteus maximus muscle. An *anterior recess* extends forward well toward the body of the pubis between the levator ani, the ischiopubic ramus and the urogenital diaphragms. A *posterior recess* may likewise be traced backward beneath the lower edge of the gluteus maximus (figs. 431, 432). The fossa is filled with loose fatty tissue continuous with that of the tela subcutanea. Through it pass the hemorrhoidal, and long and short perineal branches of the pudic artery and nerve. The main trunks of these vessels and nerves lie in a special fascial compartment (Alcock's canal) in the lateral wall, fig. 432.

FIG. 431.—SAGITTAL SECTION THROUGH THE UROGENITAL DIAPHRAGM AND ISCHIORECTAL FOSSA TO THE LEFT OF THE MIDDLE LINE. (Diagrammatic.)



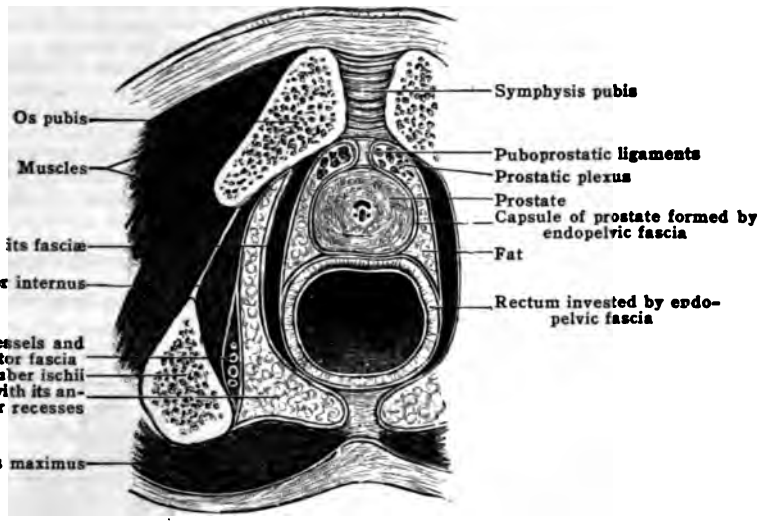
The external genitalia are covered by a special deep layer of the tela subcutanea, the **superficial perineal (Colles') fascia** (fig. 433). This is attached on each side to the lower margin of the ischiopubic ramus and to the ischial tuberosity. At the posterior margin of the superficial transverse perineal muscle it fuses with the two fascial layers of the trigone. It is adherent to the central tendon of the perineum and to the raphe of the bulb. Anteriorly it is continuous with the deep layer of the tela subcutanea covering the scrotum, the penis, and the lower part of the abdominal wall. In rupture of the urethra urine is prevented, by the attachments of the tela, from getting further back than the posterior edge of the trigone, but anteriorly it may extend to the surface of the abdomen. Here it may extend upward for a considerable distance, but it is kept from the thighs by the attachments of the deep layer of the tela subcutanea (Scarpa's fascia) to the inguinal ligament. Beneath the superficial perineal fascia are found the crura of the penis and their muscles, the bulb of the corpus spongiosum and its muscles, the superficial transverse perinei muscles, and the perineal vessels and nerves (fig 433).

Muscle fasciæ.—The muscles of the urogenital diaphragm, the urogenital (urethral) sphincter and the transversus perinei profundus, are contained between two fascia layers, which constitute the superficial (inferior) and deep (superior) layers of the urogenital diaphragm (trigone) (the superficial or inferior and the deep or superior layers of the triangular ligament).

The *superficial (inferior) layer* (figs. 423, 425, 431, 433, 434) which lies between the external genitalia and the urogenital diaphragm, is composed of strong bands of fibrous tissue which extend transversely across the subpubic arch and are attached to a ridge on the ischiopubic rami. It is separated from the arcuate (subpubic) ligament by a mass of fibrous tissue through which the dorsal veins and nerves of the penis (clitoris) run, and in which there is a venous plexus.

[illegible]ath this tissue a fibrous band, the *transverse ligament* of the pubis, extends between the [illegible]ding pubic rami. This represents a region of fusion of the deep and superficial layers of [illegible]fascia of the trigone. Posterior to the deep transverse muscle the two layers are likewise [illegible]d. The superficial layer is better developed in the front than in the back part of the space. [illegible]pierced by the urethra (about 3 cm. below the symphysis) by the ducts of the bulbourethral [illegible]wper's) glands, the arteries of the bulb, and the dorsal nerves and arteries of the penis. [illegible]the female it is pierced by the vagina as well as by the structures mentioned above.

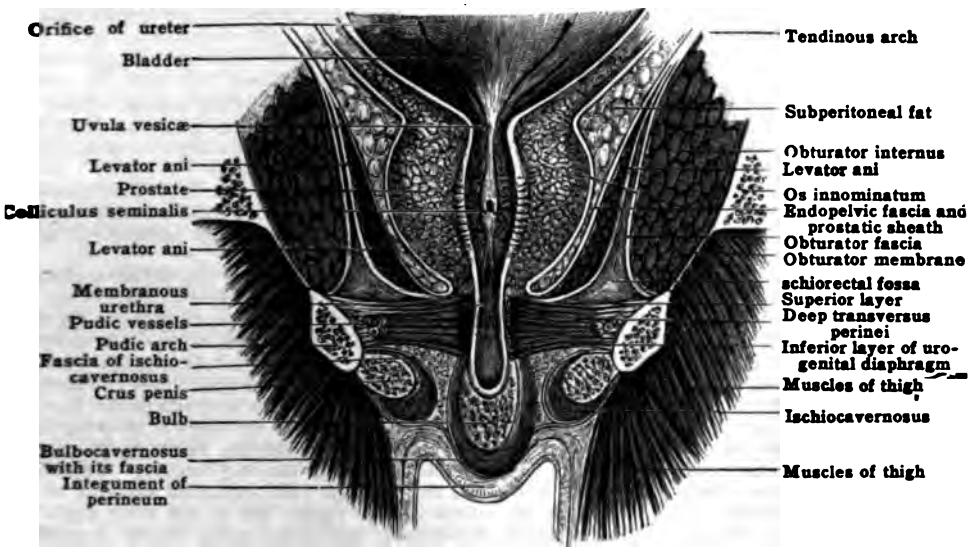
FIG. 432.—SECTION SHOWING THE ISCHIORECTAL FOSSA AND ITS RELATIONS.



Beneath the superficial layer of the fascia of the trigone, in addition to the muscles of the urogenital diaphragm, there are found the membranous urethra, the bulbourethral glands. (Cowper's), the internal pudic arteries and the pudic nerves (in part).

The *deep (superior) layer of the urogenital diaphragm* (figs. 431, 433, 434) lies between the muscles of the urogenital diaphragm and the ischiorectal fossa and levator ani. It may be looked upon as a continuation of the obturator fascia across the pubic arch. Posterior to the

FIG. 433.—VERTICAL FRONTAL SECTION OF THE PELVIS, SHOWING FASCIÆ.
(Modified from Braune.)



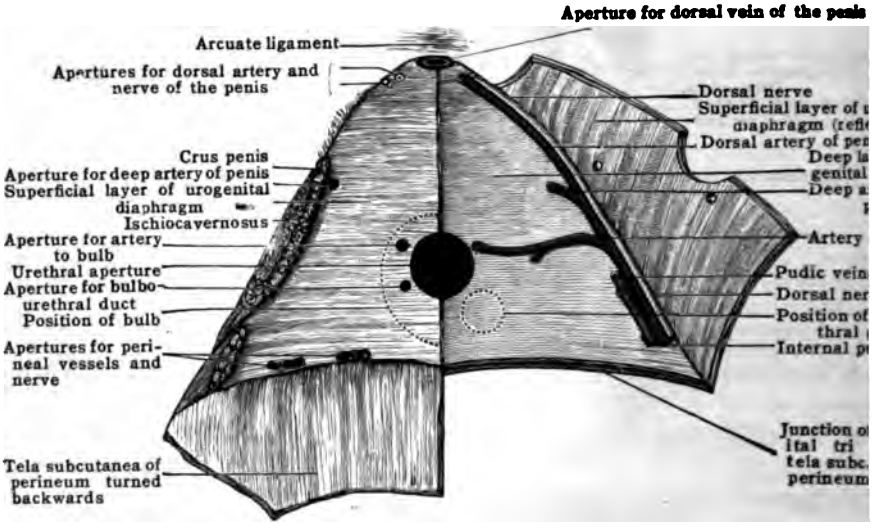
deep transverse perineal muscle it fuses with the superficial layer of the fascia of the urogenital diaphragm. In this region in the male it fuses with a fascial membrane, the *prostaticoperineal* fascia, which extends upward between the rectum and prostate, and is attached to the posterior wall of the latter. In the female it is fused with the fibrous tissue which lies between the vagina and the rectum.

The **muscle fasciæ of the pelvis** (figs. 430-433, 438B) have been described in vari by different authors. They may be subdivided into parietal and diaphragmatic. The **parietal fasciæ** (fig. 430) cover the muscles which extend from the interior of tl to the thigh (the obturator internus and piriformis muscles). Above, the fascia on e is attached to the linea terminalis and is continuous with the fascia transversalis and fascia. It is attached to the margins of the greater and lesser sciatic notches and to th pubic ramus and the body of the pubis. Between the ischiopubic rami it is stretche the subpubic arch and forms the superior or deep layer of the urogenital diaphragm d above. The portion of parietal pelvic fascia over the obturator internus muscle is c obturator fascia.

The **diaphragmatic pelvic fasciæ** cover both surfaces of the pelvic diaphragm an flected upon the viscera. The fasciæ covering the two surfaces of the levator ani are to the parietal (obturator) fascia along the line of origin of the muscle.

The line of attachment of the levator ani divides the obturator fascia into two p 430), a pelvic part above the line of attachment, covered by peritoneum, and an isc part below the line of attachment. The latter bounds the lateral wall of the ischiorec The former part is much the thicker. It consists morphologically of two fused membr obturator fascia proper and the aponeurosis of the iliococcygeal portion of the lev which although usually fused with the obturator fascia, may frequently be traced to minal (iliopectineal) line from which in tailed mammals this portion of thelevator tak

FIG. 434.—DIAGRAM OF THE SUPERFICIAL AND DEEP LAYERS OF THE UROGENITAL DIA



The two layers of fascia also become continuous at the medial margin of the muscle faces the urogenital passage (fig. 430). Posteriorly, the inner layer fuses with the insertion of the pubococcygeus portion of the muscle and the fasciæ of the muscles of are continuous. It also fuses with a fascia covering the coccygeus muscle.

The thin perineal layer of the levator fascia behind the rectum fuses with that of th side and is attached to the coccyx and the anococcygeal raphe. About the anus i form a covering for the external sphincter. Ventrally it is attached to the ischiop It forms the medial wall of the ischiorectal fossa.

Endopelvic fascia (figs. 432, 433).—The peritoneum is reflected from the pelvic the viscera much higher up than the level at which the viscera are attached to the phragm. Between the pelvic fascia covering the deep surface of the pelvic diaphragm ani and coccygeus muscles) and the peritoneum there is thus left a space, subperitor In the median plane in this region in the male are found the bladder, prostate, semin the ureter and ductus deferens in their course near the bladder, and the ampulla of th In the female we find here the bladder, the vagina, the uterus, and the ampulla of th Between these medially placed viscera and the lateral wall of the pelvis there is an i shaped space, *cavum pelvis subperitoneale*, bounded above by peritoneum, below by covering the pelvic diaphragm and filled with connective tissue of varying density. in this space in the female is continuous with that between the two peritoneal surfa broad ligament. Between the viscera in the subperitoneal region and about their connective tissue is more or less definitely condensed into membranes which the endopelvic fascia, variously described by different authors. The fascia covering diaphragm, especially that on the deep surface, is fused to the endopelvic fascia whe cera pass through the pelvic diaphragm. In the connective tissue of the subperitor are found the hypogastric artery and vein and their chief branches, and various viscer The subperitoneal space above the pelvic diaphragm is to be compared with the sub space below the pelvic diaphragm known as the ischiorectal fossa and described abo

MUSCLES

A. Muscles of the Pelvic Diaphragm, Coccyx, and Anus

The coccygeus (figs. 424, 426, 427, 428).—*Origin.*—From the ischial spine and the neighboring margin of the great sciatic notch. *Structure and insertion.*—The fiber-bundles diverge to be inserted partly directly, partly by means of an aponeurosis, into the lateral margin of the fourth and fifth sacral vertebræ and of the coccyx. Usually the muscle is composed in considerable part of tendinous connective tissue, especially on the dorsal side of the cranial portion, and on the ventral side of the caudal portion.

Nerve-supply.—From the pudendal plexus several small nerves enter the cranial margin and pelvic surface of the muscle. They arise usually from the third and fourth sacral nerves.

Action.—Insofar as the muscle is active it flexes and abducts the coccyx.

Relations.—Ventrally the muscle bounds the pelvic cavity, from which it is separated by the pelvic fascia, beneath which runs the nerve to the levator ani muscle. The dorsal surface is partly covered by the sacrospinous (lesser sciatic) ligament and helps to bound the ischiorectal fossa (posterior recess).

Variations.—The muscle varies greatly in the extent of its fleshy development. It may be doubled. It may be partially fused with the levator ani. Occasionally it is absent.

The sacrococcygeus anterior (fig. 424).—This inconstant muscle, when well developed, arises from the sides of the fourth and fifth sacral and from the front of the first coccygeal vertebra and from the sacrospinous ligament. The short fiber-bundles which compose it make up a somewhat irregular belly which is inserted into the anterior sacrococcygeal ligament and into the second to fourth coccygeal vertebrae dorsal to the insertion of the levator ani. The innervation is from the fourth and fifth sacral nerves.

The sacrococcygeus posterior is an inconstant muscle consisting of a few muscle bundles which extend from the dorsal surface of the lower sacral vertebræ or from the posterior iliac spine to the dorsal surface of the coccyx. It lies beneath the superficial layer of the sacrotuberous (great sciatic) ligament.

The levator ani (figs. 423, 425,–427, 430, 432) is divisible into three portions, the iliococcygeus, the pubococcygeus and the puborectalis.

The *iliococcygeus* (fig. 428) *arises* from the ischial portion of the arcus tendineus (white line). This extends from the ischial spine and posterior part of the arcuate line to the superior ramus of the pubis near the obturator canal, curving downward for a variable distance below the obturator canal. The constituent fiber-bundles form a muscular sheet which is inserted into the side of the coccyx and into the median raphe (anococcygeal) which extends from the tip of the coccyx to the rectum. Many fiber-bundles cross the median line.

The *pubococcygeus* (figs. 426, 428) *arises* from the inner surface of the os pubis, along a line extending from the lower margin of the symphysis pubis to the obturator canal, and from the arcus tendineus as far backward as the origin of the iliococcygeus. The fiber-bundles form a sheet of muscle which passes backward, downward, and medialward past the urogenital organs and the rectum on each side and is *inserted* by means of an aponeurosis into the anterior sacrococcygeal ligament. Back of the rectum some of the fiber-bundles of the muscle sheets of each side interdigitate across the median line. Some of the more superficial fibers are inserted into the deep part of the anococcygeal raphe. Some of the fiber-bundles which arise nearest the symphysis are inserted on each side into the rectum. The pubococcygeus lies to some extent on the pelvic surface of the insertion of the iliococcygeus.

The *puborectalis* (fig. 426) *arises* (a) from the body and descending ramus of the pubis beneath the origin of the *pubococcygeus*, (b) from the neighboring part of the obturator fascia and (c) from the fascia covering the pelvic surface of the urogenital diaphragm. The fiber-bundles form a thick band on each side of the rectum behind which those of each side are inserted into the anococcygeal raphe. Many fiber-bundles may be traced into the muscle of the opposite side. Some of the more superficial fiber-bundles are reflected medialward in front of rectum and may be followed into the superficial transverse perineal muscle, others may be followed into the sphincter ani externus, or even to the skin.

Nerve-supply.—By a special nerve which arises usually from the fourth sacral, runs across the pelvic surface of the muscle and gives a special branch to each portion.

Action.—To flex the coccyx, raise the anus and constrict the rectum. It resists the downward pressure which the thoracoabdominal diaphragm exerts on the viscera during inspiration.

Relation.—Between the right and left muscles in front lie the urethra and the lower part of the prostate in the male, the urethra and vagina in the female. In the triangle between the ischiopubic rami of each side lies the urogenital diaphragm separated from the puborectal part of the muscle by the deep layer of the trigone from which some of the fibers of the latter arise. Back of the urogenital diaphragm the muscle helps to bound the ischiorectal fossa.

Variations.—The muscle shows great individual variation in structure which causes it to be variously described by different authors.

The sphincter ani externus (figs. 423, 425, 427, 428, 430) is made up of bundles of muscle fibers which surround the anus for nearly two centimeters. It is elliptical in form. Behind the anus the fiber-bundles of each side in part interdigitate, forming a ring. They are attached to the skin, and in part are attached through a tendon, the *ligamentum anococcygeum*, to the back of the coccyx. In front of the anus the fiber-bundles also in part interdigitate with one another, in part are inserted into the skin and in part interdigitate with the fiber-bundles of the transverse perineal and bulbocavernosus muscles. At the point where these muscles meet, about two and a half centimeters in front of the anus, there may be a visible mass of fibrous tissue, the *central tendon of the perineum*, but this is not always distinct. It is usually better developed in the female than in the male perineum. The external sphincter is divisible into three portions, a subcutaneus, a superficial and a deep (fig. 428). The three parts are connected by

fiber-bundles, and are not always distinct. The *subcutaneous division* is small and immediately encircles the anal orifice. The *superficial division* lies external to the subcutaneous ring and descends further toward the rectum. It is shown in figs. 423, 425. It is the only part attached to the coccyx. In front it is attached to the central tendon of the perineum, but some fibers are continued into the bulbocavernosus. The *deep portion* forms a heavy ring above the rectum beneath the superficial part. It is distinctly, though not completely, separated from the puborectal portion of the levator and by fascial tissue containing the inferior hemorrhoidal vessels. Some of the fiber bundles of the deep portion may be traced in front of the anus across the midline to the ascending ramus of the opposite side and form part of the superficial transverse transverse perineal muscle.

Nerve-supply.—From the inferior hemorrhoidal branches of the pudendal (internal pudic) and frequently also by a perineal branch from the fourth sacral.

Action.—To keep the anus closed.

Relations.—Externally it is surrounded by the fat of the ischiorectal fossa, internally near the skin it surrounds the sphincter ani internus, composed of smooth muscle, deeper it lies next the mucous membrane, for a distance of two centimeters from the skin.

Variations.—The muscle shows considerable individual variation in structure.

The *rectococcygeus* or muscle of Treitz, is a triangular bundle of smooth muscle-fibers. The origin of the muscle is from the second and third coccygeal vertebræ. It is inserted by its apex into the posterior wall of the rectum and the perirectal fascia. It retracts and elevates the rectum.

B. Muscles of the Urogenital Diaphragm

The urogenital diaphragm (or trigone) is composed of two closely united muscles, the deep transverse perineal muscle and the urogenital sphincter.

The **transversus perinei profundus** (fig. 429) is a flat muscle which *arises* from the inner side of the inferior ischial ramus and is *inserted* into the median raphé. Many of the fiber-bundles interdigitate with those of the opposite side and some may be followed into the external sphincter of the anus and into the urogenital spincter and other perineal muscles.

Nerve-supply.—By the perineal branch of the pudendal (internal pudic).

Action.—The pair of muscles draw back and fix the central tendon of the perineum and thus give firm support for the action of the urogenital sphincter.

Relations.—The inferior surface is separated (often incompletely) by the inferior layer of the urogenital trigone from the superficial transverse perineal muscle. The superior surface is covered by the deep layer of the urogenital trigone, into which the superficial layer is reflected about the anal margin of the muscle.

Variations.—The muscle is variable in structure and may be absent. It is more frequently absent in the female than in the male.

The **sphincter urogenitalis** differs in the male and female owing to the passage of the vagina through the perineum in the latter. In each sex it is convenient to consider the muscle as divided into two parts, a periurethral and an infraurethral (vaginal).

In the male (fig. 429) the periurethral part, the *m. sphincter urethrae membranaceæ* is composed of fiber-bundles which are circularly placed about the membraneous urethra. The more external fiber-bundles are attached to the crura of the penis near their junction, to the transverse ligament of the pubis and to the fasciae of the trigone. Some of them partially ensheath the lower part of the prostate, and others envelop the bulbourethral (Cowper's) glands. Some of the fiber-bundles take a longitudinal course along the urethra. Bundles of smooth muscle fibers are intermingled with the striated, and the fibrous framework of the musculature is marked by the large amount of elastic tissue which it contains. The infraurethral part, the *m. transversus urethræ* is closely associated with the urethral part. The fiber-bundles arise on each side from the inferior ramus of the pubis. They pass for the greater part beneath the urethra and interdigitate with those of the opposite side or are inserted into a median raphe. A few fiber-bundles may pass above instead of below the urethra. The transverse urethral muscle, first described by Guthrie (On the anatomy and diseases of the neck of the bladder, London, 1834) is inconstant. Its existence as a normal constituent of the male perineal musculature has been disputed by Delbet (Poirier and Charpy) and others.

In the *female* the periurethral part, *sphincter urethrae*, differs in no essential respects from the corresponding muscle in the male. Some of the fiber-bundles form a true sphincter about the urethra. The *infraurethral* part, on the other hand, seems to vary greatly in different individuals so that the descriptions given by different authors are somewhat contradictory. It is better developed in women who have not borne children than in those who have. It may be looked upon as composed of two portions, a *m. transversus vaginae* and an *m. constrictor vaginae*. The *transversus vaginæ* arises from the ischiopubic rami and is inserted into the lateral wall of the vagina. Some of the fiber-bundles pass above and some below the vagina. This muscle corressponds with the transversus urethræ of the male but is, apparently, seldom fully developed The *m. constrictor vaginæ*, on the other hand, seems to be more constant. It is composed of fiber-bundles which embrace the lateral wall of the vagina and are inserted above into the periurethral framework, below into the raphe between the two deep transverse perineal muscles. Some of the fiber-bundles are attached to the vaginal wall. Some interdigitate with the sphincter urethræ, others with the deep transverse perineal muscle and with the transversus vaginæ.

Nerve-supply.—By a branch from the perineal nerve.

Action.—To compress or close the urethra and in the male to compress the prostate and Cowper's glands, in the female to compress the vagina and Bartholin's glands.

Relations.—On the pelvic side it is separated from the levator ani by the deep layer of the urogenital diaphragm, and on the perineal side it is separated from the superficial muscles by the

superficial layer of the fascia. Toward the anus it is closely associated with the deep transverse perineal muscle. Venous plexuses are well developed near the sphincter urethræ in both sexes, but especially in the female.

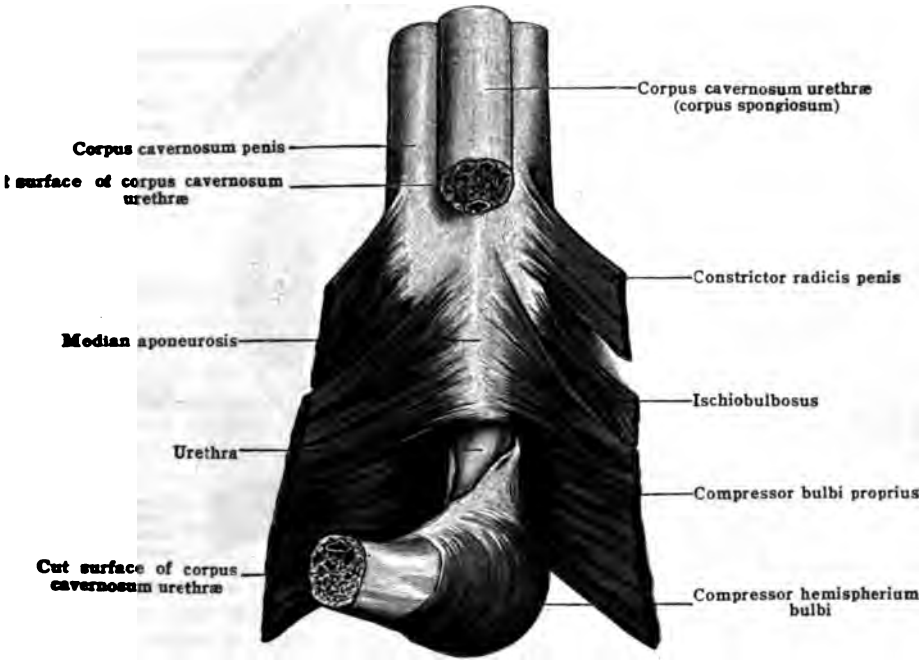
Variations.—It has already been pointed out that there is considerable variation in the muscles composing urogenital sphincter. Occasionally a rudimentary *ischiopubicus* is found arising from the ischiopubic ramus and terminating in a tendon which unites with that of the opposite side beneath the dorsal vein of the penis (clitoris). The tendon may be present as the transverse ligament of the pelvis when the muscle itself is absent. It represents the compressor of the dorsal vein found in lower mammals.

C. External Genital Muscles

The **bulbocavernosus** (figs. 425, 435) in the male ensheaths the bulb. The fiber-bundles arise from the dense tissue covering the corpus cavernosum at the root of the penis and from the subpubic connective tissue dorsal to the bulbar part of the urethra and are *inserted* into its median raphé on the ventral side of the bulb and into the central tendon of the perineum. Several parts may be more or less clearly distinguished.

Fig. 435.—Bulbocavernosus in the Male.

The two halves have been reflected from the median raphé, and the bulb turned downward after division of the corpus spongiosum. (The ischiobulbosus is not present on the right side.)



1. *The constrictor radicis penis arises* usually from the lateral surface of the corpus cavernosum penis at the base of the penis, but may arise from the under surface or from the dorsal surface, or even from the suspensory ligament of the penis. The fiber-bundles pass obliquely backward and medialward and are *inserted* into the median raphé on the perineal surface of the bulb.

2. The *compressor bulbi proprius arises* (1) from a strong fibrous aponeurosis situated between the corpus spongiosum and the united crura of the penis and firmly adherent to the former, and (2) from the superficial layer of the trigone. The fiber-bundles ensheath the bulb and are *inserted* into the posterior part of the median raphé and into the central tendon of the perineum. To a greater or less extent, depending on the development of the two muscles, the compressor covers the more posterior part of the constrictor.

3. The *compressor hemispherium bulbi arises* from a tendon common to the muscles of the two sides on the dorsum of the bulbous part of the urethra near the membranous part. The fiber-bundles embrace the hemisphere of the bulb and are inserted into the median raphé. This muscle is covered by the preceding. It not only compresses the bulb, but also is a sphincter of the urethra.

4. The *ischiobulbosus* is placed by Holl in this group. It *arises* from the pelvic surface of the tuberosity and of the inferior ramus of the ischium and when well developed is inserted into the median raphé, superficial to the compressor bulbi proprius or the constrictor radicis penis. Frequently, however, it does not extend over the bulb but is *inserted* into the inferior surface of the corpus cavernosum. It is more frequently absent than present. (See fig. 435.)

Nerve-supply.—The perineal division of the pudic nerve sends several branches to the bulbocavernosus.

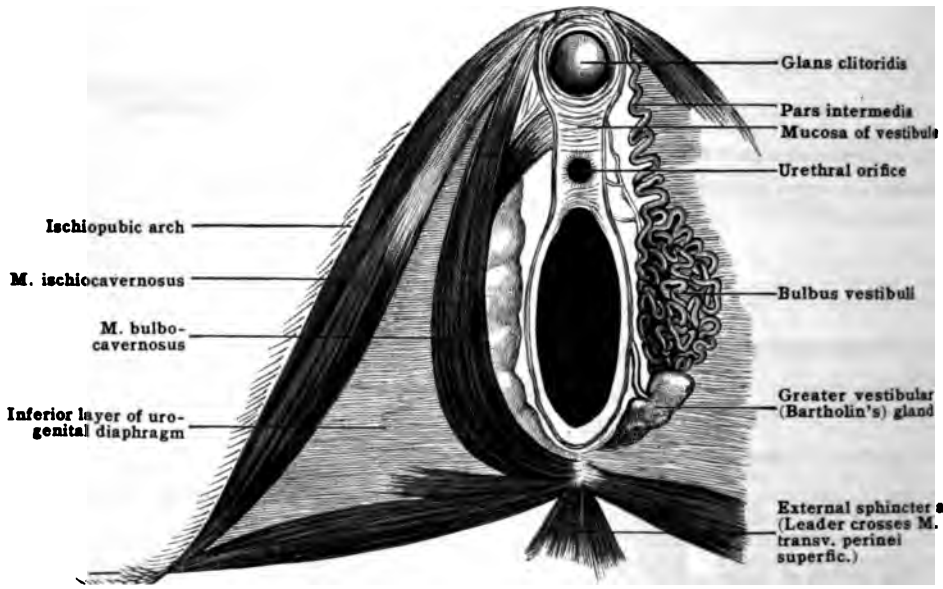
Action.—It compresses the bulb and at the same time the bulbous portion of the urethra. The turgescence of the penis is thus increased and urine or semen is expelled from this portion of the urethra.

Relations.—It lies beneath the skin and subcutaneous tissue.

Variations.—The muscle is variable in structure as is indicated by the different descriptions given by different authors. The *compressor venæ dorsalis* described by Houston is composed of a few fasciculi which arise from the sheath of the corpus spongiosum, and from the median raphé and are united to those of the opposite side by a tendon which passes over the dorsal vein.

The *bulbocavernosus* (*sphincter vaginæ*) (figs. 423, 436) in the female arises (1) from fibrous tissue dorsal to the clitoris, (2) from the tunica fibrosa of the corpus cavernosum and from the superficial layer of the urogenital diaphragm in the angle between the crura of the clitoris. The fiber-bundles form a band of tissue about two centimeters wide at the side of the vagina and are inserted into the posterior part of the superficial (inferior) layer of the trigonum and into the central tendon of the perineum where some of the fiber-bundles interdigitate with those of other muscles attached here. The fiber-bundles arising from the back of the clitoris correspond with those of the constrictor radicis penis in the male. The other fiber-bundles correspond with those of the compressor bulbi proprius in the male.

FIG. 436.—DIAGRAMMATIC REPRESENTATION OF THE PERINEAL STRUCTURES IN THE FEMALE



Nerve-supply.—From the perineal division of the pudic.

Action.—To compress the vagina.

Relations.—It covers the bulb of the vestibule and the great vestibular gland (Bartholin's). It is covered by skin and superficial fascia.

The **ischiocavernosus** (figs. 429, 436) (erector penis or clitoridis) *arises* from the pelvic surface of the tuberosity and inferior ramus of the ischium, back and on each side of the attachment of the crus. The fiber-bundles form a thin sheet which is spread over the crus into the medial and inferior surfaces of which it is *inserted* near the symphysis pubis. It is better developed in the male than in the female.

Nerve-supply.—By branches of the perineal nerve.

Action.—By constricting the crus to maintain turgescence of the penis or clitoris.

Relations.—Superficially it is covered by skin and subcutaneous tissue. Laterally it lies next the ischiopubic ramus. Medially it bounds a space lying between the crus and the bulb and filled with fat.

Variations.—The muscle in the male is much larger than in the female. Some of the more anterior fiber-bundles may extend to the dorsal surface of the penis (clitoris) and form a *pubocavernosus* or levator penis muscle.

The **transversus perinei superficialis** (figs. 423, 425, 436) arises from the inferior ischial ramus. The fiber-bundles extend in front of the rectum superficial to the deep transverse muscle and are inserted into the central tendon of the perineum. Some cross to the opposite side. Some of the fiber-bundles are continuous with those of the external sphincter or of the puborectalis of the opposite side.

Action.—It acts with the deep transverse muscle in fixing the central part of the perineum.

Nerve-supply.—By a branch from the perineal division of the pudic.

Variations.—It is frequently absent or poorly developed.

VI. MUSCULATURE OF THE LOWER LIMB

The lower limbs are used chiefly for the support and propulsion of the body. Variety of movement is subordinated to strength and precision. In contrast with the upper limbs, which perform a vast variety of complex movements under conscious control, the lower limbs are called upon to perform chiefly the relatively simple movements which are used in walking or running, without our paying much attention to them.

The contrast between the two extremities is best marked in the girdles, the relations of which to the trunk have already been described, p. 477. The shoulder-girdle is constantly called upon for movements in various directions which increase the freedom of action of the whole extremity. The sternoclavicular and acromioclavicular joints are movable so that the scapula can be carried in various directions over the thorax. The bones of the hip-girdle on each side, on the other hand, are ossified into a single hip-bone (os innominatum). The two hip-bones are almost immovably united to one another in front by the symphysis pubis and behind each is united to the sacrum by a joint which, although a diarthrosis, likewise permits but slight movement. The sacrum in turn is composed of vertebræ firmly ossified together. The pelvis, composed of the two hip-bones and the sacrum forms a strong support for the trunk. Such movements as it makes are due chiefly to the lumbosacral joint and to a less extent to the joints between the lumbar vertebræ. These joints permit the pelvis, in a limited manner, to be flexed and extended, abducted, adducted, and rotated. Flexion is produced by the rectus and the oblique muscles of the abdomen (fig 418) and by the psoas muscles (fig 437), extension is produced by the quadratus lumborum (fig 437) and the sacrospinalis (fig 412). Rotation and abduction are produced when these muscles act on one side only. The weight of the body in the sitting posture is transmitted through the sacrum and hip-bones to the ischial tuberosities. In this position the pelvis is flexed. The weight of the body in the standing position s transmitted to the femora through the acetabulum on each side. In this osition the pelvis is extended. In walking the pelvis is rotated forward toward he limb that is being advanced.

The hip-joint is a true ball-and-socket joint, but freedom of movement is reatly limited by the powerful musculature which surrounds it, as well as by the gaments. Movements here, however, are freer than at the shoulder-joint, if ie shoulder girdle be left out of consideration. At the hip-joint the most fre- uent and most free movements are those of flexion and extension, the main ovements in walking or running; but abduction, adduction, circumduction, id rotation are of the greatest importance in balancing the body.

At the knee-joint the main movements are also those of flexion and extension id the musculature is so arranged that the chief flexors of the knee which lie at ie back of the thigh are extensors of the hip (fig. 439) while the extensor mus- ulature of the knee which lies at the front of the thigh flexes the hip (fig. 442). lexion of the hip, however, through the action of gravity on the foot passively rings about flexion at the knee, while flexion of the knee likewise passively rings about flexion of the hip, since the flexed knee tends to swing forward. hese passive movements, due to gravity, are of importance in walking. The astrocnemius (fig. 444), the most powerful extensor of the ankle-joint, is also a owerful flexor of the knee-joint. At the knee-joint, in addition to flexion and xtension, some rotation is possible, best marked when the knee is flexed. This otation is of value in walking over rough ground in that it helps to accommodate ie foot to the ground. It is also of value in sitting on a flat surface. While iere is thus some rotation at the knee-joint not found at the elbow-joint, the free ovement of the radius about the ulna which accompanies pronation and supina- on in the forearm, is unrepresented in the leg where the fibula is firmly united the tibia at each end.

The joint between the bones of the leg and the tarsus permits merely of flexion id extension in contrast to the wrist-joint which also permits of adduction and oduction. Flexion and extension are also more limited at the ankle than at the rist. On the other hand, the movements of inversion and eversion which take ace in the intertarsal joints are not needed in the wrist because of the prona-

tion and supination of the forearm. Inversion and eversion of the foot are of value in walking on rough ground.

The movements of the toes resemble those of the fingers except that they are, in most individuals, far more restricted. The greatest restriction is seen at the joint between the metatarsal of the big toe and the tarsus, as compared with that between the metatarsal of the thumb and the carpus.

The musculature of the inferior extremity, like that of the superior, can be divided according to its development and innervation into two great subdivisions which correspond with the musculature on the dorsal and ventral sides of the shark's fin. The dorsal musculature is supplied by nerve branches which arise from the back of the lumbodorsal plexus (femoral, gluteal, and peroneal nerves), the ventral musculature by branches which arise from the front of the plexus (obturator and tibial nerves). Owing, however, to the rotation which the limb makes during embryonic development, the musculature which primitively lies on the dorsal side of the limb-bud comes to lie on the front and lateral side of the extremity and the musculature of the ventral side of the limb-bud comes to lie on the back and medial side of the extremity or in the sole of the foot. The side of the limb which primitively was toward the head becomes the medial side of the limb, and that which faced caudalward comes to lie laterally. While this makes the primitive relations of the musculature of the limb at first somewhat confusing, it is possible to approximate these primitive conditions by abducting the limb and rotating it so that the sole of the foot faces forward. An understanding of the innervation of the limb is thus greatly facilitated.

In the region of the hip the musculature of the **dorsal division is that which** arises from the spinal column and ilium and is inserted into the upper part of the femur and into the fascia of the thigh. It includes the chief flexor of the thigh, the *iliopsoas* (fig. 437), and the most powerful extensor, the *gluteus maximus* (fig. 444), as well as several important rotators and abductors, *gluteus medius* and *minimus*, *piriformis* and *tensor fasciæ latæ* (fig. 439). The iliopsoas is innervated by nerves from the back of the lumbar, the other muscles by nerves from the back of the sacral plexus. The musculature of the **ventral division arises from** the pubis and ischium, is inserted into the femur near the great trochanter and serves to adduct the thigh and rotate it lateralward, *obturator internus*, *gemelli*, *quadratus femoris* (fig. 439) and *obturator externus* (fig. 437). The obturator externus is innervated by the obturator nerve from the front of the lumbar plexus, the other muscles by special branches from the front of the sacral plexus.

In the thigh there are three groups of muscles, an **anterior or extensor group** (fig. 442), a **medial or adductor group** (fig. 442), and a **posterior or flexor group** (fig. 439). The anterior group belongs to the primitive dorsal division, the other two groups to the ventral division.

In the leg there are also three groups of muscles, an **anterior, a lateral and a posterior.** The two former belong to the dorsal division and are innervated by the peroneal nerve. The last belongs to the ventral division and is innervated by the tibial nerve.

In the foot one muscle on the dorsum represents the primitive dorsal division, the *extensor digitorum brevis* (fig. 449), supplied by a branch from the peroneal nerve. On the other hand the primitive ventral division is well represented in the sole of the foot, not only by the muscles associated with the long flexor tendons, quadratus plantæ, lumbricales (fig. 451), but also by the short flexor of the toes (fig. 450), by the special musculature of the big and little toes (fig. 452) and by the interosseous muscles (fig. 453).

The **muscle-fasciæ** of the inferior extremity are well developed. **The *fascia lata*, which** encloses the musculature of the back of the hip and the musculature of the thigh, is especially strong on the lateral side where it includes the longitudinal bundles of fibers which compose the iliotibial band [tractus iliotibialis]. From the fascia lata strong intermuscular septa extend on each side of the quadriceps group of muscles to the femur. Medially beneath the sartorius muscle (fig. 441), septa help to bound Hunter's canal in which lies the femoral artery on its way to the popliteal space behind the knee. In the leg there is likewise a strong cylindrical fascial sheath which encloses the musculature and sends septa on each side of the peroneal group to the fibula. A transverse septum also separates the deep from the superficial muscles of the calf. The fascia of the leg is especially well developed near the ankle where it helps to hold in place the tendons which pass from the muscles of the leg into the foot. Muscle-fasciæ are well developed both on the dorsum and in the sole of the foot.

A. MUSCULATURE OF THE HIP

1. Iliofemoral Musculature

The iliac blade divides these muscles into an **anterior group** (iliopsoas), supplied by nerves from the lumbar plexus, and a **posterior group** (the gluteal muscles, piriformis, and tensor fasciæ latæ), supplied by nerves from the sacral plexus.

In most of the limbed vertebrates these two groups of muscels are represented, but they present marked specific variations in the different forms. Primitively, the iliacus group lies on the proximal portion of the lateral surface of the ilium.

(*a*) Anterior Group
(Figs. 437, 442)

The fan-shaped **iliacus** muscle arises from the iliac fossa. The fusiform **psoas major** muscle arises from the sides of the last thoracic and of the lumbar vertebræ and extends along the medial margin of the iliacus muscle. The two muscles are inserted by a common tendon into the lesser trochanter of the femur. Together they constitute the **iliopsoas** muscle. The small, flat, fusiform **psoas minor** lies on the medial surface of the psoas major and extends from the twelfth thoracic vertebra to the iliopectineal eminence. The iliopsoas flexes the thigh at the hip and the pelvis on the trunk. The psoas minor aids in flexing the pelvis.

The iliopsoas muscle arises in the human embryo from a blastema which at first surrounds the femoral nerve and later extends proximally over the ilium (iliacus) and toward the lumbar vertebræ (psoas). The iliacus is phylogenetically the more primitive. In the shoulder it is probably represented by the infraspinatus. The psoas minor is much better developed in many of the lower mammals than in man.

FASCIÆ

The fasciæ and the relations of these muscles are shown in figs. 415 and 438.

The iliac and psoas muscles are covered by a dense fascia which is but slightly adherent to the underlying muscles. It is best developed in the pelvic region, where it extends from the iliac crest and iliolumbar ligament to the iliac portion of the linea arcuata and is called the **iliac fascia.** Superiorly it is continued over the psoas muscle as the **psoas fascia** and is attached medially to the sacrum and the lumbar region of the spinal column. Laterally it unites with the lumbar fascia and superiorly it is strengthened to form the medial lumbocostal arch (fig. 422). Inferiorly the **iliopectinal fascia** extends over the iliopsoas muscle to its femoral insertion. It is firmly united on each side of the muscle to the capsule of the hip-joint and to the femur. As it passes beneath the inguinal ligament it is united to this by tendinous processes. Beyond the ligament it is less dense than in the pelvic region.

MUSCLES

The psoas major (figs. 437, 442).—*Origin.*—(1) By a series of thick fasciculi from the intervertebral disks between the twelfth thoracic and the fifth lumbar vertebra, from the adjacent parts of the bodies of these vertebræ and from tendinous arches which bridge over the middle of the sides of the first four lumbar vertebræ; and (2) by a series of more slender fasciculi from the lower borders and ventral surfaces of the transverse processes of the lumbar vertebræ

Structure and insertion.—From these origins parallel fiber-bundles descend nearly vertically and give rise to a fusiform muscle which lies at the side of the vertebral bodies and extends along the border of the true pelvis toward its insertion. A tendon arises deep in the muscle near the last lumbar vertebra, and becomes free on its dorsolateral surface slightly above the inguinal (Poupart's) ligament. On the medial side the attachment of fiber-bundles continues to the insertion of the muscle into the small trochanter. The iliacus muscle is attached to the lateral side of the tendon from near the iliopectineal eminence downward.

Nerve-supply.—Delicate branches pass into the psoas muscle from the trunks which unite to form the femoral (anterior crural) nerve, i.e., from the fourth, third, second, and often the first lumbar nerves.

The iliacus (figs. 437, 442).—*Origin.*—(1) From the iliac crest, the iliolumbar ligament, and the greater part of the iliac fossa, the anterior sacroiliac ligaments, and often from the sacrum, and (2) from the ventral border of the ilium between the two anterior spines.

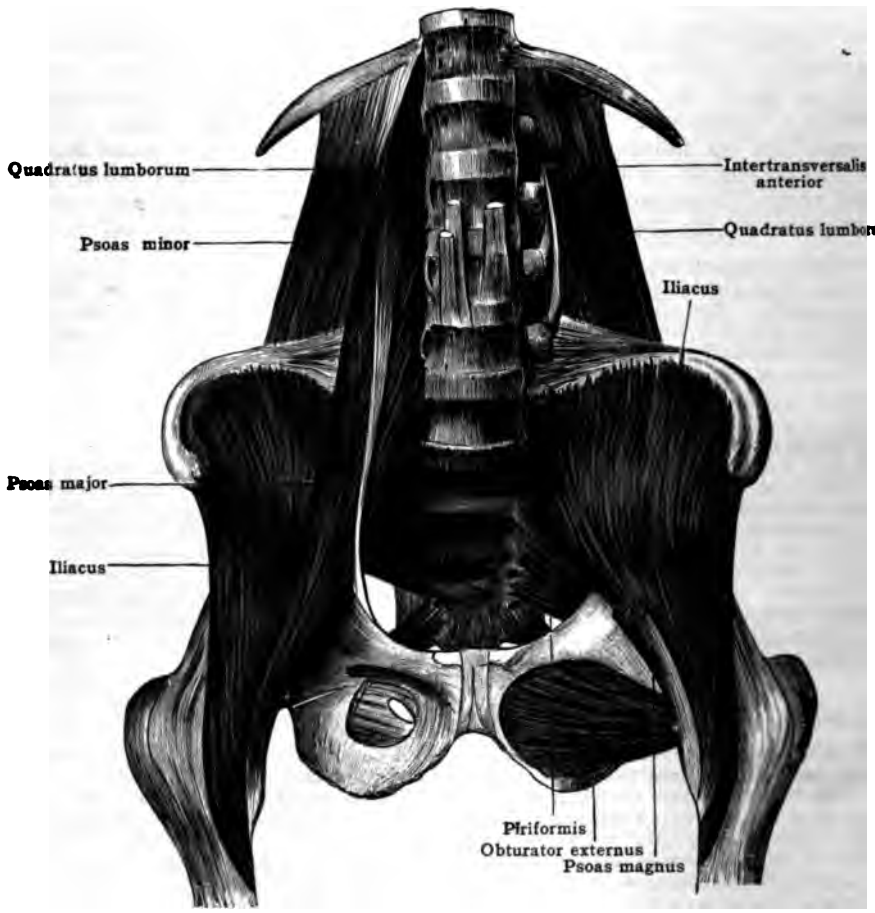
Structure and insertion.—From these areas of origin the fiber-bundles pass to be inserted—(1) in a penniform manner on the lateral surface of the tendon which emerges from the psoas above the inguinal (Poupart's) ligament, and (2) directly on the femur immediately distal to the small trochanter. The lateral portion of the muscle arises from the ventral border of the ilium and is adherent to the direct tendon of the rectus femoris and the capsule of the hip-joint. It is sometimes more or less isolated (*m. iliacus minor, ilio-capsulo-trochantericus*, etc.).

Nerve-supply.—Nerve branches, often united in a plexiform manner, arise from the femoral (anterior crural) nerve and pass *across the surface* of the iliacus muscle about midway between

the crest of the ilium and the combined iliopsoas tendon. Special nerve branches are usually likewise distributed from the main trunk of the femoral nerve to the fleshy portion of the muscle which extends over the acetabulum and the head of the femur.

Relations.—The psoas major lies lateral to the lumbar vertebræ and in front of the quadratus lumborum and intertransverse muscles. The psoas minor passes downward across its ventral surface. Both psoas muscles are crossed by the crura of the diaphragm. The kidney with its adipose capsule lies lateral to them opposite the first two lumbar vertebræ. For the rest, their fascia is covered ventrolaterally by retrointestinal and retroperitoneal tissue in which the vena cava inferior runs in front of them on the right side, the inferior mesenteric vein in front of them on the left side, and the ureter, the spermatic or ovarian, and the renal and colic vessels on each side. The external iliac artery lies medial to the psoas major in the pelvis, and beyond the inguinal (Poupart's) ligament the femoral artery lies ventral to it. The lumbar plexus arises between its origins from the vertebral bodies and disks and those from the transverse processes. The nerves springing from the lumbar plexus take courses subject to much individual variation

FIG. 437.—PSOAS, ILIACUS, AND QUADRATUS LUMBORUM.



through the muscle on the way to their destinations. Fasciculi of the muscle may thus be separated by the femoral (anterior crural) nerve or other branches of the lumbar plexus.

The iliacus muscle in the region of the pelvis is covered by retroperitoneal fat. The psoas muscle crosses its medial margin and from between the two muscles the femoral nerve usually emerges to pass into the thigh above the iliacus. Beyond the inguinal ligament the iliacus lies in front of the capsule of the hip-joint and the straight tendon of the rectus femoris, and is crossed by the sartorius.

Action.—The iliopsoas is a powerful flexor of the thigh at the hip and a weak medial rotator and adductor. It also serves to flex and abduct the lumbar region of the spine.

Variations.—The psoas muscle may be separated from the iliacus as far as the femoral insertion. The part of the psoas arising from the distal lumbar vertebræ may form a distinct muscle. Slips may pass from the psoas major to the psoas minor. A separate lamina of the iliacus muscle may be attached to the iliac fascia. From the anterior inferior iliac spine a small muscle slip may run to the intertrochanteric line or the iliofemoral ligament. To this slip the term iliacus minor has been applied as well as to the larger fasciculus mentioned above.

The psoas minor (fig. 437).—*Origin.*—From the twelfth thoracic and first lumbar vertebræ and the intervening disk

ture and insertion.—The fiber-bundles pass to be attached as far as the level of the fifth vertebra to a flat tendon which appears about the midlumbar region and is inserted iliopectineal eminence. It is intimately united to the iliac fascia.
e-supply.—The branch to the psoas minor arises usually from the first and second lum-res, often in company with the genitofemoral (genitocrural).
on.—To flex the pelvis.
tions.—It is closely applied to the ventral surface of the psoas major.
iations.—The muscle is inconstant in development and is frequently absent. Gruber nd it absent on both sides in 183 out of 450 bodies, on one side in 69.

Bursæ

liopectinea.—A large bursa between the iliopsoas muscle, the iliopectineal eminence, e capsule of the hip-joint. **B. iliaca subtendinea.**—A small bursa between the tendon tion of the iliopsoas and the lesser trochanter.

(*b*) Posterior Group
(Figs. 418, 438, 439, 444)

e muscles of this group arise from the ilium and and sacrum, cover the dorso- surface of the hip, and are inserted into the great trochanter and shaft femur and into the iliotibial band. They lie in three planes. In the **first** (fig. 418) are the flat, quadrilateral **tensor fasciæ latæ,** which arises from nt of the crest of the ilium and is inserted into the iliotibial band, and the rhomboid **gluteus maximus,** which arises from the dorsal portion of the a, the lumbodorsal fascia, the sacrum and coccyx, and the sacrotuberous sacrosciatic) ligament, and is inserted in part into the iliotibial band and into the back of the upper part of the shaft of the femur. The **iliotibial** tract) is a flat tendon which descends, closely fused with the fascia lata, to eral side of the upper extremity of the tibia. In the **second layer** (fig. 439) e flat, thick, triangular **gluteus medius** and the 'pear-shaped' **piriformis.** rmer arises from the upper and back part of the outer surface of the ala of ım, the latter from the ventral surface of the sacrum and the posterior of the great sciatic notch. Both are inserted into the top of the great nter. The **third layer** (fig. 440) is composed of the triangular **gluteus us,** which arises from the inferior ventral portion of the outer surface of ı of the ilium, and is inserted into the front of the great trochanter of nur.

e muscles of this group extend, flex, abduct, and rotate the thigh at the hip. luteus maximus and medius are in part extensors, the gluteus minimus e tensor fasciæ latæ are flexors of the hip-joint. All the muscles serve to t, the gluteus maximus acting thus when the hip is flexed. When the thigh nded the lower part of the gluteus maximus is an adductor. The gluteus ıus and posterior part of the gluteus medius and the piriformis act as , the anterior part of the gluteus medius, the gluteus minimus, and the fasciæ latæ as medial, rotators. The gluteus maximus and the tensor latæ through the iliotibial band keep the extended knee-joint firm. luteus maximus is supplied by the inferior gluteal nerve, the piriformis cial nerves, and the other muscles of the group by the superior gluteal

All these nerves arise from the upper part of the back of the sacral

gluteus medius, gluteus minimus, and piriformis form a group of muscles which in the have a common origin and are more or less fused in the adult. The gluteus maximus ı two distinct, though associated, portions, and the tensor fasciæ latæ as another dis-ırtion. The two muscles, however, are probably to be considered as parts of a primitive elvo-tibial musculature, while the gluteus medius group is represented in the lower forms iofemoral musculature. The former group is often closely associated with the extensor of the thigh in the lower forms (frog), and in some of the lower mammals extends its n to the plantar fascia (ornithorhynchus). In the arm this group is perhaps represented deltoid, the latissimus dorsi, and the teres major, while the gluteus medius group is ıted by the subscapularis.

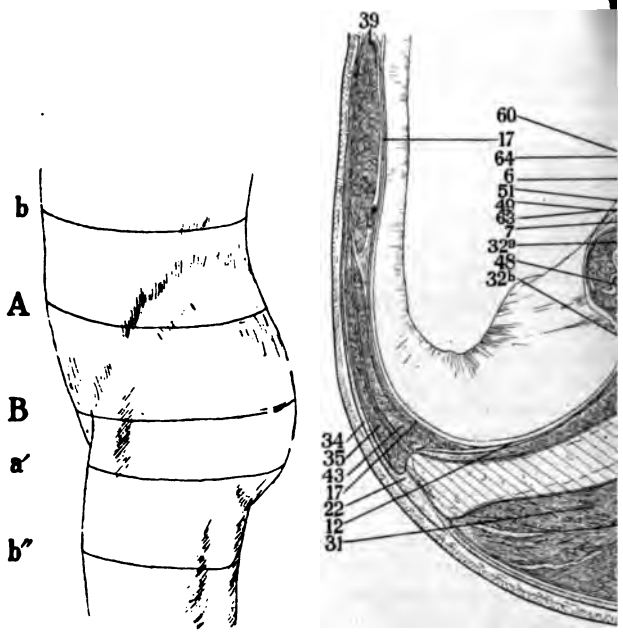
Fasciæ

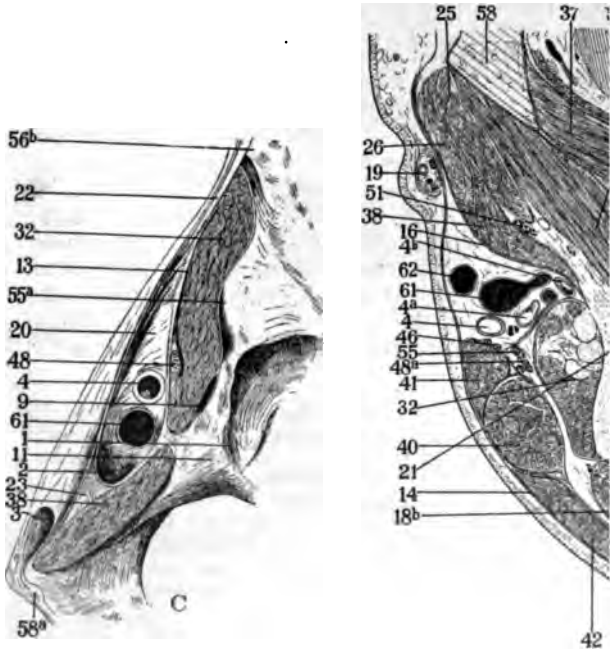
tela subcutanea of the gluteal region is very thick, contains much fat, and is often e into two layers, of which the deeper is closely adherent to the fascia lata and through he gluteus maximus. Over the great trochanter a subcutaneous bursa is usually found rochanterica subcutanea).

Muscle fascia.—The muscles of the hip and th
lata (figs. 418, 438). This arises from the tuber is
ligament, the back of the sacrum and the coccyx, the

FIG. 438, A and B.—TRANSVERSE SECTIONS THROUG
REGIONS INDICATED IN T

C. Section through the muscles of the left inguinal re
ligament (after Spalteholz). *b* in the diagram
indicate sections *A* and *B*, fig. 441. (For legends,





ligament, and the pubic and ischial rami, and extends to
muscles of the leg. It is composed mainly of bundles of fi
axis of the limb. In the region of the gluteal groove it is
which arises from the tuberosity of the ischium and
gluteus maximus muscle.

The superficial portion is the larger, and includes all of that part of the muscle which from the ilium and the more superficial portion of that arising from the sacrum and th part of the coccyx. The deep portion includes that part of the muscle attached to the the sacrum and the coccyx, and to the sacrotuberous ligament. The superficial porti some of the fiber-bundles of the deep portion terminate in the iliotibial band along a tending from the great trochanter to the end of the upper third of the femur. The de tion is inserted chiefly by a flat tendon into the gluteal tuberosity, and also directly i adjacent portion of the origin of the vastus lateralis.

FIG. 439.—THE LATERAL ROTATORS AND THE HAMSTRING MUSCLES.

Nerve-supply.—Two branches (inferior gluteal) arising from the sacral plexus eit rately or united, are usually given to the muscle. One of these curves anteriorly across surface of the proximal superficial portion of the muscle in the middle third between the of origin and insertion, the other descends to enter the middle third of the distal dee of the muscle.

Action.—It is the most powerful extensor of the thigh. It also serves slightly to limb lateralward and to make tense the fascia lata, and through the iliotibial band to extended knee-joint steady. When the thigh is extended the major part of the mu

ior but the upper part is a weak abductor. The whole muscle is an abductor when the s flexed. It is brought powerfully into play in climbing and in walking up hill.
lations.—It is covered by the fatty superficial tissue of the buttock. It extends over the ior portion of the ilium, the lateral surface of the sacrum and coccyx, the sacrotuberous nt, and the great trochanter. It covers the tuber of the ischium in the standing but not sitting position. Immediately beneath the muscle lie portions of the gluteus medius, mis, obturator internus, gemelli, quadratus femoris, obturator externus, and hamstring es, and of the gluteal vessels and nerves and the sciatic nerve.
riations.—Few anomalies are recorded. The deep distal portion of the muscle may be isolated than normal in the adult. A special coccygeofemoral muscle may run from the x to the linea aspera, or from the sacrotuberous ligament to the fascia of the leg. A l fasciculus, the **ischiofemoralis**, may arise from the tuberosity of the ischium and become ed into the lower border of the muscle near the great trochanter. The sacral, ischial, or geal origin may be lacking, or the origin of the muscle may be from the sacrum only.

II. Second Layer

ıe muscles of this layer are the gluteus medius and the piriformis.
ıe **gluteus medius** (fig. 439).—*Origin.*—From (1) the ventral three-fourths of the iliac and the outer surface of the ilium between the anterior and posterior gluteal lines and (2) vesting fascia.
ructure and insertion.—The fiber-bundles converge upon both surfaces of a broad tendon ' to its insertion on an oblong impression on the posterosuperior angle and the external e of the great trochanter. The more posterior fiber-bundles of the superficial stratum ventral portion of the muscle cross obliquely those of the deeper dorsal portion near ndon of insertion. From the tendon an aponeurotic extension is usually continued into ndon of the vastus lateralis.
rve-supply.—From the superior gluteal nerve a branch passes to the dorsal portion of the : and one or more twigs of the branch to the tensor fasciæ latæ enter the ventral portion of ıscle. The branches enter the middle third of the muscle between its tendons of origin sertion. The nerve-fibers arise usually from the fourth and fifth lumbar and first sacral . The branch to the dorsal portion of the muscle has a lower spinal origin than those ventral portion.
ion.—To abduct the thigh. The anterior portion of the muscle is a flexor and a medial ; the posterior a lateral rotator and an extensor. When the muscle acts as a whole, it is al rotator.
ations.—Upon the muscle lie the tensor fasciæ latæ and gluteus maximus muscles and the lata; beneath it lie the gluteus minimus muscle, the superior gluteal nerve and vessels, e great trochanter.
riations.—It may be divided into two distinct portions, or it may be fused with the nis or the gluteus minimus or both. A special fasciculus may extend to the superior ı of the great trochanter.
ə **piriformis** (fig. 439).—*Origin.*—From (1) the lateral part of the ventral surface of the , third, and fourth sacral vertebræ; (2) the posterior border of the great sciatic notch;) the deep surface of the sacro-tuberous (great sacrosciatic) ligament near the sacrum.
ucture and insertion.—The fiber-bundles converge upon a tendon which is inserted upon terior and inner portion of the upper border of the great trochanter. The insertion of undles continues nearly to the great trochanter. An accessory slip of insertion may pass gluteus minimus.
ve-supply.—From a nerve which arises either directly from the first or second sacral or from a loop between them. The nerve enters the deep surface of the muscle in its third. There may be two or more nerves.
tion.—It is an extensor, abductor, and lateral rotator of the thigh. It causes medial n when the hip is flexed.
ations.—Its ventral surface faces the sacral plexus, the rectum, and the hip-joint. It is l dorsally by the gluteus maximus. It lies between the gluteus medius and the superior us. Between the piriformis and the superior gemellus the sciatic nerve usually passes e thigh. The superior gluteal nerve and vessels pass dorsally above its superior margin; erior nerve and vessels beneath its inferior margin.
riations.—It is rarely absent. The origin may extend to the first sacral or to the fifth vertebra and the coccyx. It may be fused with the gluteus medius or minimus or more with the superior gemellus. Its tendon of insertion may be fused with that of the gluteus ı or the obturator internus. In about 20 per cent. of bodies it is divided partly or com- into two portions, between which the sciatic nerve or its peroneal (external popliteal) n usually passes. Rarely the tibial instead of the peroneal portion may pass between the sciculi, or the muscle may be divided into three or more fasciculi, between which the es of the sciatic nerve pass.

III. Third Layer

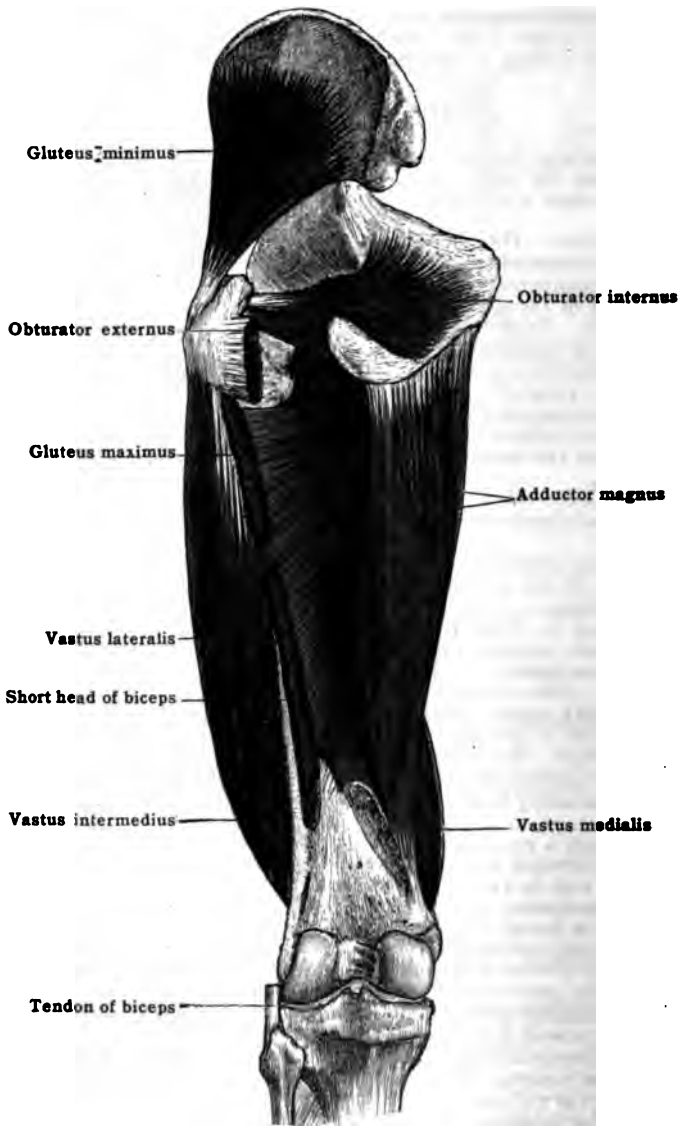
ə **gluteus minimus** (fig. 440).—*Origin.*—From the outer surface of the ilium between terior and inferior gluteal lines;(2) from the septum between it and the gluteus medius ıe anterior superior iliac spine; and (3) from the capsule of the hip-joint.
ucture and insertion.—The fiber-bundles converge upon a tendon which appears on the of the ventral border and gradually spreads over the lateral surface. The muscle is t in front, where it is usually bound by an intermuscular septum to the gluteus medius. ndon is inserted into the ventral surface of the great trochanter of the femur.

Nerve-supply.—From twigs of the branch of the superior gluteal nerve which goes to the tensor fasciæ latæ. These twigs enter the middle third of the muscle as the tensor branch passes across it.

Action.—To abduct the thigh and rotate it medialward. The anterior part of the muscle is a flexor, the posterior an extensor.

Relations.—It is covered by the gluteus medius and piriformis muscles. Beneath it lie the inferior part of the iliac ala, the hip-joint (to the capsular ligament of which it is bound), and the direct tendon of the rectus femoris muscle.

FIG. 440.—THE DEEP MUSCLES OF THE BACK OF THE THIGH.



Variations.—It may be fused with the gluteus medius or the piriformis. It may send a slip to the fascia lata or the vastus lateralis. It may be divided into two distinct divisions, an anterior and a posterior. Very frequently from the anterior margin of the muscle a special fasciculus is more or less isolated (the scansorius, invertor femoris, small anterior gluteal, etc.). The accessorius of the gluteus minimus is a small muscle fasciculus which may lie under cover of the gluteus minimus and extend to be inserted into the capsule of the hip-joint.

BURSÆ

B. ischiadica m. glutei maximi.—A small inconstant bursa between the tuber ischii and the gluteus maximus muscle. B. trochanterica m. glutei maximi.—A large bursa constantly present between the fascial tendon of the gluteus maximus and the posterior lateral surface of the great trochanter and the origin of the vastus lateralis muscle. B. gluteofemoralee.—

Two or three small bursæ on each side of the tendon of attachment of the gluteus maximus to the femur. **B. trochanterica m. glutei medii anterior.**—A small bursa constantly present between the tendon of the gluteus medius muscle and the lateral surface of the great trochanter. **B. trochanterica m. glutei medii posterior.**—A small bursa frequently present between the tendons of the piriformis and the gluteus medius. **B. trochanterica m. glutei minimi.**—A fairly large bursa generally present between the margin of the great trochanter and the tendon of this muscle. **B. m. piriformis.**—A small bursa frequently present between the tendons of the piriformis and superior gemellus muscles and the femur.

2. Ischio-pubo-femoral Musculature of the Hip

The muscles belonging to this group, the obturator internus, the two gemelli, the quadratus femoris and the obturator externus, extend from the pubis and ischium across the back of the hip-joint to the great trochanter and the neighboring part of the shaft of the femur. They are powerful lateral rotators of the thigh. The **obturator internus** (fig. 440), a large, flat, triangular muscle, arises from the pelvic surface of the innominate bone and from the obturator membrane. At the lesser sciatic notch its tendon is joined by the two **gemelli** (fig. 439), one of which arises on each side from the bony projections which make the notch, and the combined tendon is inserted into the trochanteric (digital) fossa. The **quadratus femoris** (fig. 439) passes from the tuber of the ischium to the femur behind and below the great trochanter. These muscles are supplied by special nerves which arise from the front of the sacral plexus and enter the deep surfaces of the muscles. A fifth muscle, attached to the greater trochanter and associated with this group, the **obturator externus,** is differentiated near the adductor muscles of the thigh and is supplied by a branch from the obturator nerve. It arises from the outer surface of the bones bounding the ventral two-thirds of the obturator foramen and is inserted by a tendon into the trochanteric (digital) fossa.

These muscles seem to have no certain representatives in the arm, where the shoulder-joint is entirely ensheathed by the dorsal musculature. It is possible that the pectoral group has a corresponding embryonic origin. The group is represented, with marked variations, in the lower extremities of amphibia and all higher vertebrates.

FASCIÆ

Within the pelvis the obturator internus lies on the obturator membrane. It is covered by the **obturator fascia,** which is attached to the body of the pubis, to the iliac portion of the arcuate line, to the ventral margin of the great sciatic notch, to the ischial spine, to the sacrotuberous (great sacrosciatic) ligament, and with the falciform process of that ligament, to the ischial and pubic rami. Near the upper part of the obturator foramen the fascia instead of being attached to bone is reflected over the muscle and attached to the obturator membrane. It here helps to bound the canal for the obturator vessels and nerve. The upper part of the fascia lies beneath the pelvic peritoneum and the levator ani. The lower part forms the outer boundary of the ischiorectal fossa. The fascia is continued as a thin, adherent membrane over the obturator internus and the gemellus muscles to their attachment. The quadratus femoris is invested by a thin adherent fascial sheet.

MUSCLES

The obturator internus (fig. 440).—*Origin.*—From (1) the pelvic surface of the pubic rami near the obturator foramen; (2) the pelvic surface of the ischium between the foramen and the great sciatic notch; (3) the deep surface of the obturator internus fascia; (4) the fibrous arch which bounds the canal for the obturator vessels and nerve; and (5) the pelvic surface of the obturator membrane except in the lower part.

Structure and insertion.—From this extensive area of origin the fiber-bundles converge toward the lesser sciatic notch and become applied to the broad tendon of insertion. At the notch the muscle curves laterally and extends outward and upward to its insertion into the fore part of the trochanteric fossa of the femur. The tendon is formed of five or six bands which begin high in the muscle and converge into a common tendon situated on the deep surface of the muscles as the latter curves about the ischium. The tendon bands at first throw the tendon into folds which run in ridges in the fibrocartilage which lines the notch. The attachment of fiber-bundles continues upon the dorsal surface of the tendon to half way between the lesser sciatic notch and the great trochanter.

Nerve-supply.—A special nerve to the obturator internus arises from the front of the sacral plexus, usually from the lumbosacral cord and the first and second sacral nerves. This nerve passes lateral to the sacrospinous (lesser sciatic) ligament, then re-enters the pelvis through the lesser sciatic notch and sends out branches of distribution on the pelvic surface of the obturator internus.

Action.—This muscle with its two companions, the gemelli, is a powerful lateral rotator of the thigh. It is also an extensor and abductor when the thigh is bent at a right angle.

Relations.—The chief pelvic relations have been described in connections with the obturator fascia which completely covers the medial surface of the muscle. The muscle passes out between the two sacroischial (sacrosciatic) ligaments. Outside the pelvis the gemellus muscles run on each side of the tendon, which is here closely applied to the capsule of the joint. Dorsal to it lie the gluteus maximus, the sacrotuberous (great sacrosciatic) ligament, the inferior gluteal (sciatic) vessels, and the sciatic and posterior cutaneous nerves. The nerve of the quadratus femoris runs beneath the obturator internus and gemellus muscles.

Variations.—It varies in the extent of its insertions. It may be divided into two parts, a pubic and an ischial. Fasciculi may be sent to the posteroinferior part of the iliopectineal eminence, the tendon of the psoas minor, the tuber ischii, the sacrotuberous (great sacrosciatic) ligament, the ischial spine, etc.

The gemellus superior (fig. 439).—*Origin.*—From the outer surface of the ischial spine and the neighboring edge of the lesser sciatic notch.

Structure and insertion.—The fiber-bundles encircle the upper border and ventral aspect of the tendon of the obturator internus. They are inserted into the upper border of this tendon, and sometimes also into the trochanteric fossa.

Nerve-supply.—From a small nerve which arises either directly from the plexus or as a branch of the nerve to the obturator internus or of that to the quadratus femoris. This nerve usually enters the deep surface of the muscle near the junction of its ischial and middle thirds.

Action.—It is essentially a part of the obturator internus.

Relations.—It lies between the piriformis and the tendon of the obturator internus. Proximally it adjoins its fellow beneath this tendon; distally, the two gemelli enclose the tendon in a musculotendinous sheath.

Variations.—It may be wanting or may have a more extensive origin than usual. It may be joined to the piriformis or to the gluteus minimus or be joined more closely than usual to the obturator tendon.

The gemellus inferior.—*Origin.*—From the upper part of the inner border of the tuberosity of the ischium, the sacrotuberous (great sacrosciatic) ligament and from the neighboring edge of the lesser sciatic notch.

Structure and insertion.—The fiber-bundles converge upon the inferior border of the tendon of the obturator internus, and are inserted by tendon-fibers into this or into the great trochanter below the obturator internus tendon.

Nerve-supply.—From a branch of the nerve to the quadratus femoris. This branch enters the deep surface of the muscle near the junction of the ischial with the middle third.

Action.—It is essentially a part of the obturator internus.

Relations.—It lies between the quadratus femoris and the tendon of the obturator internus.

Variations.—It is rarely absent. It may be joined to the quadratus femoris. It is frequently closely bound up with the obturator internus. It may be doubled.

The quadratus femoris (fig. 439).—*Origin.*—From the upper part of the outer border of the tuber of the ischium.

Structure and insertion.—The fiber-bundles take a nearly parallel course and are inserted into the vertical ridge which terminates above on the inferior dorsal angle of the great trochanter.

Nerve supply.—From a nerve which arises usually from the lumbosacral cord and the first sacral nerve and passes under the gemelli and the tendon of the obturator internus. The nerve enters the deep surface of the muscle near the junction of the ischial and middle thirds.

Action.—It is a powerful lateral rotator and a weak adductor of the thigh.

Relations.—It is covered by the gluteus maximus. Between this muscle and the quadratus femoris runs the sciatic nerve. The obturator externus muscle lies in front. The inferior gemellus extends along its superior border. The adductor minimus adjoins it distally.

Variations.—It is absent in from 1 to 2 per cent. of instances. (Schwalbe and Pfitzner.) It may be double near its femoral insertion. It may be fused with the inferior gemellus or the adductor magnus. It may send a fasciculus to the semimembranosus.

The **obturator externus** (figs. 438, 440, 443).—*Origin.*—From the lateral surface of the pubic and ischial rami, where they bound the obturator foramen, and from the surface of the obturator membrane.

Structure and insertion.—Often the muscle is distally divided into three fasciculi, a superior from the superior pubic ramus, a middle from the inferior pubic ramus and the obturator membrane, and an inferior from the ischium. The fiber-bundles converge upon a tendon which is at first deeply buried, then appears on the lateral surface of the muscle and is continued as a rounded tendon over the capsule of the joint to its insertion into the dorsal part of the trochanteric fossa.

Nerve-supply.—The obturator nerve gives rise, usually in the obturator canal, to a branch which bifurcates to enter the superior border and ventral surface of the muscle in its middle third.

Action.—It is a powerful lateral rotator of the thigh and is also a weak adductor.

Relations.—It is covered by the pectineus, the iliopsoas, and the adductor magnus muscles in front, and by the quadratus femoris behind near its insertion. It covers over the obturator membrane. The obturator nerve passes either above the muscle or through its upper portion.

Variations.—The reported variations are few. It may be joined by a slip from the adductor brevis.

BURSÆ

B. m. obturatoris interni.—A fairly large bursa constantly present between the tendon of the obturator internus muscle and the lesser sciatic notch. It may extend on each side beneath the gemellus muscles. **B. m. quadrati femoris.**—A small bursa frequently found between this muscle and the small trochanter. **B. m. obturatoris externi.**—A bursa is sometimes found between the tendon of this muscle and the capsule of the joint.

B. MUSCLES OF THE THIGH

In the thigh three groups of muscles may be recognized, an anterior or extensor (figs. 442, 443), a medial or adductor (figs. 440, 442, 443), and a posterior, flexor or hamstring group (figs. 439, 444).

In the proximal part of the thigh the anterior group of muscles is separated from the medial group by the iliopsoas muscle (fig. 442) and by the femoral blood-vessels and nerve, and from the posterior group by the gluteus maximus (fig. 444). More distally it is separated from the medial group by the medial intermuscular septum and from the posterior by the lateral intermuscular septum (see p. 499). The medial and posterior groups are closely associated. The adductor magnus belongs ontogenetically to both.

The three groups of muscles, with numerous modifications, are represented in the thighs of amphibia and all higher vertebrates. In the human arm they are likewise represented, the adductor group in a much reduced form by the coracobrachialis. The quadriceps is represented by the triceps in the arm, the long head of the triceps corresponding with the rectus femoris. The hamstring muscles are represented by the biceps and the brachialis.

FASCIÆ

The **fasciæ** and the relations of the musculature of the thigh may be followed in the cross-sections, figs. 438, 441, 445.

The **tela subcutanea** of the thigh varies considerably in thickness in different regions, but is well developed throughout and contains a considerable amount of fat. Over the front of the thigh, especially in the upper medial region, one or more deeper membranous layers may usually be separated from the superficial adipose layer. Between the former and the latter are situated the inguinal lymphatic nodes and the saphenous vein. The deepest layer near the inguinal (Poupart's) ligament is fused with the fascia lata (see below). Medially it is attached to the pubic arch. Thus fluids beneath the tela subcutanea of the abdomen and perineum do not readily pass into the region of the thigh.

Over the lower half of the patella a subcutaneous bursa (**b. præpatellaris subcutanea**) is found. Another is usually found over the upper end of the patellar ligament (**b. infrapatellaris subcutanea**).

The muscles of the thigh are enclosed in a dense fascial sheet, the **fascia lata** (figs. 418, 441). The gluteal portion of this and the iliotibial band have already been described (p. 491). The ventral portion of the fascia, composed chiefly of transverse fibers, is a dense, fibrous membrane. Above it is attached to the inguinal ligament from the anterior superior spine to the pubic tubercle. Below it extends over the knee, where it is united to the capsule of the joint and is strengthened by expansions from the vastus lateralis and medialis. Between the front of the patella and the fascia is a bursa (**b. prepatellaris subfascialis**). Above the knee the fascia is strengthened by an *arciform process* which extends obliquely distally across the fascia from the iliotibial band to the capsule of the knee. This gives rise to a fold in the skin when the leg is extended and the muscles are not tense. Over the medial and posterior regions of the thigh the fascia is less dense. It extends from the body and inferior ramus of the pubis, the inferior ramus and tuber of the ischium, and the sacrotuberous ligament into the fascia of the back of the leg. Above the popliteal space it is strengthened by a transverse band of fibers. Near the knee the tendons of the quadriceps, sartorius, gracilis, and semitendinosus become bound to the fascia by membranous laminæ.

The relations of the fascia lata to the inguinal ligament and the iliac fascia are somewhat complex. The fascia of the iliopsoas muscle extends over the muscle to its femoral insertion. Above the inguinal ligament this fascia is called the **fascia iliaca**; below the ligament, the **fascia iliopectinea**. This fascia is firmly united to the lateral extremity of the inguinal ligament. The pectineus muscle is likewise invested with a fascial membrane which extends over the muscle from the pubis to the femur and is fused laterally with that of the iliopsoas. This combined fascia is firmly bound between the muscles to the iliopectineal eminence. The iliopectineal fascia divides the space beneath the inguinal ligament into a lateral **lacuna musculorum**, which contains the iliopsoas muscle and the femoral (anterior crural) nerve, and a medial **lacuna vasorum**, which contains the femoral artery and vein. Medial to the vein is the **femoral ring**, bounded medially by the **lacunar (Gimbernat's) ligament**. This is closed off from the abdominal cavity by a septum derived from the transversalis fascia, the **femoral septum**, but offers passage for lymph-vessels.

Beyond the inguinal ligament the fasciæ of the iliopsoas and pectineal muscles line a triangular space, **Scarpa's triangle** [trigonum femorale], a space bounded by the inguinal (Poupart's) ligament and the sartorius and long adductor muscles. Within this triangle is a depression, the **iliopectineal fossa**, through which run the femoral vessels (fig. 438). The sartorius muscle partly overlies the distal lateral margin of this fossa. The fascia lata is here reflected from the surface of the sartorius to the iliopsoas fascia, and becomes fused with it. From the medial margin of the sartorius a process of the fascia is continued over the lateral and upper part of the fossa, and is attached to the inguinal and lacunar (Gimbernat's) ligaments (fig. 420). Over the lower extremity of the fossa a process is continued medially into the pectineal fascia. On the medial margin of the fossa the fascia lata is continued directly into the pectineal fascia. The lateral concave margin of the fascia overlying the fossa is called the **falciform margin**; the upper extremity of this, the **superior cornu**; the distal extremity, the **inferior cornu**. The oval space bounded by the margo falciformis is called the **fossa ovalis** (saphenous opening).

FIG. 441, A–D.—TRANSVERSE SECTIONS THROUGH THE LEFT THIGH IN THE REGIONS INDICATED IN THE DIAGRAM.

More distally the same [illegible] sartorius on the lateral margin [illegible] the medial margin to a [illegible] magnus. Beneath the sartorius and between the [illegible] triangular space bounded by the sheaths of these muscles [illegible] in which run the chief blood-vessels of the thigh. This space [illegible] is known as **Hunter's canal**, or the **adductor canal**. [illegible] surrounding fibrous tissue pass through the [illegible] adductor magnus and the femur, to the back of the thigh [illegible] posterior surface of the vast[illegible] to the femur.

MUSCLES

1. The Anterior Group

Figs. 442, 443

This group, which forms a semiconical mass [illegible] the quadriceps femoris and the sartorius muscles [illegible] nerve.

The **sartorius** is a long, ribbon-like muscle [illegible] superior spine of the ilium and extends along the [illegible] passing obliquely across the upper part of the thigh [illegible] dorsomedial side of the knee, whence its tendon [illegible] into the ventromedial surface of the superior extremity of the tibia.

The **quadriceps femoris** is composed of four muscles differentiated from a common embryonic origin. Of these, the **rectus femoris**, which arises from the ventrolateral margin of the ilium by two tendons, is the most superficial and the most completely differentiated. The **vastus lateralis**, which arises from the superior extremity of the ventral surface of the shaft of the femur and from the lateral lip of the linea aspera; the **vastus medialis**, which arises from the medial lip of the linea aspera and from the intertrochanteric line; and the **vastus intermedius** (crureus), which arises between these two and beneath the rectus from the surface of the femur, are less distinctly differentiated from one another. The vastus intermedius and vastus lateralis are partly fused at the insertion. The

intermedius and medialis at their origins. From the four muscles arises a ten which is inserted into the tuberosity of the tibia. In this tendon, which closely applied to the capsule of the knee-joint, lies a sesamoid bone, the pate

The sartorius and the rectus flex the thigh; the quadriceps extends the the sartorius flexes the leg and rotates the thigh lateralward and the medialward.

FIG. 442.—MUSCLES OF THE FRONT OF THE THIGH.

In the embryo the sartorius has an origin distinct from that of the quadriceps. anthropoid apes it is much more developed than in man.

In addition to supplying the muscles of this group, the femoral nerve also gives br to the iliacus muscle (p. 487) and the pectineus muscle (p. 503).

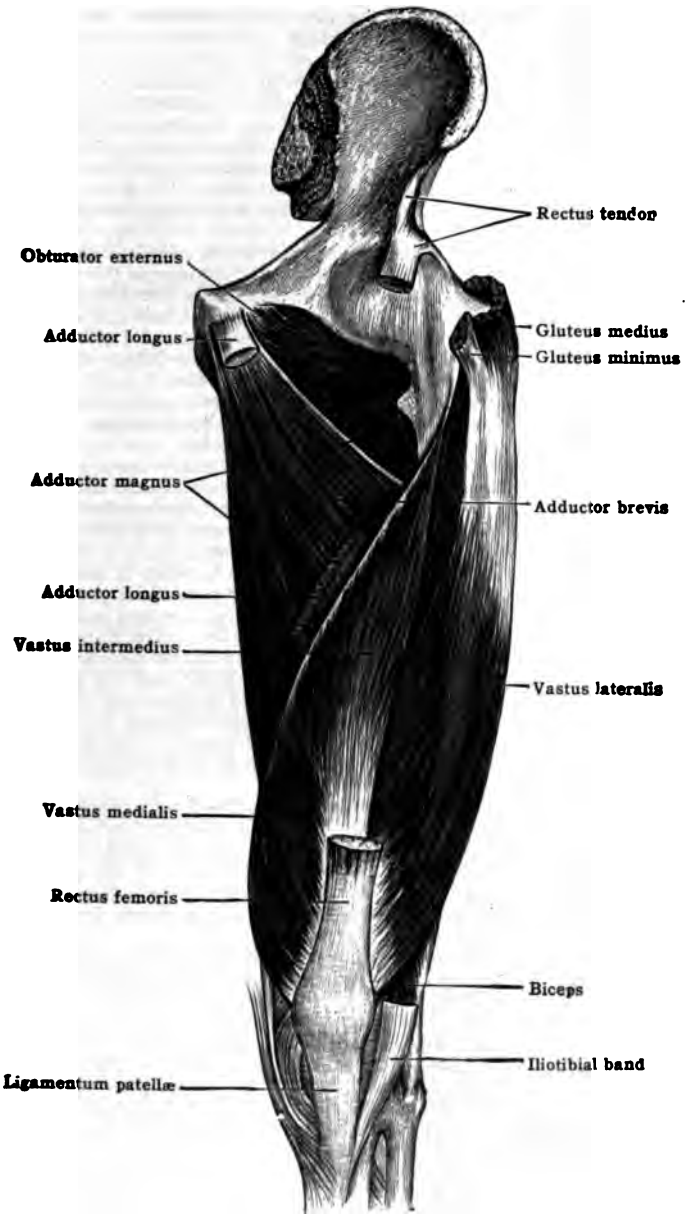
The sartorius (fig. 442).—*Origin.*—From the anterior superior spine of the ilium a area immediately below this.

Insertion.—Into the medial surface of the tibia near the tuberosity and into the neigh fascia of the leg.

ire.—The muscle arises by short tendinous strands. The fiber-bundles take a nearly ırse. The component muscle-fibers are said to be the longest in the body. Near the icondyle of the femur the tendon of insertion makes its appearance on the deep as- ıe muscle. On the superficial surface of the tendon the muscle-fibers are inserted the distal margin of the knee-joint. From there the tendon turns forward to its

supply.—Usually two branches enter the deep surface of the proximal third of the One or both of them may be bound up with an anterior cutaneous nerve passing

FIG. 443.—THE DEEP MUSCLES OF THE FRONT OF THE THIGH.



ıe muscle. The first of the branches is distributed chiefly to the lateral and proximal, i to the medial and distal, portions of the muscle. Within the muscle is a complex

.—(1) To flex the thigh at the hip, abduct and rotate it lateralward; (2) to flex the leg ı it slightly medialward; (3) to make tense the medial part of the fascia lata.
ns.—The sartorius lies in a fascial canal bounded by the fascia lata and by inter- septa which descend from this. It crosses the rectus femoris, iliopsoas, the adductor d magnus, and the vastus medialis muscles, the femoral vessels and nerve, and the . At its insertion its tendon covers the gracilis and semitendinosus.

Variations.—It may arise from the inguinal ligament or be inserted into the fascia lata, the medial epicondyle, or the capsule of the knee-joint. It may be longitudinally divided into two parts. The tendon of the secondary slip is in such instances usually attached to the capsule of the knee-joint, but sometimes is attached to the fascia over the vastus medialis or to the anterior wall of the adductor canal. More frequently the muscle is partly divided proximally or distally. The secondary tendon of origin may arise from the anterior inferior spine, the iliopectineal eminence, etc. The muscle is very rarely absent. It may be crossed by a tendinous inscription, or more rarely it is rendered digastric by an intervening tendon.

The quadriceps femoris (figs. 442, 443).—This, as pointed out above, is composed of the rectus femoris and the vastus lateralis, intermedius, and medialis.

The rectus femoris (fig. 442).—*Origin.*—By two tendons. The anterior 'straight' tendon is attached to the anterior inferior spine of the ilium; the posterior 'reflected' tendon to the posterosuperior surface of the rim of the acetabulum. The two tendons unite so as to form a small arch above the capsule of the joint.

Structure and insertion.—From this arch an aponeurotic expansion descends upon the front of the muscle nearly to the middle of the thigh. This expansion is broad above, becomes narrower as it descends, and is continued a short distance as a narrow intramuscular tendon after it disappears from the surface. The tendon of insertion begins on the back of the muscle above the middle of the thigh, expands into a broad aponeurosis, and finally becomes a strong band which is inserted into the proximal border of the patella. The fiber-bundles pass in a bipenniform manner from the back and sides of the tendon of origin to the front and sides of the tendon of insertion.

Nerve-supply.—As a rule, two branches enter the muscle. One of these enters the deep surface of the muscle in its upper fourth, and is distributed mainly to the proximal part of the lateral half. The other enters the medial margin of the muscle near the junction of the proximal and middle thirds, and is distributed chiefly to the medial half and distal portion of the muscle.

The vastus lateralis (vastus externus) (fig. 443).—*Origin.*—From—(1) the shaft of the femur along the anteroinferior margin of the great trochanter and in front of the gluteal tuberosity; and (2) the lateral intermuscular septum along the upper half of the linea aspera.

Insertion.—By a flat tendon into—(1) the proximolateral border of the patella; and (2) the front of the lateral condyle of the tibia and the fascia of the leg.

Structure.—The fiber-bundles arise partly from the bone, partly from an aponeurosis which covers the proximal two-thirds of the muscle, and from the lateral intermuscular septum. They take a parallel course distally in a ventromedial direction, and are inserted into an aponeurosis which lies on the deep surface of the muscle and receives fibers until within a few centimeters of the patella. Ventrally this aponeurosis fuses with the rectus tendon, laterally with that of the vastus medialis, and dorsally it receives some of the fiber-bundles of the vastus intermedius. Commonly the muscle is distinctly divisible for the greater part of its course into two sheets, a superficial and a deep. The deep sheet is often subdivided into two laminæ.

Nerve-supply.—Usually there are three nerves, one of which, accompanied by blood-vessels, runs on the inner surface of the superficial sheet midway between the tendons of origin and insertion, the second between the two laminæ of the deep layer, and the third passes through the innermost lamina to be distributed in part to the vastus intermedius (crureus) muscle.

The vastus medialis (vastus internus) (fig. 443).—*Origin.*—From the whole extent of the medial lip of the linea aspera and from the distal half of the intertrochanteric line. The origin takes place by means of an aponeurosis which is adherent to the tendons of insertion of the adductor muscles.

Structure and insertion.—The fiber-bundles arise from the deep surface of this aponeurosis and are inserted on the medial surface and margin of a tendon which begins on the deep surface of the muscle about its middle near the lateral margin. On the distal lateral border of the muscle it is inserted into the medial half of the proximal margin of the patella and into the medial condyle of the tibia and the fascia of the leg. For some distance near the knee the lateral margin of the tendon is united to the tendons of the vastus intermedius (crureus), lateralis (externus) and the rectus.

Nerve-supply.—The nerve to this muscle descends on its medial surface, often bound up with the saphenous nerve for a part of its course. It gives off successive branches and finally sinks into the muscle substance. These branches enter about midway between the origin and insertion of the fiber-bundles of the muscle.

The vastus intermedius (crureus) (figs. 441, 443).—*Origin.*—From (1) the distal half of the lateral margin of the linea aspera and its lateral bifurcation; (2) the anterolateral surface of the shaft of the femur. Between the origin of the vastus intermedius (crureus) and that of the vastus medialis the shaft of the femur is free from muscle attachment.

Structure and insertion.—On the ventral surface of the muscle lies an aponeurosis which extends from its proximal fourth to the proximal margin of the patella. The fiber-bundles of the muscle are inserted into the deep surface of this and into the deep surface of the aponeurosis of insertion of the vastus lateralis. The proximal fiber-bundles descend vertically, the medial and lateral, especially the latter, obliquely to their insertion. Medially the tendon is more or less fused with that of the vastus medialis, and laterally with that of the vastus lateralis. The muscle is composed of muscle lamellæ superimposed concentrically about the shaft of the femur. The deepest, most distal of these is called the **articularis genu** (**suberureus**). The fiber-bundles of this layer are inserted into the capsule of the joint or into the superior margin of the patella.

Nerve-supply.—Several branches are usually distributed to this muscle. To the lateral region a branch from the nerve to the vastus lateralis is usually given; to the middle of the muscle another branch descends from the femoral (anterior crural) nerve; to the medial portion there extend several twigs from the nerve to the vastus medialis.

Tendon of the quadriceps.—The quadriceps tendon may be more or less distinctly divided into layers, of which the superficial layer belongs to the rectus, the deep to the vastus

...rmedius, and the intermediate to the vastus lateralis and medialis. Some of the more **...rficial fibers of the tendons of the two vasti, however, cross in front of the rectus ten-** The combined tendon of the quadriceps is in part attached to the superior and lateral **...rgins of the patella, and in part extends over the patella into the patellar ligament. A ...rt of the tendon fibers of the vastus lateralis and medialis run on each side of the patella to ...e ventral surface of the condyles of the tibia. These form the retinacula patellæ mediale and ...erale.** The medial is the broader and better developed. With the retinacula are included **...ndles of fibers which run from the epicondyles to the patella and into which some muscle ...er-bundles are inserted. From the apex of the patella to the tuberosity of the tibia the ...adriceps tendon is continued as the patellar ligament** (fig. 446).

Nerve-supply.—The relations of the branches of distribution to the various parts of the **...uscle** have been pointed out above in connection with each head. The general relations of **...ese** branches of the femoral nerve are as follows:—From the femoral nerve near the proximal **...d** of the vastus medialis the branches for the vastus lateralis, vastus intermedius (crureus), and **...ctus** pass distally and laterally between the rectus and vastus intermedius (crureus) to be **distributed** to the muscles named, while the chief nerve for the vastus medialis descends on the **...edial** side of this muscle in company with the saphenous nerve. The branches to the vastus **...teralis** and intermedius are commonly bound up in a single nerve-trunk for some distance. **The** branches to the rectus are usually bound up with this trunk for a shorter distance. The **...erve** to the vastus medialis may be united to this trunk for a slight distance, but more **frequently** it is more or less bound up with the saphenous nerve.

Action.—The quadriceps is the extensor of the leg. The rectus femoris also flexes the thigh **at** the hip and is a weak abductor of the thigh. The articularis genu makes tense the capsule **of** the knee-joint.

Relations.—The quadriceps is covered ventrally immediately by the fascia lata. The **...rtorius** runs along its medial margin; the tensor fasciæ latæ lies over the proximal quarter **of** its lateral surface. Dorsal to the vastus lateralis lie the gluteus maximus and biceps; dorso-**...edial** to the vastus medialis, the three adductor muscles and the semimembranous. Next **to** vastus medialis lies the adductor canal with the femoral vessels and the saphenous nerve.

Variations.—The variations of this muscle, aside from a greater or less fusion of its parts, **are** not marked. The attachment of the rectus femoris to the anterior inferior spine, which **takes** place in the embryo later than its insertion above the acetabulum, may be wanting. On **the** other hand, this tendon may extend to the anterior superior spine. Occasionally the deep **reflected** tendon may be wanting. The **rectus accessorius** is a fasciculus rarely found, which **arises** by a tendon from the rim of the acetabulum and is inserted into the ventral edge of the **vastus** lateralis. It is innervated by a twig from the branch to the rectus.

Bursæ

B. m. recti femoris (superior).—A small bursa between the deep tendon of the rectus femoris **and the edge of the acetabulum. Rare. B. m. recti femoris (inferior).**—Between the tendon **of the rectus and combined tendon of the vastus lateralis and medialis. Occasional. B. præpatellaris subtendinea.**—A bursa between the tendon of the quadriceps and the periosteum **of the patella. Of the three præpatellar bursæ—the subcutaneous, subfascial, and subten-dinous—as a rule only one occurs. When two or three exist, they usually communicate freely with one another. B. suprapatellaris.**—A bursa between the anterior surface of the lower end **of the femur and the tendon of the quadriceps. It usually communicates with the joint cavity. B. infrapatellaris profunda.**—A bursa between the patellar ligament and the tibia. It seldom **communicates with the joint cavity. B. m. sartorii propria.**—A bursa, fairly large, between the **tendon of the sartorius and the tendons of the semitendinosus and gracilis muscles. This usually communicates with the bursa anserina** (see p. 506).

2. The Medial (Adductor) Group
(Figs. 440, 442, 443)

To this group of muscles belong the gracilis, the pectineus, the adductors brevis, longus, and magnus, and the obturator externus. The most superficial of the group is the **gracilis** (figs. 439, 442). This ribbon-shaped muscle arises from the inferior pubic and ischial rami, extends along the medial side of the thigh, and gives rise to a tendon which curves forward from behind the medial condyle of the femur to be inserted under the tendon of the sartorius into the medial side of the upper extremity of the tibia. The quadrilateral **pectineus** arises from the body and superior ramus of the pubis; the triangular **adductor longus** from the superior ramus medial to this (fig. 442). The pectineus is inserted into the pectineal line of the femur; the adductor longus into the middle third of the linea aspera. The triangular **adductor brevis** (fig. 443) arises from the inferior pubic ramus below the adductor longus. It is inserted into the pectineal line and the upper third of the linea aspera. The large, triangular **adductor magnus** (figs. 440, 443) arises from the inferior ramus and the tuber of the ischium and is inserted behind the short and long adductors into the whole length of the linea aspera, and by a special tendon into the adductor tubercle of the femur. The deepest muscle of the group, the **obturator externus,** which arises from the outer

surface of the bones bounding the ventral two-thirds of the obturator foramen and is inserted by a tendon into the trochanteric (digital) fossa, has been described in connection with the ischio-pubo-femoral muscles of the hip.

All the muscles of this group adduct the thigh. The gracilis, obturator externus, adductor brevis and the lower part of the adductor magnus (when the thigh is extended) rotate it lateralward. The pectineus, adductor longus, and the adductor magnus rotate it medialward. Those attached to the pubis flex the thigh. The gracilis flexes the leg and rotates it medialward. The inferior part of the adductor magnus extends the thigh.

The muscles of this group are supplied by the obturator nerve, except the pectineus, which usually gets its whole supply from the femoral (anterior crural) nerve, and the adductor magnus, which gets a part of its supply from the sciatic nerve.

In embryonic development the pectineus arises in close conjunction with the obturator group, and in the adult it may get the whole or a part of its nerve-supply from the obturator nerve or from the accessory obturator nerve. In the lower mammals the nerve-supply may come from the femoral (anterior crural) or the obturator nerve or from both. It is not certain whether the innervation from the femoral nerve indicates that the muscle belongs phylogenetically, if not ontogenetically, with the primitive dorsal musculature of the limb. By some it is considered to be derived in part from the primitive dorsal, in part from the primitive ventral, musculature. The adductor magnus arises in the embryo as two distinct portions, one connected with the flexor group of muscles, the other with the adductor group. These two portions later become fused. Primitively the sciatic portion of the adductor magnus and the semimembranosus constitute a single medial flexor muscle.

The gracilis (figs. 439, 442).—*Origin.*—By a flat tendon from the medial margin of the inferior ramus of the pubis and the pubic extremity of the inferior ramus of the ischium.

Structure and insertion.—The nearly parallel fiber-bundles which arise between two laminæ of the tendon form a thin band of muscle which is narrower and thicker distally than proximally. They are inserted on a tendon which begins as an aponeurosis on the posterior border and medial surface of the muscle in the distal third of the thigh, becomes free as a rounded cord a little proximal to the medial condyle of the femur, runs behind the condyle, and then turns forward to be inserted by an expanded process into the tibia below the medial condyle.

Nerve-supply.—The nerve enters the deep surface of the muscle near the junction of the superior and middle thirds.

Action.—To adduct, flex and (slightly) rotate the thigh lateralward, and flex the leg. With the knee flexed, it acts as a medial rotator of the leg.

Relations.—It occupies a position beneath the fascia lata and superficial to the adductor brevis, longus, and magnus muscles. Distally the sartorius lies in front, the semimembranosus behind. Its tendon crosses the tibial collateral ligament of the knee-joint and the tendons of the semitendinosus and the semimembranosus, and is overlapped by that of the sartorius.

Variations.—The pubic origin of the muscle may be much reduced or may be double. Its tendon of insertion may give rise to an accessory fasciculus which extends distally in the leg. In some of the apes the tendon descends normally much farther down the leg than in man.

The pectineus (fig. 442).—*Origin.*—(1) From the pecten (crest) of the os pubis, the bone in front of this, and the pectineal fascia near this origin; and (2) from the anterior margin of the obturator sulcus and from the pubocapsular ligament. Laterally the two areas of origin are usually separated by most of the superior surface of the body of the pubis. Medially they come together.

Structure and insertion.—From each area of origin a separate lamina arises. The fiber-bundles of each layer take a nearly parallel course and terminate between two tendinous lamellæ which fuse to be inserted into the upper half of the pectineal line behind the small trochanter. The fiber-bundles of the superficial layer cross those of the deep slightly obliquely. The muscle faces ventrally at its origin, laterally at its insertion.

Nerve-supply.—From a branch of the femoral (anterior crural) nerve, which passes behind the femoral artery and vein and through the pectineal fascia to enter the ventral surface of the muscle. It may also be supplied by the accessory obturator nerve, when present, or by a branch from the obturator. When both the femoral (anterior crural) and obturator nerves supply this muscle, the femoral supplies the superficial, the obturator, the deep lamina (Paterson).

Action.—To flex and adduct the thigh (as in crossing the legs).

Relations.—It is covered by the pectineal fascia, lies between the iliopsoas and the adductor longus muscles, and crosses the obturator externus and adductor brevis muscles. The medial circumflex artery runs between it and the iliopsoas, the deep femoral artery between it and the adductor longus.

Variations.—The extent of the division of the pectineus into superficial and deep portions varies considerably. It may also be divided into a lateral and a medial division. Often the pectineus is fused with the adductor longus. It may receive an accessory fasciculus from the capsule of the hip-joint, the iliacus muscle, the obturator externus, or the adductor brevis muscles, or the small trochanter. It may send a fasciculus to the sartorius.

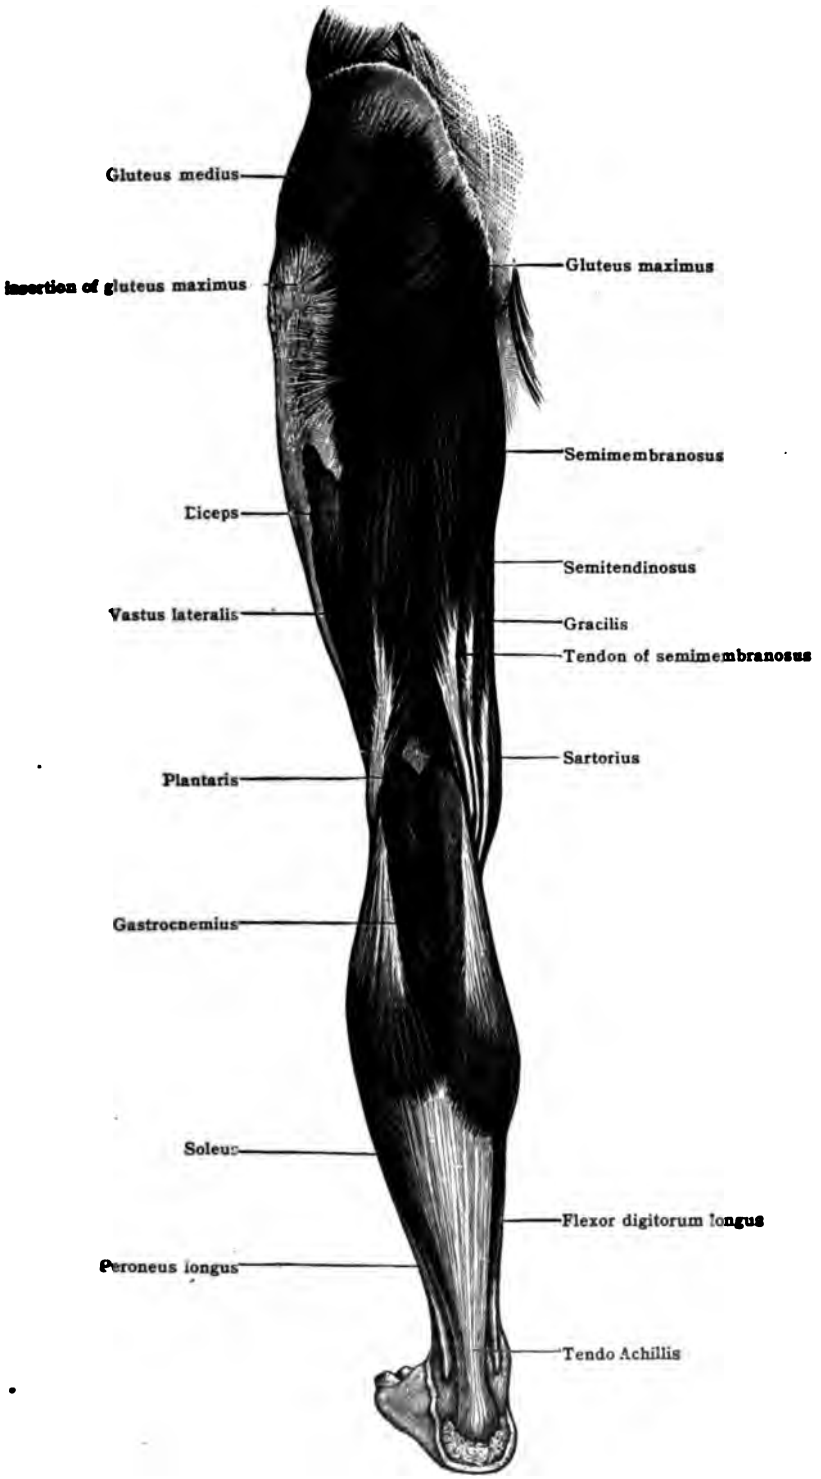
The adductor longus (fig. 442).—*Origin.*—From the medial corner of the superior ramus of the pubis by a strong tendon which extends for some distance on the medial border of the muscle.

Structure and insertion.—From this tendon the fiber-bundles diverge toward their insertion. This takes place between two lamellæ of a short tendon attached to the middle third of the linea

The tendon is usually fused to the medial intermuscular septum and sends an expan- the long tendon of the adductor magnus.

ve-supply.—A branch from the anterior division of the main obturator trunk gives off

FIG. 444.—SUPERFICIAL MUSCLES OF THE BACK OF THE THIGH AND LEG.



twigs which enter the middle third of the deep surface of the muscle. Occasionallya ranch from the femoral (anterior crural) nerve enters the muscle. This is probably in nature.

Action.—To adduct and flex the thigh, and rotate it medialward.

Relations.—The sartorius, the vastus medialis, and the femoral vessels lie anterolat to it. Behind it lie the adductor brevis and adductor magnus muscles. Between these the longus run the profunda vessels. Its lateral border touches the pectineus above, bu separated from it toward the insertion.

Variations.—It may be fused with the other adductors, including the pectineus. It m be doubled. The femoral insertion may extend to the medial epicondyle.

The adductor brevis (fig. 443).—*Origin.*—From the medial part of the outer surface of t inferior ramus of the pubis directly, and by means of short tendinous processes or a short f tendon.

Structure and insertion.—From their origin the fiber-bundles diverge into a sheet which inserted by short tendinous bands into the distal two-thirds of the pectineal line and the up third of the linea aspera. The muscle is more or less completely divided into two fasciculi alo its insertion. The place of division is near where the intertrochanteric line curves away fro the linea aspera.

Nerve-supply.—Usually from the anterior but also sometimes from the posterior branch of the main obturator trunk. The rami enter the middle third of the muscle near the proximal border.

Action.—It is chiefly an adductor and to a less extent a flexor and a lateral rotator of the thigh.

Relations.—In front lie the pectineus and adductor longus; behind, the obturator externus quadratus femoris and adductor magnus. It is crossed by the profunda artery. The first perforating artery passes usually between the two fasciculi of the insertion.

Variations.—It may be fused with other members of the group. It may be divided completely into two fasciculi, rarely into three.

The adductor magnus (figs. 440, 443).—The *origin* of this muscle begins on the inferior ramus of the pubis posterior to the origins of the adductor brevis and gracilis muscles. From here it extends backward along the inferior margin of the ventrolateral surface of the ischium to the tuberosity. The muscle in passing from this curved origin to its extensive femoral insertion presents posteriorly a longitudinal groove in which rest the hamstring muscles. The adductor magnus is composed of three superimposed fasciculi, of which the first is frequently fairly distinct and is called the **adductor minimus**, while the other two are normally fused, but are occasionally distinct.

The **superior fasciculus** (**adductor minimis**) *arises* directly from the inferior rami of the pubis and ischium. From here the fibers diverge to form a thin sheet *inserted* by tendinous bands to the medial side of the gluteal ridge and the superior part of the linea aspera. The **middle fasciculus** *arises* directly from the inferior margin of the ventrolateral surface of the inferior ramus and the tuber of the ischium, and from a tendon which descends along the dorsomedial margin of the muscle from the tuber ischii. The fiber-bundles diverge to be inserted between the lamellæ of a narrow flat tendon attached to the distal three-fourths of the linea aspera. This tendon is pierced by the perforating vessels. The **inferior fasciculus** arises dorsal to and in common with the middle fasciculus. The fiber-bundles converge toward a strong tendon which begins in the distal third of the thigh and is *inserted* into a tubercle at the distal end of the medial supracondylar ridge.

Nerve-supply.—The chief nerve-supply is from the posterior ramus of the obturator. This enters by one or more branches the proximal portion of the ventral surface of the muscle about midway between its pubic and femoral attachments. It also receives a branch from the sciatic which enters the dorsal surface of the muscle in the middle third of the thigh. To the adductor minimus a branch may be sent from the nerve to the quadratus femoris.

Action.—It is the strongest of the adductors. The superior and middle fasciculi rotate the thigh medialward and flex it; the inferior rotate it lateralward when the thigh is extended, but medialward when the thigh is flexed. The latter also extend the thigh.

Relations.—In front are the pectineus, the short and long adductor and the vastus medialis muscles, and the profunda artery. Behind lie the hamstring muscles and the gluteus maximus. Medially lies the gracilis muscle. The femoral and perforating arteries pass through its attachment to the shaft of the femur.

Variations.—The divisions of the muscle may be more or less distinct. It may be partly fused or exchange fasciculi with neighboring muscles—the semimembranosus, quadratus femoris, adductor brevis, and adductor longus.

Bursæ

B. m. pectinei.—A small bursa frequently present between this muscle and the iliopsoas and small trochanter. **B. anserina.**—A fairly large bursa which lies between the tendons of the sartorius, gracilis, and semitendinosus muscles and the tibial collateral ligament of the knee-joint. (See also B. M. Sartorii Propria, p. 503.)

3. The Posterior (Hamstring) Group

(Figs. 439, 444)

The muscles of this group are the semitendinosus, semimembranosus, and biceps. They flex the leg and extend and adduct the thigh. The semitendinosus and semimembranosus rotate the thigh and the leg medialward; the biceps, lateralward. The semitendinosus and the long head of the biceps constitute a superficial layer; the semimembranosus and the short head of the biceps a deep

er. The **semitendinosus** and the **long head of the biceps** arise by a common don from the tuber of the ischium. The somewhat fusiform semitendinosus es rise to a tendon in the lower half of the thigh. The tendon curves forward ind the knee to be inserted under that of the sartorius into the medial side of e tibia. The penniform **short head of the biceps** arises from the linea aspera the lower part of the thigh, and is inserted, together with the fusiform long ad, into a tendon that passes over the lateral side of the knee and is attached the head of the fibula. The **semimembranosus** arises from the tuber ischii rough a long, flat, triangular tendon. The belly of the muscle incresaes in ckness toward the knee. It is inserted by a strong tendon on the back of the edial condyle of the tibia. From the tendons of all the hamstring muscles pansions are sent into the crural fascia.

The muscles of this group are all supplied by the tibial portion of the sciatic, cept the short head of the biceps, which is supplied from the peroneal portion.

The femoral head of the biceps is characteristic of the anthropoid apes and man. In many mmals its place is taken by a slender muscle, the **tenuissimus**, which extends from the caudal rtebræ, the sacrotuberous (great sacrosciatic) ligament, or the gluteal fascia to the fascia the back of the leg. In some forms this muscle is broad instead of slender. According to stut, the long head of the biceps may be looked upon as arising by two fasciculi, one primirely attached to the posterior part of the ilium, the other to the caudal vertebræ or coccyx. e sacrotuberous (great sacrosciatic) ligament represents the reduced upper portion of this scle. In the fetus the origin of the muscle extends higher on the sacrotuberous ligament an in the adult. In many of the lower mammals the origins of the semimembranosus and nitendinosus take place in part from the sacrocaudal vertebræ.

In the mammals below man the insertion of the biceps, gracilis, and semitendinosus takes ce chiefly into the fascia of the back of the leg, and extends more distally than in man. is insertion of these flexor muscle is associated with a permanent position of flexion the leg at the knee. In the human embryo likewise these muscles are inserted more tally than in the adult. In the lower primates the semimembranosus is chiefly a medial ator of the leg.

Biceps femoris (figs. 439, 444).—**Long head.**—*Origin.*—From a tendon common to it and semitendinosus. This tendon arises from the more medial of the two facets on the back of tuber of the ischium and from the sacrotuberous (great sacrosciatic) ligament. It is tinued for a third of the distance to the knee as a septum between the biceps and the semidinosus, and for a short distance as an aponeurotic sheath on the deep surface of the biceps.

Structure and insertion.—The fiber-bundles begin to arise from the tendon some distance m the ischium. They form a thick fusiform belly which is inserted into the deep surface of endon that begins laterally on the back of the muscle about the middle of the thigh. The ertion of the fiber-bundles of the long head continues on the medial margin of the deep surface the tendon nearly as far as the lateral condyle of the femur.

Short head.—*Origin.*—By short tendinous fibers from the lateral lip of the linea aspera of femur from the middle of the shaft to the bifurcation of this line, the proximal two-thirds the supracondylar ridge, and the lateral intermuscular septum.

Structure and insertion.—The fiber-bundles take a nearly parallel course, to be inserted on deep surface of the common tendon of insertion. The most distal fibers are inserted nearly the skeletal attachment of the tendon. The tendon is inserted into the superior extremity the head of the fibula, into the lateral condyle of the tibia, and into the fascia of the leg.

Nerve-supply.—Commonly two branches are given to the long head of the biceps. One these branches is given off proximal to the ischium, and enters the proximal third of the deep face of the muscle. The other is given off more distally and usually enters the middle third. ther or both branches may be doubled or the two may be combined for some distance in a mmon trunk. The nerve-fibers arise usually from the first, second, and third sacral nerves. e branch to the short head arises from the peroneal (external popliteal) portion of the sciatic rve about the middle of the thigh. It enters the posterior surface near the lateral margin of gin and insertion. The nerve-fibers come chiefly from the fifth lumbar, first and second ral nerves.

Action.—To extend and adduct the thigh and flex the leg. The short head acts only on the . The long head acts as a lateral rotator of the thigh, and of the leg when flexed.

Relations.—The upper extremity of the muscle is covered by the gluteus maximus. Below is the long head and tendon of insertion lie beneath the fascia lata and overlie the short head. ntral to the muscle lie the tendon of origin of the semimembranosus, the adductor magnus d vastus lateralis muscles, and the lateral head of the gastrocnemius. The medial border is contact with the semitendinosus and semimembranosus. Distally it forms the upper lateral rder of the popliteal space. The sciatic nerve runs between it and the adductor magnus.

Variations.—The short head is rarely absent. It may be more isolated from the long ad than usual, and at times has a separate tendon of insertion. It may itself be divided into o distinct laminæ. Its origin may take place higher up on the femur than usual or from the cia lata. Variations of this sort suggest the tenuissimus muscle of some of the lower mamals (see above). The long head of the biceps may receive accessory fasciculi from the coccyx, rum, sacrotuberous (great sacrosciatic) ligament, tuber of the ischium, or the deep surface the gluteus maximus. These fasciculi suggest the iliac and sacrococcygeal origin of the scle found in lower vertebrates (see above). Inferiorly, a muscle fasciculus may take place of the fibrous prolongations from the tendon of the biceps into the sural fascia (the

tensores fasciæ suralis). This may extend to the tendon of Achilles. The long head may have a tendinous inscription similar to that of the semitendinosus.

The **semitendinosus** (figs. 439, 444).—*Origin.*—Partly from a mediodorsal facet on the distal margin of the tuber of the ischium by direct implantation of the fiber-bundles, partly from the medial surface of the tendon common to it and the long head of the biceps.

Structure and insertion.—The fiber-bundles spread out to form a flat, fusiform belly which about the middle of the thigh, again contracts toward the tendon of insertion. This begins on the medial margin and dorsal surface of the muscle, becomes free from the muscle slightly above the medial condyle of the femur, passes behind this and curves forward to be inserted by a triangular expansion into the proximal part of the medial surface of the tibia behind and distal to the insertion of the gracilis. An aponeurotic expansion is continued into the fascia of the leg. About the middle of the muscle a narrow irregular tendinous inscription more or less complete divides the belly into proximal and distal divisions.

Nerve-supply.—To the muscle two nerves are commonly given. One arises from the sciatic nerve or directly from the plexus, proximal to the tuber of the ischium, sometimes in company with a branch to the long head of the biceps. It enters the middle third of the deep surface of the proximal portion of the muscle. The other branch arises from the sciatic nerve, usually distal to the ischial tuber, sometimes in common with a nerve to the biceps or the semimembranosus. It enters about the middle of the deep surface of the distal half of the muscle. Either or both branches may be represented by two nerves. The nerve fibers of the first branch arise chiefly from the first and second sacral nerves, those of the second from the lumbar and first sacral nerves.

Action.—To extend and adduct the thigh and rotate it medialward and to flex the leg and with knee flexed, to rotate the leg medialward.

Relations.—It is covered by the gluteus maximus and fascia lata; on the lateral side by the biceps; and in front, the semimembranosus and adductor magnus.

Variations.—It may be completely separated from the biceps at its origin. It may be fused with neighboring muscles. There may be two tendinous inscriptions. It may have a femoral head (a condition characteristic of many birds). A muscle fasciculus may extend from the body of the muscle to the fascia of the back of the leg.

The **semimembranosus** (figs. 439, 444).—*Origin.*—By a long, flat tendon which lies beneath the proximal half of the semitendinosus, and which arises from the more lateral of the two facets on the back of the tuber of the ischium, between the tendons of the biceps and the quadratus femoris. The tendon is at first adherent to the tendon of the adductor magnus in front and to that of the biceps and semitendinosus behind. It descends to the middle of the muscle.

Structure and insertion.—From both surfaces of the medial side and distal extremity of the tendon of origin fiber-bundles arise which take an oblique course to their insertion on the aponeurosis of the tendon of insertion. This appears on the deep surface and medial margin of the muscle opposite the end of the tendon of origin and descends on the medial side and deep surface of the muscle. Near the back of the medial condyle of the femur the insertion of muscle-fibers ceases and the tendon is inserted directly on the back of the medial condyle of the tibia, and by aponeurotic expansions into the capsule of the joint, into the lateral condyle of the femur, into the tibial collateral ligament, and into the fascia of the popliteus muscle.

Nerve-supply.—By several branches from the sciatic nerve, which usually arise from a common trunk in company with the branches to the adductor magnus. These branches enter the deep surface of the muscle about midway between the origin and insertion of the constituent fiber-bundles.

Action.—To flex the leg and rotate it medialward and to extend and adduct the thigh and rotate it medialward.

Relations.—It is covered by the gluteus maximus, the long head of the biceps, the semitendinosus, and the fascia lata. It lies dorsal to the quadratus femoris, the adductor magnus, and the knee-joint.

Variations.—It may be fused with the semitendinosus or the adductor magnus. It may be doubled. Its tendons may have a more extensive attachment than usual. The extent of the belly of the muscle varies considerably. A muscle fasciculus may be sent into the popliteal space. An extra head may arise from the ischial spine.

Bursæ

B. m. bicipitis femoris superior.—A fair-sized bursa which frequently lies between the tendon of origin of the long head of the biceps and semitendinosus and the tendon of the semimembranosus and the ischial tuber. **B. m. bicipitis femoris inferior.**—A small bursa which separates the tendon of insertion from the fibular collateral ligament of the knee-joint. **B. m. bicipitis gastrocnemialis.**—A bursa infrequently found between the tendon of the biceps and the tendons of origin of the lateral head of the gastrocnemius and the plantaris muscles. **B. m. semimembranosi.**—This is a large double bursa constantly present. One part extends between the semimembranosus, the medial head of the gastrocnemius, and the knee-joint. With the cavity of the joint it frequently communicates. The other part extends between the tendon of the semimembranosus and the medial condyle of the tibia.

C. MUSCULATURE OF THE LEG

(Figs. 444, 446 447)

The musculature of the leg arises in part from the distal end of the femur, but in the main from the tibia and fibula. The muscle-bellies are best developed in the proximal half of the leg, where they give rise to the 'calf' behind and to less

narked ventral and lateral protrusions. Toward the ankle the muscle- give way to tendons which attach the muscles of the leg to the skeleton of ot.

he musculature is divisible into **anterior, a lateral** and a **posterior group** of es. The anterior and lateral groups are separated from one another by an uscular septum. The anterolateral groups are separated from the pos- group by the tibia and fibula, the interosseous membrane, and by an **muscular** septum which extends from the lateral margin of the shaft of the to the fascia enveloping the leg. Medially the separation is well marked e broad medial surface of the tibia. Laterally the line of division is not so y marked externally. In the proximal part of the leg the dorsal musculature udes somewhat ventrally; in the distal part of the lateral musculature passes l to the lower end of the fibula. The posterior group is divided by a trans- septum into superficial and deep divisions.

he anterior group of muscles flexes the ankle dorsally, everts the foot and nds the toes. The lateral group extends the ankle (plantar flexion) and rts the foot. The posterior group flexes the knee, extends the ankle, inverts foot and flexes the toes.

While in the forearm the extensor-supinator muscles extend proximally on the radial side he arm to the humerus, and the flexor-pronator muscles on the ulnar side, in the leg both he corresponding sets of muscles extend primitively on the fibular side of the leg to the femur. he higher vertebrates the superficial layer of the flexor musculature of the leg takes origin n both sides of the distal extremity of the femur, and the origin of the extensor musculature s to extend to the femur. The crural musculature is primitively inserted into the bones of leg, the tarsus, and the aponeuroses of the foot. On the extensor side of the leg the muscula- ultimately becomes attached wholly to the foot by means of tendons differentiated, in part ast, from the dorsal aponeurosis. The lateral portion of the extensor musculature, which itively extends from the femur to the fibula, in the higher vertebrates extends from the a to the tarsus and metatarsus (peroneal musculature). On the flexor side of the leg the superficial musculature maintains a tarsal attachment through the tendon of Achilles. deeper musculature in part extends from the femur to the tibia, and in part arises from fibula and tibia, and is inserted into the metatarsus and the digits through tendons differ- ated from the plantar aponeuroses. The musculature of the sole of the foot is highly devel- l in five-toed vertebrates, but in those which walk on the toes, and especially in hoofed mals, it is very greatly reduced.

FASCIÆ OF THE LEG

(Fig. 445)

he **tela subcutanea** of the leg contains a considerable amount of fat where it overlies the les, but less where it overlies the bones and joints. Subcutaneous bursæ are found over tuberosity of the tibia (**b. subcutanea tuberositatis tibiæ**) and over each of the malleoli **subcutanea malleoli medialis et lateralis**). Over the dorsum of the foot the tela contains paratively little fat, but on the sole of the foot and plantar surface of the toes it contains h fat interposed between dense fibrous tissue. The **b. subcutanea calcanea** lies beneath uber calcanei.

he **crural fascia**, or external layer of fascia of the leg, extends from the knee to the ankle. rms an enveloping cone-like sheath for the muscles and is adherent to the periosteum of medial surface of the tibia. It is formed of transverse, oblique, and longitudinal fibers is thickest in front.

entrally the fascia of the thigh, to which the tendons of the quadriceps, sartorius, gracilis, tendinosus, and biceps muscles and the iliotibial band are closely united, becomes attached these tendons to the tibia and fibula. From these attachments, therefore, the fascia of front of the leg may be said to arise. Into it extend processes from the tendons men- d. Dorsally the fascia of the thigh is continued uninterruptedly into that of the leg. ally the crural fascia is attached to the two malleoli and to the posterior surface of the neus.

n the proximal part of the leg in front the underlying muscles in part take origin from the a; in other places the fascia is separated from the underlylng muscles by loose tissue.

rom the fascia two main intermuscular septa arise. One, the **anterior intermuscular um**, extends between the extensor digitorum longus and peroneal muscles to the anterior of the fibula; the other, the **posterior intermuscular septum**, between the peroneal muscles the soleus to the lateral crest of the fibula. These septa separate compartments for the rior, lateral, and posterior groups of muscles.

s the heads of the gastrocnemius pass over the back of the knee they are held in place by a ial deep lamina of the fascia lata, which distally becomes fused with the crural fascia (fig. A).

he semimembranosus has a special fascial investment which, on the back of the knee mes bound on each side of the muscle and its tendon to the capsule of the joint. This a extends into a transverse septal membrane which is continued over the deep muscles of ack of the leg to the ankle. It is united on one side to the tibia, on the other to the fibula.

Proximally the fibers are continued into it from the tendon of the semimembranosus. Over the back of the tibia the septum is interrupted by the attachment of the soleus to the popliteal line. Beyond the tibial origin of the soleus it is fused on the medial side of the flexor digitorum longus to the crural fascia.

In addition to the two intermuscular septa and the longitudinal transverse septum, other septa serve to separate the individual muscles of the different groups.

Above the ankle the fascia is enforced by bands of tissue so that ligaments are formed which serve to retain in position the various tendons which pass from the leg into the foot.

The transverse crural ligament (upper part of anterior annular ligament) (fig. 446) lies on the front of the lower part of the leg above the ankle. It is composed of fascia strengthened by transverse bundles which pass from the medial side of the tibia to the ventral margin of the fibula. From its deep surface a strong, broad septum descends to the tibia and divides the underlying space into two osteofibrous canals, a medial for the tibialis anterior and a lateral for the long extensor muscles. The lateral compartment is further subdivided by a slightly marked septum into a medial division for the extensor hallucis longus and a lateral for the extensor digitorum longus and the peroneus tertius.

The cruciate ligament (lower part of anterior annular ligament) (fig. 446) serves to hold the tendons of the anterior muscle group in place as they pass to the dorsum of the foot. In part it is formed by a dense fibrous band lying in the fascia over the ankle, in part of a ligament which passes from the bones of the ankle to the deep surface of this band. The superficial band is V-shaped. It arises from the lateral surface of the body of the calcaneus and passes across the dorsum of the foot, one arm of the V going to the medial malleolus, the other to the side of the foot, where it terminates in the fascia over the first cuneiform bone. The apex of the V lies over the tendons of the extensor digitorum longus and peroneus tertius muscles. The distal arm extends over the tendons of the extensor hallucis longus and tibialis anterior muscles. The proximal arm passes over the tendon of the extensor hallucis longus and then divides into two layers, between which the tendon of the tibialis anterior passes. The deeper ligament mentioned above arises from deep within the tarsal sinus, some of its fibers even from the sustentaculum tali. It then passes forward and medially beneath the long extensor

tendons, and divides into two parts, one of which curves about the medial margin of the don of the extensor digitorum longus, the other about the extensor hallucis longus tend the under surface of the proximal arm of the V-shaped band.

The **peroneal retincula** are strengthened regions in the fascia which serve to hold tendons of the peroneal muscles in place. The **superior** extends from the lateral malleolus the fascia on the back of the leg, and to the lateral surface of the calcaneus. The in overlies the tendons on the lateral surface of the calcaneus, and is attached to this bone each side of them. Between the tendons it sends a septum to the bone. It is connected w the superficial layer of the cruciate ligament.

The **laciniate ligament** (internal annular) (fig. 447) is found on the medial side of the ank Here the fascia is strengthened by fiber-bands which form a well-marked ligament that ho in place the tendons of the deep dorsal cruropedal muscles. This ligament extends from dorsal and distal margins of the medial malleolus to the calcaneus. It is closely bound to tibia and the talotibial (tibioastragaloid) ligament until the tendon of the tibialis posterior reached. It passes over this and becomes bound to the bony structures on the poste margin of the tendon. From this attachment two layers, a deep and a superficial, ext backward. The superficial layer extends to the tuber calcanei, and is connected superio with the crural fascia. The deep layer, which represents a continuation distally of the tra verse septum, extends over the tendons of the flexor digitorum longus and flexor hallucis lon to the medial surface of the calcaneus, and is closely united to the underlying bone on ea side of these tendons, thus giving rise to osteofibrous canals.

MUSCLES

1. Muscles of the Front of the Leg
(Figs. 446, 449)

The anterior musculature of the leg consists of four muscles, the tibialis anterior, extensor digitorum longus, peroneus tertius, and extensor hallucis longus. The **tibialis anterior** has a quadrangular prismatic belly which arises from the lateral side of the tibia and adjacent interosseous membrane in the proximal half of the leg. The tendon passes over the front of the tibia to the first metatarsal. The **extensor digitorum longus** is a transversely flattened, fusiform muscle, which arises from the superior extremity of the tibia, the anterior crest of the fibula, and the adjacent interosseous membrane, and gives rise to a tendon which passes over the front of the distal extremity of the tibia and sends tendons to the terminal phalanges of the four more lateral toes. The **peroneus tertius** represents a more or less completely differentiated portion of the preceding muscle. Its tendon passes laterally through the same osteofibrous canal in the same synovial sheath and terminates on the fifth metatarsal. The **extensor hallucis longus** is a narrow muscle which arises from the distal half of the medial surface of the fibula and the interosseous membrane. Its tendon extends over the ankle to the great toe. The tendons of these muscles are held in place by the transverse and cruciate ligaments described above.

All the muscles of this group flex the foot. The extensors extend the toes; the peroneus tertius and the extensor digitorum longus evert the foot. The nerve supply is from the deep peroneal (anterior tibial) nerve.

The tibialis anterior is represented in the arm probably by the **brachioradialis** and the two radial extensors; the extensor digitorum longus by the extensor **digitorum communis** and extensor digiti quinti proprius; and the extensor hallucis longus by the extensor **pollicis longus**. Two abnormal muscles not infrequently found, the abductor **hallucis longus** and extensor **primi** internodii hallucis, represent probably the corresponding normal muscles of the hand.

The tibialis anterior (fig. 446). *Origin.*—From the distal surface of the lateral condyle of the tibia, and the lateral surface of the proximal half of the shaft of the tibia, the adjacent interosseous membrane, the overlying fascia near the condyle (tuberosity) of the tibia, and the intermuscular septum between it and the extensor digitorum longus.

Structure.—Bipenniform. The fiber-bundles converge upon a flat tendon which begins high in the muscle and emerges on the anterior margin of the muscle about the middle of the leg. On the deep surface the implantation of fiber-bundles continues to the transverse crural (anterior annular) ligament.

Insertion.—The tendon passes over the front of the tibia to the medial side of the foot, where it is inserted into the medial surface of the first cuneiform and the base of the first metatarsal.

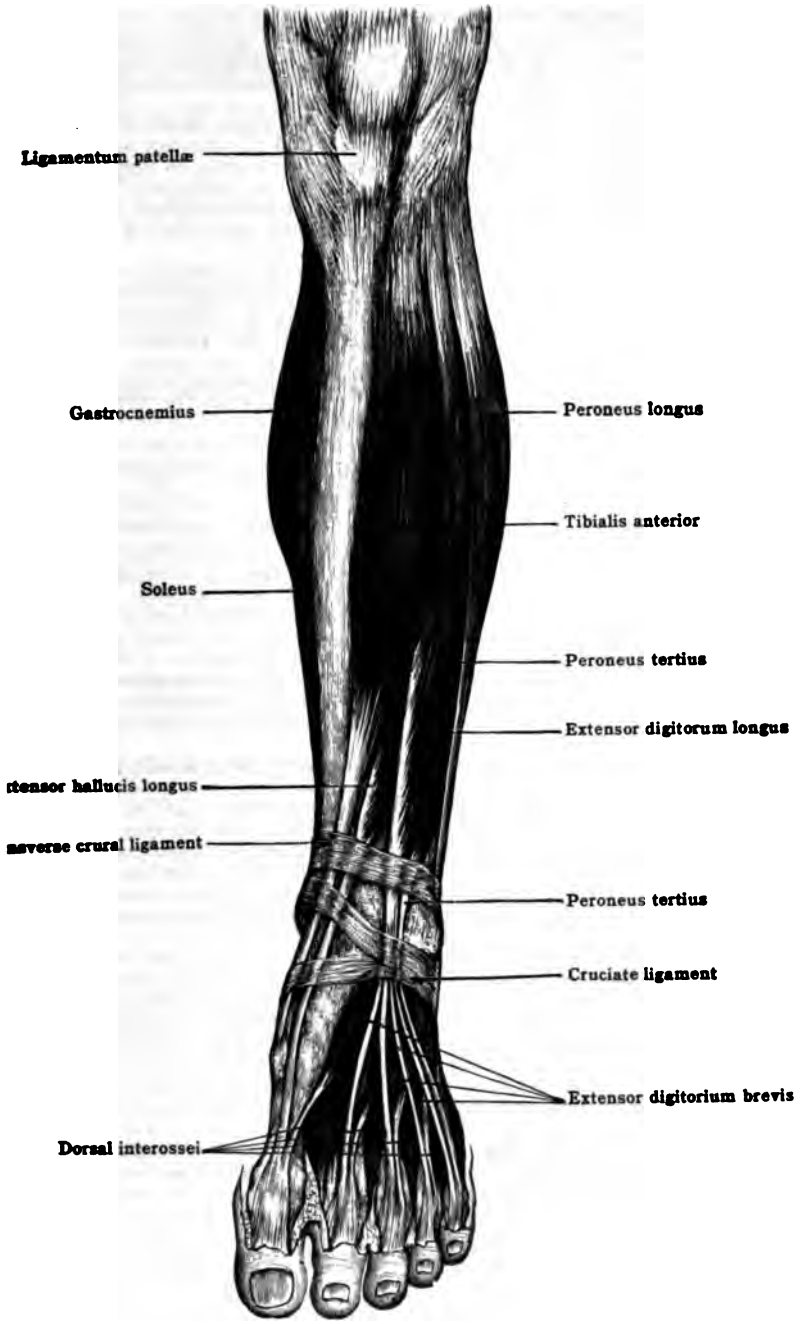
Nerve-supply.—As a rule, a branch from the common peroneal (external popliteal) nerve enters the proximal portion of the muscle by several twigs, and another from the deep peroneal (anterior tibial) enters near the middle of the belly on the lateral edge.

Relations.—In the proximal half of the leg the extensor digitorum longus lies lateral to it; and between the two muscles, the anterior tibial artery and vein. It is covered by the crural fascia and rests on the interosseous membrane. Distally it lies over the extensor hallucis

he tendon passes in special compartments beneath the transverse and the cruciate nnular) ligaments.

tensor digitorum longus (fig. 446).—*Origin.*—From the lateral condyle of the tibia, ›r crest (surface) of the fibula, the intermuscular membrane between it and the erior, the lateral margin of the interosseous membrane, the septum between it and us lungus, and the fascia of the leg near the tibial origin.

FIG. 446.—THE MUSCLES OF THE FRONT OF THE LEG.



ɛ.—Penniform. The fiber-bundles converge upon the posterior surface of a tendon ns at the middle of the leg. The implantation of fibers continues nearly to the ually at the distal margin of the transverse (anterior annular) ligament the tendon o two parts which pass between the two layers of the cruciate (lower part of an- ılar) ligament, and then each divides again into two parts, thus giving rise to four or each of the four lateral toes.

Insertion.—Each tendon on the dorsal surface of the toe to which it goes divides into three fasciculi: an intermediate, which is attached to the dorsum of the base of the second phalanx, and two lateral, which converge to the dorsum of the base of the third phalanx. The margins of the tendon are also bound by fibrous tissue to the sides of the back of the first phalanx.

Nerve-supply.—Most frequently two branches of the deep peroneal (anterior tibial) enter the deep surface of the muscle, one near its tibial origin, one about the center of the belly.

Relations.—In the proximal half of the leg it lies on the interosseous membrane, and beneath the fascia of the leg, and adjoins medially the tibialis anterior, laterally the peroneus longus. Distally it lies over the extensor hallucis longus and adjoins laterally the peroneus brevis. The tendon passes beneath the transverse crural and the superficial layer of the cruciate (anterior annular) ligaments and over the extensor digitorum brevis muscle. The superficial peroneal (musculocutaneous) nerve runs in the septum between it and the peroneal muscles; the anterior tibial artery and deep peroneal nerve pass beneath the head of the muscle, and then between it and the tibialis anterior.

The peroneus tertius (fig. 446).—*Origin.*—From the distal third of the medial surface of the fibula, the neighboring interosseous membrane, and the anterior intermuscular septum.

Structure.—It is essentially a fasciculus of the extensor digitorum longus, from which it is seldom completely differentiated. The fiber-bundles descend obliquely forward to be inserted in a penniform manner on a tendon which runs along the lateral margin of the tendons of the extensor digitorum. The attachment of fiber-bundles continues to the cruciate ligament (lower part of anterior annular ligament).

Insertion.—On the base of the fifth metatarsal and often also on the base of the fourth.

Nerve-supply.—The more distal nerve to the extensor digitorum continues into this muscle.

Relations.—It lies lateral to the extensor digitorum longus. Its tendon passes into the foot beneath the transverse crural and the superficial layer of the cruciate ligament in the same compartments with those of the extensor longus.

The extensor hallucis longus (fig. 446).—*Origin.*—From the middle two-fourths of the medial surface of the fibula near the interosseous crest, and from the distal half of the interosseous membrane.

Structure.—Penniform. The fiber-bundles are attached as far as the cruciate ligament to the back and sides of a tendon which begins on the anteromedial margin of the distal third of the muscle.

Insertion.—On the base of the second phalanx of the big toe. On the back of the first phalanx the margins of the tendon are attached to the bone by bands of fibers.

Nerve-supply.—As a rule, a branch from the deep peroneal (anterior tibial) nerve enters the deep surface of the muscle near the junction of the upper and middle thirds, and passes distally across the middle of the obliquely running muscle fiber-bundles.

Relations.—It lies on the distal half of the interosseous membrane, partly covered by the extensor digitorum longus and the tibialis anterior muscles. Its tendon passes over the front of the distal extremity of the tibia and the medial side of the dorsum of the foot and is held in place by the transverse and cruciate ligaments and by a strengthening band in the fascia over the base of the first metatrsal. In the distal part of the leg the anterior tibial artery and the deep peroneal (anterior tibial) nerve pass beneath the muscle to enter the foot of the lateral side of its tendon.

Actions of the muscles of this group.—All flex the ankle. The tibialis anterior and extensor hallucis longus evert the foot at the talocalcaneonavicular joint, and invert it at the talonavicular and calcaneocuboid joints. In certain positions the tibialis anterior may, however, invert the foot at the latter joint. The peroneus tertius and the long extensor of the toes evert the foot. The force of the extensor hallucis longus is exerted powerfully on the first phalanx and weakly on the second. The short muscles of the big toe aid in extending the second phalanx. The extensor digitorum longus extends the first phalanx of each toe powerfully, but exerts less force on the second and third. The lumbrical muscles assist in extending the last two phalanges.

Variations.—The origin of the tibialis anterior may extend to the femur. Its tendon of insertion may give accessory slips to the cuneiforms, metatarsals, and phalanges. More rarely its belly is divided into two portions, one of which sends a tendon to the first cuneiform and one to the first metatarsal. A slip, the **tensor fasciæ dorsalis pedis** (Wood), may pass to the dorsal fascia of the foot. Another, the **tibioastragalus anticus** (Gruber), to the talus (astragalus) or calcaneus. The bellies or the tendons of the extensor hallucis and extensor digitorum may be more or less completely fused, or tendon slips may pass from the tendon of one muscle to that of the other. Tendon slips may pass to the metatarsal bones or from the tendon of one toe to that of a neighboring toe. The tendon to each toe may be doubled. The belly of the extensor digitorum longus may be more or less completely subdivided to correspond with the tendons to individual toes. The peroneus tertius is frequently fused with the long extensor. It may be doubled. More often its tendon may bifurcate or trifurcate and be inserted into the extensor tendons of the fifth toe or into the fourth or third metatarsal. It is absent in about 8.5 per cent. of bodies (Le Double).

Abnormal Muscles.—The **abductor hallucis longus** is rarely found as a completely independent muscle. It usually arises as a fasciculus of the extensor digitorum longus, extensor hallucis longus, or the tibialis anterior. It is inserted into the base of the first metatarsal. The **extensor primi internodii hallucis** (extensor hallucis brevis) has an origin similar to that of the long abductor above described. It is inserted into the dorsum of the base of the first phalanx of the big toe. It is not to be confounded with that portion of the extensor digitorum brevis connected with the great toe and also sometimes called the extensor **hallucis brevis.**

B. subtendinea m. tibialis anterioris.—A small bursa between the medial surface of the first cuneiform bone and the tendon of the tibialis anterior. **B. subtendinea m. extensoris hallucis longi.**—A small bursa beneath the tendon near the tarsometatarsal articulation. It may communicate with the synovial sheath of the tendon. **B. sinus tarsi.—A large bursa in**

the sinus tarsi and on the lateral surface of the neck of the talus (astragalus) beneath the tendons of the extensor digitorum longus and the fibrous bands between the talocalcaneal and the cruciate ligaments. It extends back to the talocrural, forward to the talonavicular joint, and may communicate with the joint cavity of the latter.

Synovial Tendon-sheaths

Vagina tendinis m. tibialis anterioris.—This sheath surrounds the tendon from above the transverse crural ligament to the talonavicular joint. **Vagina tendinis m. extensoris hallucis longi.**—The sheath begins above the proximal arm of the cruciate ligament, and ends near the tarsometatarsal joint beneath a band-like thickening of the dorsal fascia of the foot. **Vagina tendinum m. extensoris digitorum longi.**—This sheath surrounds the tendons of the long digital extensor and the peroneus tertius from above the cruciate ligament to the middle of the third cuneiform bone.

2. Lateral Musculature of the Leg
(Figs. 446, 447, 453)

The lateral muscles consist of the peroneus longus and the peroneus brevis. They extend and evert the foot. The thick prismatic belly of the **peroneus longus** arises from the proximal half of the lateral surface of the fibula and from neighboring structures, while the smaller belly of the **peroneus brevis** arises from the middle third of the lateral surface of this bone. The peroneus longus partly covers the peroneus brevis. The tendons of the two muscles pass behind the lateral malleolus, held in place by special retinacula (p. 512). There the tendon of the peroneus longus lies at first lateral to and then crosses behind that of the peroneus brevis and curves about the lateral side of the calcaneus and across the sole of the foot closely applied to the cuboid and to the tarsometatarsal articulations, and terminates on the base of the first metatarsal. The tendon of the peroneus brevis terminates on the lateral side of the foot at the base of the fifth metatarsal. The nerve supply is from the superficial peroneal (musculocutaneous) nerve.

The two muscles are probably represented in the arm by the extensor carpi ulnaris. In some of the lower animals the head of the peroneus longus extends to the femur. The fibular collateral ligament of the knee-joint probably represents in man the femoral head of the peroneus longus.

The peroneus longus (figs. 447, 453).—*Origin.*—Anterior head: tendinous from the anterior tibiofibular ligament, the neighboring part of the lateral condyle of the tibia, and the head of the fibula; fleshy from the proximal third of the anterior intermuscular septum and the crural fascia near the tibia. Posterior head: fleshy from the proximal half of the lateral surface of the shaft of the fibula and from the posterior intermuscular septum.

Structure.—Bipenniform. The fiber-bundles converge upon a tendon which begins high in the muscle. The constituent fiber-bundles of the anterior head are long and take a nearly vertical course. The fiber-bundles of the posterior head take a more oblique course and their attachment extends more distally on the tendon. The tendon emerges on the surface of the muscle in the distal half of the leg. The fiber-bundles of the posterior head extend to within a few centimeters of the lateral malleolus. The tendon passes through the retromalleolar groove, passes across the lateral face of the calcaneus, to and through the peroneal groove of the cuboid, and crosses the second and third tarsometatarsal joints. Where the tendon enters the groove in the cuboid it contains a fibrocartilaginous nodule which may become a sesamoid bone.

Insertion.—On the inferior surface of the first cuneiform and on the superolateral border and base of the first metatarsal. From the region of the fibrocartilaginous nodule above mentioned a fibrous slip is usually sent to the base of the fifth metatarsal.

Nerve-supply.—Most commonly the peroneal (external popliteal) nerve before dividing gives off two branches. One of these enters the deep surface of the middle third of the anterior head, the other passes across the middle third of the constituent bundles of the posterior head. The latter branch may arise from the superficial peroneal (musculocutaneous) nerve, and it may extend to supply the peroneus brevis.

The peroneus brevis (fig. 447).—*Origin.*—From the middle third of the lateral surface of the fibula; (2) from the septa which separate it from the anterior and posterior groups of muscles.

Structure.—Penniform. The fiber-bundles converge upon a tendon which begins high in the muscle and becomes visible on the lateral surface of the distal half of the belly. Behind the lateral malleolus the tendon becomes free, then passes forward below the malleolus and across the calcaneus and cuboid.

Insertion.—Into the tip of the tuberosity of the fifth metatarsal.

Nerve-supply.—The nerve arises from the superficial peroneal (musculocutaneous) nerve, or from a branch to the peroneus longus. It enters the proximal margin of the muscle and passes distally across its constituent fiber-bundles.

Relations.—The peroneal muscles in the leg are contained in a compartment bounded by the anterior and posterior intermuscular septa, by the fibula, and by the fascia of the leg. The peroneus longus to a considerable degree overlies the peroneus brevis. Beneath the upper part of the peroneus longus the peroneal (external popliteal) nerve bifurcates into its two chief branches. The deep peroneal (anterior tibial) nerve passes medially beneath the anterior head of the muscle. The superficial peroneal (musculocutaneous) nerve extends in the interval between the areas of the attachment of the two heads of the peroneus longus, and along the anterior margin of the peroneus brevis to the anterior intermuscular septum, through which it passes to its superficial distribution. The tendon of the peroneus longus at first lies lateral to and slightly overlaps that of the peroneus brevis. Toward the tip of the malleolus it lies almost directly posterior to this tendon. On the lateral surface of the calcaneus the tendon of the brevis lies superior to that of the longus, from which it is separated by bony spine, the processus trochlearis of the calcaneus. The tendon of the longus is separated from the deep surface of the abductor of the little toe, and is held in place in the groove in the cuboid by the long plantar ligament.

Action.—The peroneus brevis everts the foot. The peroneus longus extends, abducts, and everts the foot, and supports the arch of the foot. The peroneus brevis also extends the foot when this is flexed.

Variations.—The two peroneal muscles may be more or less fused. The origin of the peroneus longus may extend to the femur. The two heads of origin may be fused. Its tendon of insertion may send slips to the second, third, and rarely to the fourth and fifth metatarsals. The tendon may be united to that of the tibialis posterior (12 out of 45 bodies—Picou). Sesamoid cartilages or bones are occasionally found in the retromalleolar and calcaneal portions of the tendon. The tendon of the peroneus brevis may send a slip to the second or third phalanx or to the head of the metatarsal of the fifth toe, to its extensor tendon, or to the cuboid. It may also send a fasciculus to the fourth metatarsal or the extensor tendon of the fourth toe.

Accessory peroneals.—Poirier considers these all varieties of a muscle which in its simplest form arises from the distal fourth of the fibula and is inserted by a tendon into the fifth toe. A corresponding muscle is normally found in many of the monkeys (**peroneus digiti quinti**). In man in one form or another it is a frequent anomaly. It may be so fused with the peroneus brevis that only its tendon of insertion is apparent. It may appear as a special muscle fasciculus of the peroneus longus or brevis. It may be merely a tendinous band, or it may be tendinous at origin and insertion, with an intermediate belly. Instead of being attached to the fifth toe, it may be inserted into the fifth metatarsal, the cuboid, the tendon of the peroneus longus, the calcaneus, lateral malleolus, or posterior talofibular ligament.

Synovial Tendon-sheaths

Vagina tendinum peroneorum communis.—There is a double sheath for the tendons of the peroneal muscles as they pass back of the lateral malleolus. From this region of union the sheath sends processes along each tendon proximally above the malleolus and distally over the lateral surface of the calcaneus. This process on the tendon of the peroneus longus often communicates with the following sheath. **Vagina tendinis m. peronæi longi plantaris.**—This sheath begins in the peroneal groove of the cuboid and ends near the medial border of the long plantar ligament.

3. Musculature of the Back of the Leg

a. Superficial Group (fig. 444)

To this group belong the **gastrocnemius, soleus, and plantaris muscles.** They extend the foot and flex the leg. The two ovoid heads of the **gastrocnemius** arise one on each side from above the condyles of the femur, extend about to the middle of the back of the leg, and are inserted into the posterior surface of the tendon of Achilles, and through this into the back of the calcaneus. The broad, flat, ovoid **soleus** arises beneath the gastrocnemius from the tibia and fibula, and is inserted into the deep surface of the tendon of Achilles as far as the ankle. The two heads of the gastrocnemius and the soleus constitute the **triceps suræ.** The **plantaris** is a slender muscle which passes along the medial margin of the lateral head of the gastrocnemius and beneath the medial head, where it gives rise to a slender tendon that runs between the gastrocnemius and soleus and along the medial margin of the tendon of Achilles to the fatty fibrous tissue of the heel. The nerve-supply is from the tibial nerve.

The muscles of this group have a common embryonic origin, and are first differentiated on the fibular side of the leg, whence they extend over the posterior tibial vessels and nerve to their medial attachments. The gastrocnemius corresponds with the flexor carpi radialis and ulnaris, the plantaris with the palmaris longus, the soleus with a portion of the flexor digitorum sublimis of the forearm. In many of the monkeys and in the prosimians the plantaris is much more developed than in man.

The gastrocnemius (fig. 444).—**Medial head.**—*Origin.*—From a facet on the back of the medial condyle of the femur above the articular surface, from an area on the back of the femur superior and lateral to this, and from the femoral margin of the capsule of the knee-joint.

head.—*Origin.*—From a facet on the proximal portion of the posterolateral surface teral condyle of the femur and from a rough area situated more medially and at a istance from the joint.

ture and insertion.—The heads of the gastrocnemius are similar in structure. From the facets there descend aponeurotic bands, one on the medial margin and the medial side sterior surface of the medial head, the other on the lateral margin and the lateral side sterior surface of the lateral head. These bands descend about two-thirds of the way muscle. In the tendon of the lateral head a sesamoid bone is frequently found. The idles of the muscle pass obliquely from the supracondylar areas of origin and from the face of the aponeurosis on each side to the tendon of insertion. This tendon begins as between the two heads, and as a lamina on the deep surface of each head. The septum ns soon fuse with the broad aponeurosis which covers the dorsal surface of the soleus. achment of fiber-bundles continues to about the middle of the back of the leg. The ent of the medial head extends more distally than that of the lateral head. As a rule, al head is also the broader and thicker of the two.

soleus (fig. 583).—*Origin.*—(1) By a fibular head from the back of the head and the third of the posterior surface of the shaft of the fibula, and from the intermuscular between it and the peroneus longus; and (2) by a tibial head from the transverse septum distal margin of the popliteus, from the popliteal line, and from the middle third of the order of the tibia.

ture and insertion.—From the fibular and tibial origins arise broad aponeuroses which ximally on the deep surface of the muscle so as to form a fibrous arch over the pos- ial vessels and nerves. Distally they diverge and become more narrow, but the fibular sis is continued on the fibular side and the tibial aponeurosis on the tibial side of les as far as the distal quarter of the leg. The main portion of the belly of the muscle l by fiber-bundles which arise from the posterior surface of these aponeuroses and quely to be inserted in a bipenniform manner on the deep surface of the tendon of This tendon begins as a broad aponeurosis which covers the greater part of the surface of the muscle, and gradually converges into a heavy fibrous band that is in- to the calcaneus. The bundles of fibers of the tendon take a slightly spiral course. the posterior surface run from the medial margin toward the lateral surface of the ; those on the anterior surface in a reverse direction. The attachment of the fiber- continues to within a short distance of the heel. A few of the fiber-bundles arise rom the fibula and the posterior intermuscular septum. On the deep surface of the he muscle there is an **accessory fasciculus** which is formed by fiber-bundles that sprir g ide from the anterior surface of the aponeuroses of origin of the muscle and have a rm insertion on each side of a thin, oblique tendinous lamina which inferiorly becomes the deep surface of the tendon of Achilles.

plantaris (fig. 444).—This muscle *arises* from the distal part of the lateral line of bi- of the linea aspera, in close association with the lateral head of the gastrocnemius. -bundles give rise to a flat, short, fusiform belly, and are united to a narrow tendon tends along the medial edge of the tendon of Achilles to the lateral part of the dorsal f the calcaneus, where it *terminates* in the neighboring fibrous tissue.

-supply.—From the tibial (internal popliteal) part of the sciatic nerve in the popliteal ves arise for each head of the gastrocnemius. Each nerve enters the middle third of the ace of the head near the proximal margin. The nerve-supply for the soleus is from two One nerve arises in the popliteal space, often in company with the nerve to the lateral he gastrocnemius. It enters the posterior surface of the muscle near the proximal id divides into two branches, one for each head of the muscle. The tibial (posterior rve gives rise to a branch which, about half-way down the leg, enters the deep surface uscle and furnishes branches for the deep portion of the muscle on each side The pply of the plantaris is by a branch from the tibial (internal popliteal) portion of c. This arses in the popliteal space and enters the deep surface of the muscle.

ons.—The semimembranosus winds about the medial margin of the medial head of cnemius to its deep surface. The biceps passes to the lateral side of the lateral head strocnemius, and the plantaris along its medial margin. The semimembranosus and ove, the medial head of the gastrocnemius and the plantaris below, bound the popliteal he peroneal (external popliteal) nerve passes from the popliteal space obliquely across aris and the lateral head of the gastrocnemius. The medial sural (short saphenous) l the small saphenous vein pass between the heads of the gastrocnemius to the surface e to the lateral side of the ankle. From the peroneal (external popliteal) nerve in the space the lateral sural (communicans peronei) nerve extends distally over the calf. erior) tibial nerve and posterior tibial artery and vein run between the two heads of the mius, and then beneath the soleus to the medal side of the ankle. In the region of the f Achilles a considerable space filled with fatty tissue intervenes between the tendon ransverse septum.

.—The contraction of the triceps suræ produces extension, adduction, and inversion t. The gastrocnemius is also a flexor of the leg. The plantaris has no known function In some animals it is an extensor of the plantar fascia.

tions.—There is considerable variation in the extent of the separation of the different he triceps suræ. The tendons of the three heads may be separate nearly to the heel. both heads of the gastrocnemius or the soleus may be doubled. A slip from the biceps embranosus, from the linea aspera, or popliteal space may join the triceps and give quadriceps suræ. On the other hand, one of the heads of the gastrocnemius or the d of the soleus may be missing. A supernumerary fasciculus may extend from the ace of the soleus to the calcaneus. The plantaris is exceedingly variable in origin, , and insertion. The origin may be from the capsule of the knee-joint, the fascia of the

leg, or from the tibia. Its tendon may terminate at almost any part of its course in neighboring structures. It may be represened by a fibrous band. It is absent in about 7 per cent. of instances (Le Double).

Bursæ

B. m. gastrocnemii lateralis.—A bursa is often found between the tendon of the lateral head of the gastrocnemius and the capsule of the joint. It may communicate with the joint cavity. **B. m. gastrocnemii medialis.**—A bursa usually lies between the tendon of origin of the medial head of the gastrocnemius, the condyle of the femur, and the capsule of the joint. Another bursa (**b. m. semimembranosi**) extends between the semimembranosus and the medial head of the gastrocnemius muscle. The two bursæ frequently communicate with one another and with the joint. **B. tendinis calcanei.**—This lies between the tendon of Achilles and the upper part of the back of the calcaneus. Between the back of the tendon and the crural fascia another bursa is frequently present.

b. Deep Group

The deep posterior musculature is separated from the superficial by the transverse septum described above (p. 509). The muscles covered by this septal fascia are the **popliteus**, the **flexor digitorum longus**, the **flexor hallucis longus**, and the **tibialis posterior.** An intermuscular septum between the popliteus and the tibialis posterior, and the attachment of the soleus to the popliteal line on the back of the tibia serve to separate the popliteus from the other deep posterior muscles which lie distal to this region and send tendons into the sole of the foot. The deep posterior musculature may thus be considered as divided into a proximal femorotibial and a distal cruropedal group. Both sets of muscles are supplied by branches of the tibial nerve.

Femorotibial Muscle

The popliteus (fig. 447).—A triangular muscle which *arises* from an ovoid facet at the inferior extremity of the groove on the outer side of the lateral condyle of the femur and is *inserted* into the proximal lip of the popliteal line of the tibia and the surface of the shaft of the tibia proximal to this. It rotates the leg medialward and flexes it.

Structure.—From the origin a broad tendon glides over the condyle within the capsule of the joint, then over the lateral fibrocartilage and through a groove on the back of the tibiofibular articulation. From both surfaces of this tendon, fiber-bundles diverge toward the area of insertion. The tendon is more or less intimately united to several structures with which it comes in contact about the joint. Rarely it contains a sesamoid bone. The fibers of insertion terminate in part in the fascia covering the muscle. The popliteus is homologous with the pronator teres of the arm, or, according to some investigators, with the deep portion of that muscle.

Nerve-supply.—A nerve which arises either independently or in conjunction with that to the posterior tibial muscle enters the popliteus near the middle of its distal edge. Sometimes a branch from the chief nerve to the knee-joint enters the proximal edge of the muscle.

Action.—To flex and rotate the leg medially.

Relations.—The popliteus lies within a compartment bounded by the transverse septum, the capsules of the knee and superior tibiofibular joints, the back of the tibia, and a septum extending to the popliteal line (see above). On the transverse septum run the popliteal vessels and the tibial nerve. The proximal margin of the soleus overlaps the distal margin of the popliteus. The synovial membrane of the knee-joint sends a prolongation between its tendon and the back of the lateral condyle of the tibia.

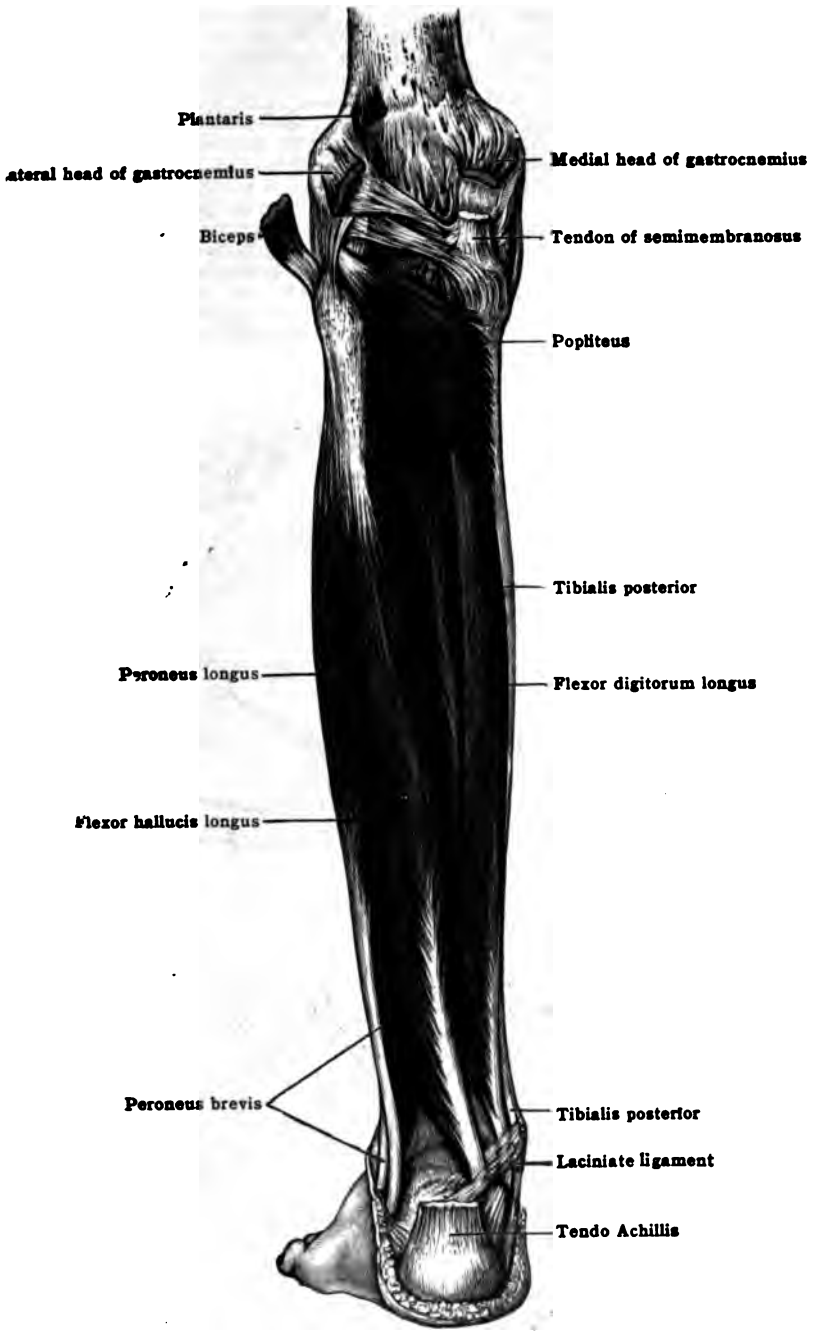
Variations.—It is rarely absent. An accessory head may arise from the medial side of the lateral condyle or from some neighboring structure. The **fibulotibialis (peroneotibialis)** is a small muscle found by Gruber in one body in seven. It arises from the medial side of the head of the fibula and is inserted into the posterior surface of the tibia beneath the popliteus.

Cruropedal Muscles (figs. 447, 451)

Of the three muscles of this group, the **flexor digitorum longus** lies on the tibial side of the leg, the **flexor hallucis longus** on the fibular side, and the **tibialis posterior** upon the interosseous membrane, partly covered by the other two muscles, beneath the former of which it crosses, distally, to the tibial side of the leg. Septa separate the flexor muscles from the tibialis. The tendons of the three muscles pass behind the medial malleolus, held in place by the transverse septum and the deep layer of the laciniate (internal annular) ligament. They lie in compartments divided by septa which descend to the tibia. The compartment for the tibialis posterior is the most medial. It is partly overlapped by that for the flexor digitorum. At the ankle the tendon of the tibialis passes

the tendon of the flexor digitorum medial to, and that of the flexor hallucis the sustentaculum tall, each in a separate osteofibrous canal bounded lly by the laciniate (internal annular) ligament. In the sole the tendon of ; flexor of the big toe passes deeper than the tendon of the flexor digitorum,

FIG. 447.—THE DEEP MUSCLES OF THE BACK OF THE LEG.



h it gives a slip, and is inserted into the terminal phalanx of the big toe. don of the long flexor of the toes passes obliquely across the sole, is joined quadratus plantæ (flexor accessorius), and gives rise to a tendon for the l phalanx of each of the four lateral toes. From these tendons the lum- nuscles arise. The tibialis posterior has an extensive insertion on the surface of the *tarsus.*

long flexors act chiefly on the toes. Together with the tibialis posterior ert and extend the foot.

ng flexors of the toes probably represent the flexor profundus and the flexor pollicis the forearm. The tendons of the deep flexors of the forearm do not, however, cross of the long flexors of the toes. In the lower mammals there is much variation in the hich the tibial and fibular flexors are distributed. The tibialis posterior has no cer- sentative in the forearm. The rare ulnocarpeus may represent it.

exor digitorum longus (figs. 447, 451).—*Origin.*—From the popliteal line, the medial e second quarter of the dorsal surface of the tibia, the fibrous septum between the id the tibialis posterior, and the fascia covering its proximal extremity.

ure and insertion.—From these areas of origin the fiber-bundles run obliquely to be n a penniform manner on a tendon which begins in the proximal quarter of the muscle ow septum, and more distally becomes a strong band on the medial margin. The of the fiber-bundles continues nearly to the medial malleous. From here the tendon hind the medial malleolus, dorsolateral to the tendon of the tibialis posterior, crosses rior talotibial ligament, and passes along the medial margin of the sustentaculum tali sole of the foot. Here it crosses the tendon of the flexor hallucis longus, from which s a tendinous slip, and divides into four parts, which pass to the second to the fifth ch tendon is bound to the phalanges of the toe to which it passes by a fibrous sheath. d to it in the sheath lies a tendon of the flexor digitorum brevis, which the flexor lon- on perforates as it passes to the base of the terminal phalanx. The tendon is connect- ose of the fingers, by vincula tendinum, to the phalanges of the toes.

supply.—From the tibial (posterior tibial) nerve a branch arises, often in company es to some other or others of the muscles of this group. The nerve divides into two one of which passes to the lateral side of the muscle, where it extends along near the the fiber-bundles of that side, while the other branch passes along near the middle er-bundles of the medial side of the muscle.

ns.—In the proximal half of the leg it lies on the tibia, in the distal half on the pos- ial muscle. Between it and the flexor hallucis lie the posterior tibial vessels and ear the ankle the plantar vessels and nerves cross the tendon of the muscle, separated the deep layer of the laciniate (internal annular) ligament. In the upper two-thirds

of its extent it is covered by the triceps suræ. In the lower third of the leg it emerges medial to the soleus and the tendon of Achilles. The relations of its tendon at the ankle have been described above. The tendon lies beneath the origin of the abductor hallucis muscle and in the sole is covered by the flexor digitorum brevis, crosses the tendon of the long flexor and the oblique adductor of the big toe and the interosseous muscles, is joined by the quadratus plantæ (flexor accessorius), and gives origin to the lumbrical muscles.

The flexor hallucis longus (figs. 447, 451).—*Origin.*—From the distal two-thirds of the posterior surface of the fibula, the septa between it and the tibialis posterior and peroneal muscles, and the fascia above its proximal extremity.

Structure and insertion.—The fiber-bundles converge upon a tendon which begins in the second quarter of the muscle, within its substance, and emerges upon the posteromedial margin in its distal half. The insertion of the fiber-bundles continues to the end of the tibia. From here the tendon passes over the dorsal talotibial (tibioastragaloid) ligament, and through the groove on the posterior surface of the talus and the under surface of the sustentaculum tali, where it lies on the fibular side of the tendon of the flexor digitorum longus. It then crosses the deep surface of this tendon, to which it gives a slip, passes over the plantar surface of the medial head of the flexor hallucis brevis, and between the sesamoid bones of this muscle into the osteofibrous canal on the plantar surface of the big toe. It is inserted into the base of the terminal phalanx of the big toe.

Nerve-supply.—The nerve arises from the tibial (posterior tibial) nerve, often in company with the nerve to the flexor digitorum longus or the other muscles of the group. It runs along the deep surface of the muscle and sends twigs into the middle third of its constituent fiber-bundles. Sometimes two nerves are furnished to the muscle.

Relations.—It lies on the fibular side of the distal two-thirds of the leg. Proximally it diverges from the preceding muscle so as to disclose the tibialis posterior, which is more deeply situated. Between it and the tibialis posterior lie the peroneal vessels. Distally its tibial margin approaches the flexor digitorum longus, but between them lie the posterior tibial vessels and nerve. Lateral to it lie the peroneal muscles. It is covered in the leg by the soleus. In the distal part of the leg its tendon lies medial to the tendon of Achilles. On entering the foot the tendon crosses beneath the abductor hallucis muscle and the lateral plantar vessels and nerve. The other relations of the tendon have been described above.

The tibialis posterior (figs. 447, 453).—*Origin.*—From—(1) the lateral half of the distal margin of the popliteal line and the middle third of the posterior surface of the tibia; (2) the medial side of the head and of that part of the body of the fibula next the interosseous membrane in the proximal two-thirds; (3) from the whole of the proximal and the lateral portion of the distal part of the posterior surface of the interosseous membrane; and (4) from the septa between its proximal portion and the long flexor muscles.

Structure.—From this extensive area of origin the fiber-bundles converge upon a tendon, which is at first deep seated within the muscle-belly, but about the middle of the leg emerges on the medial margin of the muscle. The fibular portion of the muscle is much more extensive than the tibial. The proximal fibers take a nearly perpendicular, the most distal (from the fibula) a nearly transverse, course. The insertion of fibers stops a little proximal to the medial malleolus. The tendon then extends to the medial side of the tendon of the long flexor of the toes, passes through the groove on the back of the malleolus, across the medial talotibial (tibioastragaloid) ligament, and above the sustentaculum tali to the sole.

Insertion.—The tendon divides into two chief divisions, a deep and a superficial. (1) The deep portion becomes attached chiefly to the tubercle of the navicular bone, and usually in part also to the first cuneiform. (2) The superficial spreads out to be attached chiefly to the third cuneiform and the base of the fourth metatarsal, but also in part to the second cuneiform, to the capsule of the naviculocuneiform joint, to the sulcus of the cuboid, and usually also to the origin of the short flexor of the big toe and the base of the second metatarsal. Slips may, however, also be given to other structures. A sesamoid bone is usually found in the tendon either near the calcaneonavicular ligament or the navicular bone.

Nerve-supply.—The nerve arises from the tibial (posterior tibial) in company often with branches to the other muscles of the group. It enters the posterior surface of the muscle in its proximal third, and gives off one or two branches for the tibial fasciculus. The main trunk descends across the middle third of the fasciculi arising from the fibula.

Relations.—The muscle covers the posterior surface of the interosseous membrane, and extends distally over the posterior surface of the tibia beneath the flexor digitorum longus. It is covered proximally by the soleus, distally by the two long digital flexors. The posterior tibial and peroneal arteries and the tibial (posterior tibial) nerve run upon its posterior surface. The tendon in the sole is under cover of the origin of the plantar muscles of the big toe.

Action.—The tibialis posterior adducts the foot and slightly inverts it. The flexor digitorum longus flexes the terminal phalanx on the second and the second on the first, and at the height of its contraction the first on the metatarsals. It also rotates medially to some extent the ends of the fourth and fifth toes, and inverts the foot. The flexor hallucis longus flexes the second phalanx of the big toe on the first, and, less energetically, the first on the metatarsal. It also inverts the foot. All three muscles extend the foot. The flexor hallucis is the strongest of the three in this respect.

Variations.—The muscles of the group may be more or less fused with one another or be united by fasciculi. This is especially common between the two flexors of the toes. The individual muscles vary in development. The flexor digitorum longus may be more or less divided into separate fasciculi for the individual toes. The slip from the flexor hallucis longus to the flexor digitorum longus varies greatly in extent, but usually passes mainly to the second and third toes, more rarely to the second, third, and fourth, and very rarely to the fifth. In most of the apes the tibial flexor (flexor digitorum) sends tendons to the second and fifth, the fibular flexor (flexor hallucis) to the first, third, and fourth toes. This condition is also some-

times found in man. A slip may pass from the tendon of the flexor digitorum to that of the flexor hallucis longus. There may be a sesamoid bone in the tendon of the flexor hallucis longus as it passes over the talus (astragalus) and calcaneus. The tibialis posterior may be doubled. Aberrant fasciculi may arise from various regions on the back of the leg and join any one of the three muscles of the group.

Abnormal muscles.—**The soleus accessorius.**—Arises by a tendon from the head of the fibula beneath the soleus. It is usually a slender muscle inserted into the medial surface of calcaneus. **The tibialis secundus** (tensor of capsule of ankle-joint).—A small muscle which arises from the tibia beneath the flexor digitorum and is inserted into the capsule of the ankle-joint. **The fibulocalcaneus medialis** (peroneocalcaneus internus of MacAlister, flexor accessorius long. dig. long., etc).—A fasciculus which arises from the lower third of the body of the fibula and gives rise to a tendon which passes beneath the laciniate ligament to the quadratus plantæ or to the tendon of the flexor digitorum longus.

Bursæ

B. subtendinea m. tibialis posterioris.—A small bursa between the navicular fibrocartilage and the tendon.

Synovial Tendon-sheaths

Vagina m. flexoris digitorum longi.—The tendon is surrounded by a synovial sheath from the back of the medial malleolus to where it crosses the tendon of the flexor hallucis longus below the navicular bone. It may communicate with the sheath of the tibialis anterior or with that of the flexor hallucis longus. **Vaginæ tendinum digitales.**—The tendons of the long flexor, together with those of the short flexor, are surrounded by synovial sheaths from the heads of the metatarsals to the insertions of the tendons. In structure these resemble those of the fingers. **Vagina m. flexoris hallucis longi.**—The tendon is surrounded by a sheath from the back of the medial malleolus to the crossing of the tendon of the flexor digitorum longus. Another sheath surrounds the tendon from the middle of the first metatarsal to its insertion. **Vagina m. tibialis posterioris.**—The tendon is surrounded by a synovial sheath extending from a region proximal to the medial malleolus to the insertion of the tendon.

D. MUSCULATURE OF THE FOOT
(Figs. 449–453)

On the dorsum of the foot there is a muscle not represented in the hand, the extensor digitorum brevis. In the sole of the foot there is a highly developed musculature which may be subdivided into the flexor digitorum brevis; the muscles connected with the long extensor of the toes, quadratus plantæ and lumbricales; the intrinsic muscles of the great toe; the intrinsic muscles of the little toe; and the interosseous muscles. These muscles abduct and adduct the toes, flex them at the metacarpophalangeal joints and flex and extend them at the first row of interphalangeal joints. On the second row of interphalangeal joints they seem to exert relatively little action. All the movements, excepting flexion, are weak in most individuals. The extensor digitorum brevis is innervated by the deep peroneal (anterior tibial) nerve. The muscles of the sole of the foot are all innervated by the lateral (external) plantar, except the flexor digitorum brevis, the most medial of the lumbrical muscles, and the abductor and flexor brevis of the great toe, which are innervated by the medial (internal) plantar.

FASCIÆ
(Fig. 448)

Tela subcutanea.—Over the dorsum of the foot the tela subcutanea contains little fat. On the sole of the foot and the plantar surface of the toes it contains much fat embedded in dense fibrous tissue.

Muscle fasciæ.—Over the dorsum of the foot a fascial membrane extends from the cruciate ligament mentioned above to the toes, where it is continued as fibrous sheaths for the extensor tendons. Laterally and medially it is continued into the plantar fascia. Where it overlies skeletal structures it becomes adherent to them. In the main this fascial sheet is thin. Over the base of the first metatarsal it is strengthened by a band which runs from the medial side of this bone over the extensor tendons of the big toe to the base of the second metatarsal. The extensor digitorum brevis is covered by an adherent fascial sheet. The dorsal surface of each dorsal interosseous muscle is likewise covered by an adherent membrane.

The **plantar surface** of the foot is invested by a fascia in which three distinct regions may be observed, a central, a lateral, and a medial. The central region is greatly thickened by bands of fibrous tissue, the **plantar aponeurosis,** which diverge toward the toes from the medial half of the tuber calcanei. These bands become distinct from one another as the toes are

approached, and each finally terminates partly in the skin over the head of the [illegible] metatarsal and in the digital sheath of the flexor tendons. Some of the fibers are [illegible] into the transverse capitular ligaments, the others extend through near the metatarso[illegible] articulation to the dorsum of the foot. Broader, thicker bands go to the three [illegible] than to the big and little toes. At the margins of this central area some fibers [illegible] the fascia of the lateral and medial area, some extend laterally into the skin, and [illegible] into the intermuscular septa described below. Near the toes well-marked transverse [illegible] of fibers may be seen between the digital bands. The central area of the plantar fas[illegible] densely adherent to the skin.

The digital sheaths of the flexor tendons of the toes correspond essentially with [illegible] previously described (p. 433) for the fingers.

The medial plantar fascia is thin and adherent to the skin. It extends between the [illegible] plantar and the dorsal fascia over the intrinsic muscles of the big toe. The lateral plantar fascia is thick and well-developed near the heel, thin as the little toe is approached. A band, the calcaneometatarsal ligament, strengthens it between the calcaneus and the tube[illegible] of the fifth metatarsal.

At the junction of the medial with the central region of the plantar fascia the medial intermuscular septum sinks in to be attached to the first cuniform, the navicular and the [illegible] of the posterior tibial. A similar lateral intermuscular septum sinks in between the latera[illegible] central regions of the plantar fascia and is attached to the long plantar ligament, the [illegible] sheath of the peroneus longus and the base of the fifth metatarsal. The fascia of each of [illegible] regions in considerable part extends into these septa instead of becoming continuous [illegible] them.

The sole is thus divided into three great fascial compartments by these septa, a latera[illegible] central, and a medial. In the lateral lie the intrinsic pedal muscles of the little toe; in the medial, the abductor and the flexor brevis of the big toe and the distal end of the tendon of the flexor hallucis longus. The central compartment is subdivided by transverse septa into several subcompartments. In the most superficial compartment lies the flexor digitorum brevis; in the second, the tendons of the flexor digitorum longus and its associated muscles, the quadratus plantæ (flexor accessorius) and the lumbrical muscles; in the third, the adductor muscles of the big toe; and in the fourth, the interosseous muscles.

The first two subcompartments are most clearly marked in the region of the tarsus. Distally they become merged by the disappearance of the intervening transverse septum, and longtiudinally subdivided by fibrous septa which serve to make a complete sheath over each digit for the flexor tendons. The sheath over the adductor muscle of the big toe is a thin membrane continued laterally from the medial intermuscular septum. Where the two heads of the adductor muscle advance upon their tendon of insertion, the medial septum has no skeletal attachment, so that the adductor subcompartment of the middle fascial compartment communicates freely with the medial compartment. Over the cuneiform bones the tendon of the flexor hallucis longus passes from the long flexor region of the middle compartment into the medial compartment. Here the medial intermuscular septum divides into two layers, which form a sheath for the tendon as it passes to the plantar surface of the flexor hallucis brevis.

MUSCLES

1. Muscle of the Dorsum of the Foot

The **extensor digitorum brevis** (fig. 449).—This muscle is broad and thin, lies beneath the tendons of the long extensor muscle on the tarsus, lateral to the navicular and the head of the talus, and sends tendons to the four more medial toes. It arises from the calcaneus. Its nerve-supply is from the deep peroneal.

Origin.—From the lateral and superior surfaces of the body of the calcaneus and from the apex of the cruciate ligament.

Structure and insertion.—The fiber-bundles arise directly from the ligament, and by short tendinous bands from the bone. As they extend distally they become grouped into four bellies. Those of the most medial and largest belly, the **extensor hallucis brevis**, become inserted in a bipenniform manner on the lateral and medial margins of a tendon which begins opposite the cuboid. The insertion of fiber-bundles continues to the base of the first metatarsal. The insertion of the fiber-bundles of the other bellies, which are seldom so distinctly isolated as the first, takes place in a penniform manner into their respective tendons, but the exact mode of attachment is subject to great individual variations. The tendon of the first digit is inserted mainly into the middle of the back of the base of the first phalanx, but it is often also united to the tendon of the long extensor. The other three tendons are fused with the lateral margins of the corresponding tendons of the long extensor near the bases of the three middle digits. They also usually give slips to the bases of the first phalanges of the corresponding toes.

Nerve-supply.—The deep peroneal (anterior tibial) nerve, which, accompanied by the anterior tibial artery, passes beneath the medial belly of the muscle, gives off a branch which passes transversely across the middle of the deep surface of the muscle and sends twigs into it.

Relations.—It lies on the lateral side of the tarsus, beneath the long extensor tendons of the toes. The relations of its tendons have been described above.

Action.—It aids the long extensors in extending the first phalanx of each of the four medial digits. It has but a limited action on the second and third phalanges. It serves also to pull the ends of the toes to which its tendons go toward the little toe.

Variations.—The muscle shows great variation in development. Rarely the whole muscle, more frequently one or more of its digital divisions, may be missing. On the other hand, it may

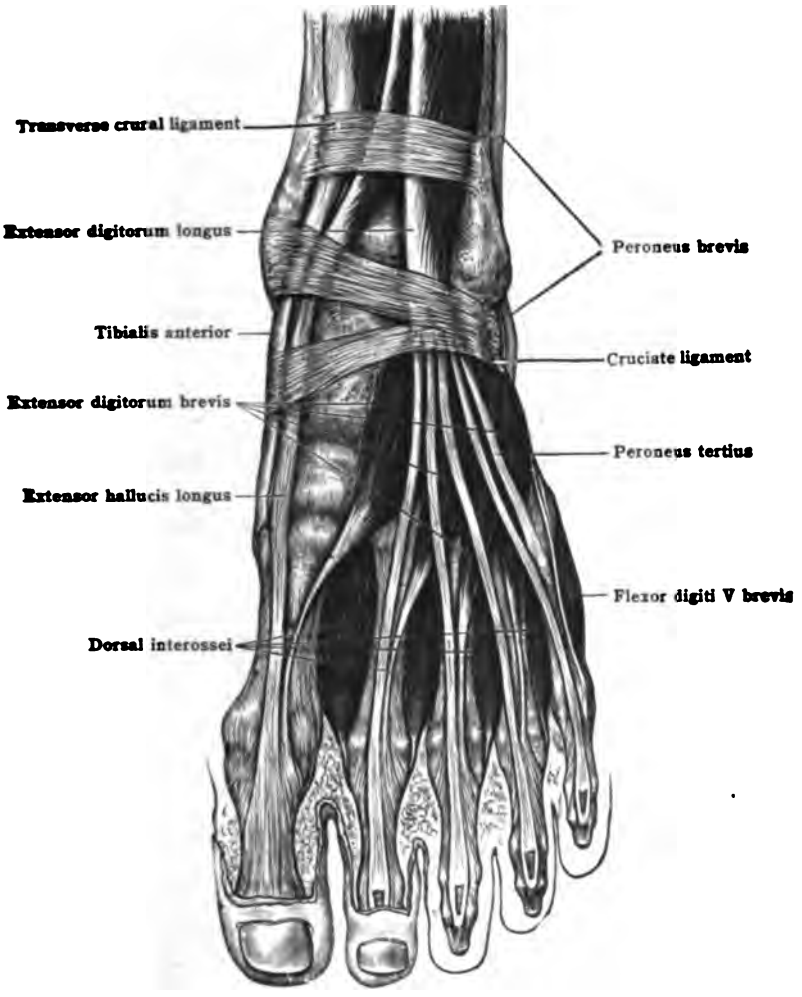
are highly developed than usual. Accessory fasciculi vary greatly in origin and termination. Most frequently their tendons go to a metacarpophalangeal articulation or to the ed or the fifth toe.

2. Muscles of the Sole of the Foot

a. Flexor Digitorum Brevis (fig. 450)

The flexor digitorum brevis, the most superficially placed of the plantar muscles, lies in the **plantar** region beneath the plantar fascia and over the tendons of the long flexor of the toes **and its** associated muscles. It arises from the calcaneus, and has a flat, elongated belly, which **ward** the middle of the sole is prolonged into four processes, each of which has a special ten**on that** is inserted into the second phalanx of one of the four lateral toes. The tendons of

Fig. 449.—The Muscle of the Dorsum of the Foot.



the muscle correspond to those of the flexor sublimis in the palm. The belly of the flexor sublimis is supposed to be represented by the soleus. The nerve supply is from the medial (internal) plantar.

Origin.—From (1) the medial process of the tuber calcanei; (2) the posterior third of the plantar aponeurosis; and (3) the medial and lateral intermuscular septa.

Structure.—The constituent fiber-bundles pass distally in a compact mass. The tendons of insertion begin within the muscle substance, and as the fiber-bundles become inserted on them, the separate fasciculi become more and more distinct. The fasciculi for the second and third toes are larger and arise more superficially than those for the fourth and fifth toes. The fasciculus for the fifth toe is often very small, and its tendon takes an oblique course to the insertion.

Insertion.—The tendons of the short flexor pass superficial to those of the long flexor into the osteofibrous canals on the flexor surface of the digits. Upon the first phalanx of each toe the tendon of the short flexor divides and forms an opening (chiasma tendinis) through which

the tendon of the long flexor passes, while the tendon of the short flexor becomes attached to the base of the second phalanx. The arrangement is essentially like that described at length for the flexors of the fingers (p. 433).

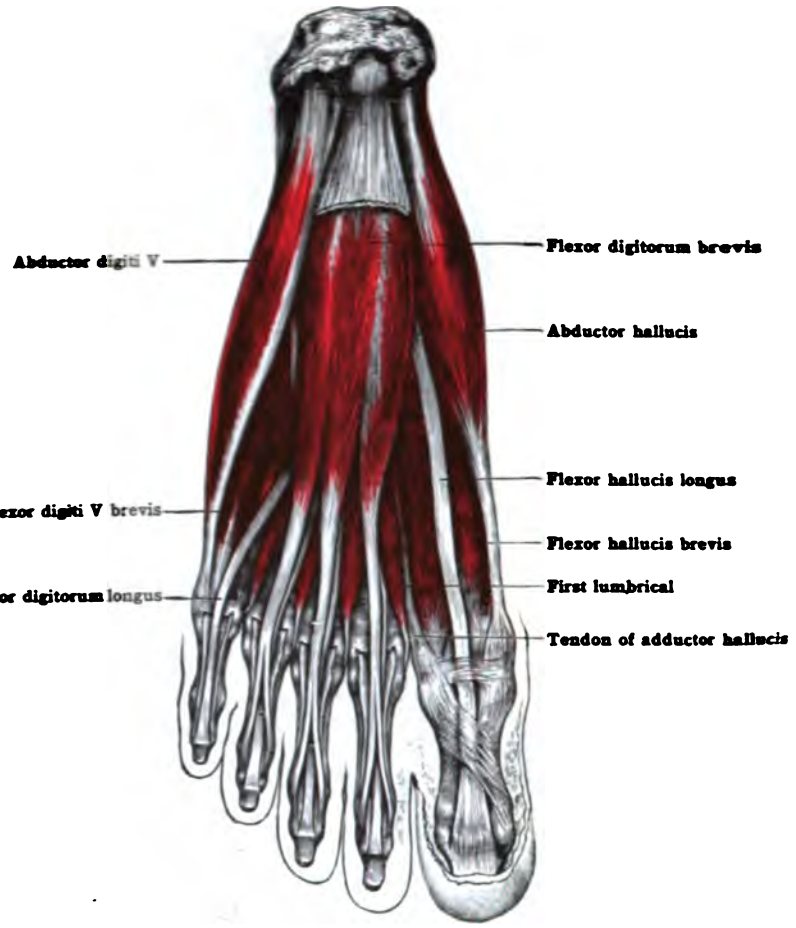
Nerve-supply.—From the medial plantar nerve by a branch which enters the middle third of the deep surface near the medial margin of the muscle.

Action.—It is a strong flexor of the second row of phalanges.

Relations.—The short flexor is separated from the abductors of the big toe and little toe by strong intermuscular septa (p. 524), and from the long flexor tendons and the quadratus plantæ (flexor accessorius) by a transverse septum in which the lateral plantar vessels and nerve cross the foot. In its distal two-thirds it is separated from the plantar fascia by loose tissue.

Variations.—The muscle shows a tendency toward reduction, one or more of its fasciculi being frequently absent, and occasionally the whole muscle. The fasciculus for the fifth toe is absent in about 20 per cent. of bodies (Le Double). When a fasciculus is absent, its tendon is usually replaced by an accessory tendon from the long flexor. The muscle or its tendons may be more or less fused to the tendons of the flexor digitorum longus.

FIG. 450.—FIRST LAYER OF THE MUSCLES OF THE SOLE.



b. MUSCLES ATTACHED TO THE TENDONS OF THE FLEXOR DIGITORUM LONGUS (fig. 451)

The muscles belonging in this group are the **quadratus plantæ** (flexor accessorius), a flat, quadrangular, bicipital muscle which runs from the medial and plantar surface of the body of the calcaneus to the dorsolateral margin and deep surface of the long flexor tendon; and the **lumbricales**, four slender bipinnate muscles which run from the medial sides of the digital slips of the tendon to the medial sides of the four more lateral toes. The quadratus aids the long flexor muscle; the lumbricales extend the last two phalanges and flex the first phalanx of each of the digits to which they pass. The lumbrical muscles correspond to

those of the hand. The quadratus is not there represented. The nerve-supply is from the lateral (external) plantar nerve except that for the first lumbrical muscle which gets its supply from the medial (internal) plantar.

The quadratus plantæ (flexor accessorius) (fig. 451).—This muscle *arises* by two heads. The *lateral head* springs by an elongated tendon from the calcaneus in front of the lateral process of the tuber, and from the lateral margin of the long plantar ligament. The *medial head* arises directly from the medial surface of the body of the calcaneus as far back as the medial process of the tuber calcanei, and from neighboring ligaments.

Structure and insertion.—The two heads are separated at their origin by a short triangular space. They soon fuse to form a single belly, but the fiber-bundles of each head in the main are separately inserted. Those from the lateral head diverge to be attached to the lateral margin of the flexor tendon. Those from the medial head are inserted on a tendon that begins on the medial margin and deep surface of this head, becomes broader, and is inserted as a flat aponeurosis on the deep surface of the flexor tendon. There are great individual variations in the structure of this muscle. The fibers of either part may be inserted with those of the other part.

Nerve-supply.—From a branch of the lateral plantar nerve which passes obliquely across the superficial surface of the muscle parallel with the tendon of the flexor digitorum longus.

Relations.—The muscle lies in a fascial compartment with the long flexor tendons. This compartment is bounded on each side by intermuscular septa, deeply by the tarsus, and plantarward by a septum which intervenes between it and the flexor digitorum brevis, and in which the lateral plantar nerve and vessels cross to the lateral side of the foot.

Action.—It assists the long flexor tendon in flexing the toes. It makes the direction of traction on the toes parallel with the long axis of the foot.

Variations.—It is frequently reduced in size. The lateral head is not infrequently missing, the medial head or the whole muscle much more rarely. The mode of attachment to the tendon varies. It may be inserted in part or wholly into the long flexor of the great toe. It may receive, in about one body in twenty (Wood), an accessory slip of origin from the fibula, one of the muscles of the leg, the fascia of the leg or foot, or the medial surface of the calcaneus, etc.

The lumbricales.—The three lateral muscles *arise* from the contiguous sides of the digital tendon-slips of the flexor digitorum longus in the angles of division. The first lumbrical arises on the medial margin of the tendon to the second toe. The fiber-bundles of each muscle converge on both sides of a tendon which becomes free near the metatarsophalangeal joint and is *attached* to the medial side of the first phalanx of the toe to which the muscle belongs. A tendinous expansion is sent into the aponeurosis of the extensor muscle.

Nerve-supply.—The three lateral lumbrical muscles are most frequently supplied by branches of the deep ramus of the lateral plantar nerve, the medial by the first common plantar digital branch of the medial plantar nerve. The latter nerve may supply the two more medial muscles or the more medial muscles may receive a double supply. The branches of the lateral plantar nerve enter the deep surfaces of the muscles in the middle third. The branches of the medial plantar enter the medial borders of the muscles near the junction of the proximal and middle thirds.

Relations.—The lumbrical muscles lie in a plane with the long flexor tendons deeper than the flexor brevis tendons and superficial to the adductor hallucis. The deep branches of the lateral plantar nerve and vessels pass across their deep surface; superficial branches of both plantar nerves across the superficial surface.

Action.—To extend the last two phalanges of the toes and to flex the first.

Variations.—One or more of the muscles may be absent. Sometimes a muscle is doubled. This is more frequently the case with the third and fourth muscles. The first may arise wholly from the tendon of the posterior tibial muscle or from this and the long flexor of the big toe. The third lumbrical may arise from the flexor digitorum brevis. The second and fourth lumbricals may be inserted into the tendons of the flexor digitorum brevis.

c. Intrinsic Muscles of the Great Toe (figs. 450–452)

These muscles are the abductor, flexor brevis, and adductor. Of the three muscles, the first two lie in the medial fascial compartment, while the last lies in the middle compartment covered by the flexor digitorum longus and its associated muscles.

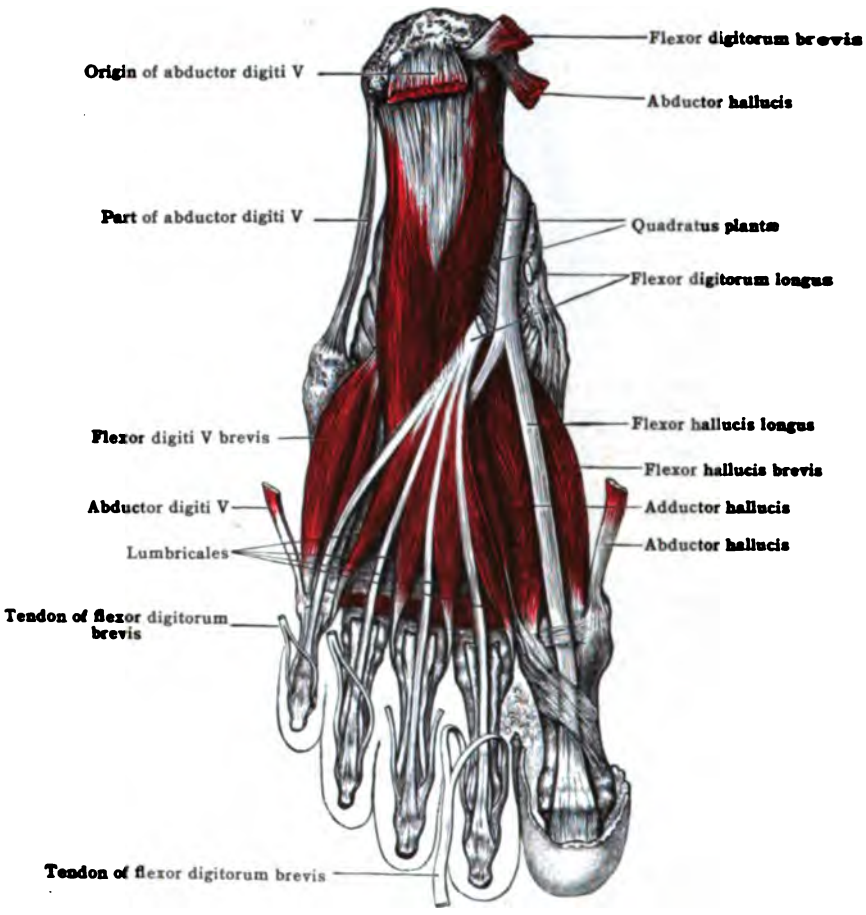
The **abductor hallucis** (fig. 450), the largest and most superficial of these muscles, lies on the border of the sole medial to the short flexor muscle. It passes from the calcaneus across the tendons of the long flexor muscles, and is inserted into the medial side of the base of the first phalanx of the great toe and into the medial side of the long extensor tendon. The **flexor hallucis brevis** (fig. 452) is a bicaudal muscle which arises in the region of the cuneiform bones and is inserted on each side of the base of the first phalanx. Its tendons are fused with those of the abductor and the oblique head of the adductor. The **adductor hallucis** (fig. 452) is composed of two distinct heads, an oblique and a transverse. The oblique head extends from the long plantar ligament to the lateral side of the base of the first phalanx of the great toe. Its tendon of insertion is joined by the transverse head, which arises from the capsules of the third to the fifth metatarsophalangeal joints.

These muscles perform not only the functions indicated by their names, but also extend the second phalanx. They correspond fairly well with those of the thumb. The opponens is not normally present in the foot. The nerve supply for the adductor is from the lateral (external) plantar nerve; that for the other muscles is from the medial (internal) plantar.

The abductor hallucis (fig. 450).—*Origin.*—From (1) the medial process of the tuber calcanei; (2) the deep surface of the neighboring plantar fascia; (3) the laciniate (internal annular) ligament; (4) the septum between the muscle and the flexor digitorum brevis; and (5) a fibrous arch which extends on the deep surface of the muscle over the plantar vessels and nerves and the long flexor tendons from the calcaneus to the navicular bone.

Structure.—From the medial process of the tuber calcanei a tendinous band passes to the deep, lateral side of the muscle. Numerous tendinous bands arise from the other areas of

FIG. 451.—SECOND LAYER OF THE MUSCLES OF THE SOLE.



origin. The fiber-bundles arise from these tendons and directly from the fibrous arch. They are attached in a penniform manner to numerous tendinous slips which extend far up in the muscle. These slips become gradually fused into a tendon which appears on the superficial plantar aspect of the muscle. Opposite the distal half of the first metatarsal bone the tendon leaves the belly of the muscle and becomes closely bound to the medial belly of the flexor hallucis brevis.

Insertion.—In conjunction with the tendon of the medial belly of the flexor brevis into the base of the first phalanx. It usually sends an expansion to the extensor tendon.

Nerve-supply.—A branch from the medial plantar nerve usually enters near the middle of the lateral border of the muscle.

Relations.—It is covered by the plantar fascia and is separated from the muscles of the medial compartment by the medial intermuscular septum. It crosses the tendons of the tibialis anterior, tibialis posterior, flexor digitorum longus, and flexor hallucis longus muscles and the plantar vessels and nerves.

The flexor hallucis brevis (fig. 452).—*Origin.*—From a tendon attached to the first (internal), second and third cuneiform bones. The more lateral of its fibers are continued into the plantar calcaneocuboid ligament and the more medial into the expansion of the tendon of the posterior tibial muscle.

Structure and insertion.—The fiber-bundles give rise to two bellies, a medial and a lateral. Those of the medial belly pass obliquely medially to be inserted into the tendon of the abductor hallucis, and by a short tendon fused with this into the medial side of the plantar surface of the base of the first phalanx. This tendon contains a sesamoid bone. Those of the lateral converge upon the tendon of the oblique head of the adductor, and the two muscles are inserted by a common tendon, which contains a sesamoid bone, into the lateral side of the plantar surface of the base of the first phalanx.

Nerve-supply.—A branch from the medial plantar (or first plantar digital) nerve divides over the plantar surface of the muscle and gives a twig to each belly near the middle third. Rarely the lateral belly may receive a branch from the lateral plantar nerve.

Relations.—The abductor hallucis covers it medially; the tendon of the flexor hallucis longus passes between its two heads. Branches of the medial plantar vessels and nerve lie on its superficial surface.

FIG. 452.—THIRD LAYER OF THE MUSCLES OF THE SOLE.

Adductor hallucis (caput obliquum)
Adductor hallucis (caput transversum)
Tendon of the flexor hallucis longus
Divided tendons of flexor digitorum brevis
Tendon of flexor digitorum longus

The adductor hallucis (fig. 452).—The **oblique head.**—*Origin.*—From (1) the tuberosity of the cuboid and the sheath over the tendon of the peroneus longus muscle; (2) the plantar calcaneocuboid ligament; (3) the third cuneiform; (4) the bases of the second and third metatarsals and (5) a fibrous arch which extends from the plantar calcaneocuboid ligament to the interosseous fascia.

Structure and insertion.—From short tendon-slips the fiber-bundles pass forward to form a thick, fusiform belly which is attached in a bipenniform manner to a flat tendon. The tendon begins about the middle of the plantar surface of the muscle and is inserted in common with that of the flexor brevis into the lateral side of the plantar surface of the base of the first phalanx, and by a slip into the aponeurosis of the long extensor muscle on the back of the big toe.

Nerve-supply.—A branch from the deep ramus of the lateral plantar nerve enters the middle third of the lateral border of the muscle on its deep surface.

The transverse head *arises* from the joint-capsules of the third, fourth, and fifth metatarsophalangeal joints and from the transverse capitular ligaments.

Structure and insertion.—Of the three fasciculi, that to the little toe lies nearest the heel, that to the middle toe the most distally. The fiber-bundles take a nearly parallel course to be attached to tendon-slips which are fused into a common tendon that splits and passes on each

of its extent it is covered by the triceps suræ. In the lower third of the leg it emerges medial to the soleus and the tendon of Achilles. The relations of its tendon at the ankle have been described above. The tendon lies beneath the origin of the abductor hallucis muscle and in the sole is covered by the flexor digitorum brevis, crosses the tendon of the long flexor and the oblique adductor of the big toe and the interosseous muscles, is joined by the quadratus plantæ (flexor accessorius), and gives origin to the lumbrical muscles.

The flexor hallucis longus (figs. 447, 451).—*Origin.*—From the distal two-thirds of the posterior surface of the fibula, the septa between it and the tibialis posterior and peroneal muscles, and the fascia above its proximal extremity.

Structure and insertion.—The fiber-bundles converge upon a tendon which begins in the second quarter of the muscle, within its substance, and emerges upon the posteromedial margin in its distal half. The insertion of the fiber-bundles continues to the end of the tibia. From here the tendon passes over the dorsal talotibial (tibioastragaloid) ligament, and through the groove on the posterior surface of the talus and the under surface of the sustentaculum tali, where it lies on the fibular side of the tendon of the flexor digitorum longus. It then crosses the deep surface of this tendon, to which it gives a slip, passes over the plantar surface of the medial head of the flexor hallucis brevis, and between the sesamoid bones of this muscle into the osteofibrous canal on the plantar surface of the big toe. It is inserted into the base of the terminal phalanx of the big toe.

Nerve-supply.—The nerve arises from the tibial (posterior tibial) nerve, often in company with the nerve to the flexor digitorum longus or the other muscles of the group. It runs along the deep surface of the muscle and sends twigs into the middle third of its constituent fiber-bundles. Sometimes two nerves are furnished to the muscle.

Relations.—It lies on the fibular side of the distal two-thirds of the leg. Proximally it diverges from the preceding muscle so as to disclose the tibialis posterior, which is more deeply situated. Between it and the tibialis posterior lie the peroneal vessels. Distally its tibial margin approaches the flexor digitorum longus, but between them lie the posterior tibial vessels and nerve. Lateral to it lie the peroneal muscles. It is covered in the leg by the soleus. In the distal part of the leg its tendon lies medial to the tendon of Achilles. On entering the foot the tendon crosses beneath the abductor hallucis muscle and the lateral plantar vessels and nerve. The other relations of the tendon have been described above.

The tibialis posterior (figs. 447, 453).—*Origin.*—From—(1) the lateral half of the distal margin of the popliteal line and the middle third of the posterior surface of the tibia; (2) the medial side of the head and of that part of the body of the fibula next the interosseous membrane in the proximal two-thirds; (3) from the whole of the proximal and the lateral portion of the distal part of the posterior surface of the interosseous membrane; and (4) from the septa between its proximal portion and the long flexor muscles.

Structure.—From this extensive area of origin the fiber-bundles converge upon a tendon, which is at first deep seated within the muscle-belly, but about the middle of the leg emerges on the medial margin of the muscle. The fibular portion of the muscle is much more extensive than the tibial. The proximal fibers take a nearly perpendicular, the most distal (from the fibula) a nearly transverse, course. The insertion of fibers stops a little proximal to the medial malleolus. The tendon then extends to the medial side of the tendon of the long flexor of the toes, passes through the groove on the back of the malleolus, across the medial talotibial (tibioastragaloid) ligament, and above the sustentaculum tali to the sole.

Insertion.—The tendon divides into two chief divisions, a deep and a superficial. (1) The deep portion becomes attached chiefly to the tubercle of the navicular bone, and usually in part also to the first cuneiform. (2) The superficial spreads out to be attached chiefly to the third cuneiform and the base of the fourth metatarsal, but also in part to the second cuneiform, to the capsule of the naviculocuneiform joint, to the sulcus of the cuboid, and usually also to the origin of the short flexor of the big toe and the base of the second metatarsal. Slips may, however, also be given to other structures. A sesamoid bone is usually found in the tendon either near the calcaneonavicular ligament or the navicular bone.

Nerve-supply.—The nerve arises from the tibial (posterior tibial) in company often with branches to the other muscles of the group. It enters the posterior surface of the muscle in its proximal third, and gives off one or two branches for the tibial fasciculus. The main trunk descends across the middle third of the fasciculi arising from the fibula.

Relations.—The muscle covers the posterior surface of the interosseous membrane, and extends distally over the posterior surface of the tibia beneath the flexor digitorum longus. It is covered proximally by the soleus, distally by the two long digital flexors. The posterior tibial and peroneal arteries and the tibial (posterior tibial) nerve run upon its posterior surface. The tendon in the sole is under cover of the origin of the plantar muscles of the big toe.

Action.—The tibialis posterior adducts the foot and slightly inverts it. The flexor digitorum longus flexes the terminal phalanx on the second and the second on the first, and at the height of its contraction the first on the metatarsals. It also rotates medially to some extent the ends of the fourth and fifth toes, and inverts the foot. The flexor hallucis longus flexes the second phalanx of the big toe on the first, and, less energetically, the first on the metatarsal. It also inverts the foot. All three muscles extend the foot. The flexor hallucis is the strongest of the three in this respect.

Variations.—The muscles of the group may be more or less fused with one another or be united by fasciculi. This is especially common between the two flexors of the toes. The individual muscles vary in development. The flexor digitorum longus may be more or less divided into separate fasciculi for the individual toes. The slip from the flexor hallucis longus to the flexor digitorum longus varies greatly in extent, but usually passes mainly to the second and third toes, more rarely to the second, third, and fourth, and very rarely to the fifth. In most of the apes the tibial flexor (flexor digitorum) sends tendons to the second and fifth, the fibular flexor (flexor hallucis) to the first, third, and fourth toes. This condition is also some-

d in man. A slip may pass from the tendon of the flexor digitorum to that of the ucis longus. There may be a sesamoid bone in the tendon of the flexor hallucis it passes over the talus (astragalus) and calcaneus. The tibialis posterior may be Aberrant fasciculi may arise from various regions on the back of the leg and join the three muscles of the group.

al muscles.—**The soleus accessorius.**—Arises by a tendon from the head of the fibula ıe soleus. It is usually a slender muscle inserted into the medial surface of cal- **The tibialis secundus** (tensor of capsule of ankle-joint).—A small muscle which ı the tibia beneath the flexor digitorum and is inserted into the capsule of the ankle- **e fibulocalcaneus medialis** (peroneocalcaneus internus of MacAlister, flexor acces- ;. dig. long., etc).—A fasciculus which arises from the lower third of the body of the gives rise to a tendon which passes beneath the laciniate ligament to the quadratus to the tendon of the flexor digitorum longus.

Bursæ

ndinea m. tibialis posterioris.—A small bursa between the navicular fibrocartilage ndon.

Synovial Tendon-sheaths

m. flexoris digitorum longi.—The tendon is surrounded by a synovial sheath from f the medial malleolus to where it crosses the tendon of the flexor hallucis longus navicular bone. It may communicate with the sheath of the tibialis anterior or with ıe flexor hallucis longus. **Vaginæ tendinum digitales.**—The tendons of the long ether with those of the short flexor, are surrounded by synovial sheaths from the he metatarsals to the insertions of the tendons. In structure these resemble those gers. **Vagina m. flexoris hallucis longi.**—The tendon is surrounded by a sheath ack of the medial malleolus to the crossing of the tendon of the flexor digitorum nother sheath surrounds the tendon from the middle of the first metatarsal to its **Vagina m. tibialis posterioris.**—The tendon is surrounded by a synovial sheath ex- ım a region proximal to the medial malleolus to the insertion of the tendon.

D. MUSCULATURE OF THE FOOT
(Figs. 449–453)

ıe dorsum of the foot there is a muscle not represented in the hand, the digitorum brevis. In the sole of the foot there is a highly developed ure which may be subdivided into the flexor digitorum brevis; the connected with the long extensor of the toes, quadratus plantæ and les; the intrinsic muscles of the great toe; the intrinsic muscles of the ; and the interosseous muscles. These muscles abduct and adduct the : them at the metacarpophalangeal joints and flex and extend them st row of interphalangeal joints. On the second row of interphalangeal ey seem to exert relatively little action. All the movements, excepting ıre weak in most individuals. The extensor digitorum brevis is in- by the deep peroneal (anterior tibial) nerve. The muscles of the sole ot are all innervated by the lateral (external) plantar, except the flexor ı brevis, the most medial of the lumbrical muscles, and the abductor r brevis of the great toe, which are innervated by the medial (internal)

FASCIÆ
(Fig. 448)

cutanea.—Over the dorsum of the foot the tela subcutanea contains little fat. On the foot and the plantar surface of the toes it contains much fat embedded in dense ıue.

fasciæ.—Over the **dorsum** of the foot a fascial membrane extends from the cru- ıent mentioned above to the toes, where it is continued as fibrous sheaths for the endons. Laterally and medially it is continued into the plantar fascia. Where skeletal structures it becomes adherent to them. In the main this fascial sheet is ır the base of the first metatarsal it is strengthened by a band which runs from the e of this bone over the extensor tendons of the big toe to the base of the second . The extensor digitorum brevis is covered by an adherent fascial sheet. The ace of each dorsal interosseous muscle is likewise covered by an adherent membrane. **ntar surface** of the foot is invested by a fascia in which three distinct regions may d, a central, a lateral, and a medial. The central region is greatly thickened by brous tissue, the **plantar aponeurosis,** which diverge toward the toes from the medial ı tuber calcanei. These bands become distinct from one another as the toes are

approached, and each finally terminates partly in the skin over the head of the corresponding metatarsal and in the digital sheath of the flexor tendons. Some of the fibers are continued into the transverse capitular ligaments, the others extend through near the metatarsophalangeal articulation to the dorsum of the foot. Broader, thicker bands go to the three middle toes than to the big and little toes. At the margins of this central area some fibers radiate into the fascia of the lateral and medial area, some extend laterally into the skin, and some sink into the intermuscular septa described below. Near the toes well-marked transverse bundles of fibers may be seen between the digital bands. The central area of the plantar fascia is not densely adherent to the skin.

The digital sheaths of the flexor tendons of the toes correspond essentially with those previously described (p. 433) for the fingers.

The **medial plantar fascia** is thin and adherent to the skin. It extends between the central plantar and the dorsal fascia over the intrinsic muscles of the big toe. The **lateral plantar fascia** is thick and well-developed near the heel, thin as the little toe is approached. A dense band, the **calcaneometatarsal ligament,** strengthens it between the calcaneus and the tuberosity of the fifth metatarsal.

At the junction of the medial with the central region of the plantar fascia the **medial intermuscular septum** sinks in to be attached to the first cuniform, the navicular and the tendon of the posterior tibial. A similar **lateral intermuscular septum** sinks in between the lateral and central regions of the plantar fascia and is attached to the long plantar ligament, the tendon sheath of the peroneus longus and the base of the fifth metatarsal. The fascia of each of these regions in considerable part extends into these septa instead of becoming continuous across them.

The sole is thus divided into three great fascial compartments by these septa, a lateral, a central, and a medial. In the lateral lie the intrinsic pedal muscles of the little toe; in the medial, the abductor and the flexor brevis of the big toe and the distal end of the tendon of the flexor hallucis longus. The central compartment is subdivided by transverse septa into several subcompartments. In the most superficial compartment lies the flexor digitorum brevis; in the second, the tendons of the flexor digitorum longus and its associated muscles, the quadratus plantæ (flexor accessorius) and the lumbrical muscles; in the third, the adductor muscles of the big toe; and in the fourth, the interosseous muscles.

The first two subcompartments are most clearly marked in the region of the tarsus. Distally they become merged by the disappearance of the intervening transverse septum, and longtiudinally subdivided by fibrous septa which serve to make a complete sheath over each digit for the flexor tendons. The sheath over the adductor muscle of the big toe is a thin membrane continued laterally from the medial intermuscular septum. Where the two heads of the adductor muscle advance upon their tendon of insertion, the medial septum has no skeletal attachment, so that the adductor subcompartment of the middle fascial compartment communicates freely with the medial compartment. Over the cuneiform bones the tendon of the flexor hallucis longus passes from the long flexor region of the middle compartment into the medial compartment. Here the medial intermuscular septum divides into two layers, which form a sheath for the tendon as it passes to the plantar surface of the flexor hallucis brevis.

MUSCLES

1. Muscle of the Dorsum of the Foot

The **extensor digitorum brevis** (fig. 449).—This muscle is broad and thin, lies beneath the tendons of the long extensor muscle on the tarsus, lateral to the navicular and the head of the talus, and sends tendons to the four more medial toes. It arises from the calcaneus. Its nerve-supply is from the deep peroneal.

Origin.—From the lateral and superior surfaces of the body of the calcaneus and from the apex of the cruciate ligament.

Structure and insertion.—The fiber-bundles arise directly from the ligament, and by short tendinous bands from the bone. As they extend distally they become grouped into four bellies. Those of the most medial and largest belly, the **extensor hallucis brevis,** become inserted in a bipenniform manner on the lateral and medial margins of a tendon which begins opposite the cuboid. The insertion of fiber-bundles continues to the base of the first metatarsal. The insertion of the fiber-bundles of the other bellies, which are seldom so distinctly isolated as the first, takes place in a penniform manner into their respective tendons, but the exact mode of attachment is subject to great individual variations. The tendon of the first digit is inserted mainly into the middle of the back of the base of the first phalanx, but it is often also united to the tendon of the long extensor. The other three tendons are fused with the lateral margins of the corresponding tendons of the long extensor near the bases of the three middle digits. They also usually give slips to the bases of the first phalanges of the corresponding toes.

Nerve-supply.—The deep peroneal (anterior tibial) nerve, which, accompanied by the anterior tibial artery, passes beneath the medial belly of the muscle, gives off a branch which passes transversely across the middle of the deep surface of the muscle and sends twigs into it.

Relations.—It lies on the lateral side of the tarsus, beneath the long extensor tendons of the toes. The relations of its tendons have been described above.

Action.—It aids the long extensors in extending the first phalanx of each of the four medial digits. It has but a limited action on the second and third phalanges. It serves also to pull the ends of the toes to which its tendons go toward the little toe.

Variations.—The muscle shows great variation in development. Rarely the whole muscle, more frequently one or more of its digital divisions, may be missing. On the other hand, it may

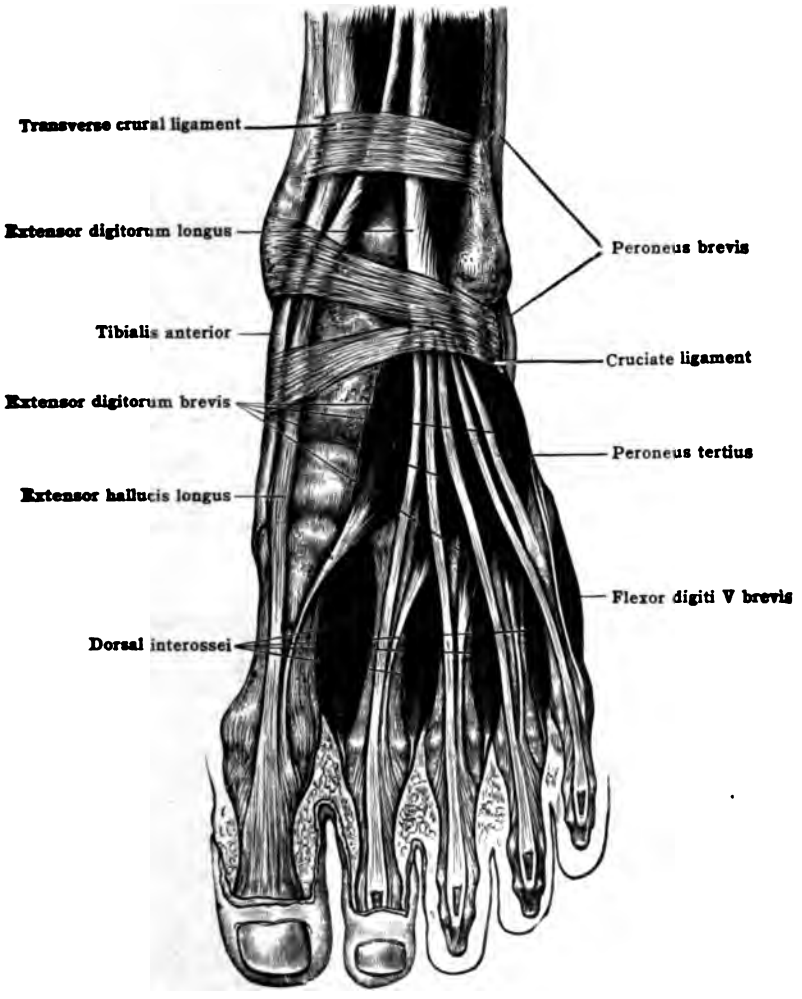
more highly developed than usual. Accessory fasciculi vary greatly in origin and termination. Most frequently their tendons go to a metacarpophalangeal articulation or to the second or the fifth toe.

2. Muscles of the Sole of the Foot

a. Flexor Digitorum Brevis (fig. 450)

The **flexor digitorum brevis,** the most superficially placed of the plantar muscles, lies in the midplantar region beneath the plantar fascia and over the tendons of the long flexor of the toes and its associated muscles. It arises from the calcaneus, and has a flat, elongated belly, which toward the middle of the sole is prolonged into four processes, each of which has a special tendon that is inserted into the second phalanx of one of the four lateral toes. The tendons of

Fig. 449.—The Muscle of the Dorsum of the Foot.



the muscle correspond to those of the flexor sublimis in the palm. The belly of the flexor sublimis is supposed to be represented by the soleus. The nerve supply is from the medial (internal) plantar.

Origin.—From (1) the medial process of the tuber calcanei; (2) the posterior third of the plantar aponeurosis; and (3) the medial and lateral intermuscular septa.

Structure.—The constituent fiber-bundles pass distally in a compact mass. The tendons of insertion begin within the muscle substance, and as the fiber-bundles become inserted on them, the separate fasciculi become more and more distinct. The fasciculi for the second and third toes are larger and arise more superficially than those for the fourth and fifth toes. The fasciculus for the fifth toe is often very small, and its tendon takes an oblique course to the insertion.

Insertion.—The tendons of the short flexor pass superficial to those of the long flexor into the osteofibrous canals on the flexor surface of the digits. Upon the first phalanx of each toe the tendon of the short flexor *divides and forms an opening* (chiasma tendinis) through which

the tendon of the long flexor passes, while the tendon of the short flexor becomes attached base of the second phalanx. The arrangement is essentially like that described at len the flexors of the fingers (p. 433).

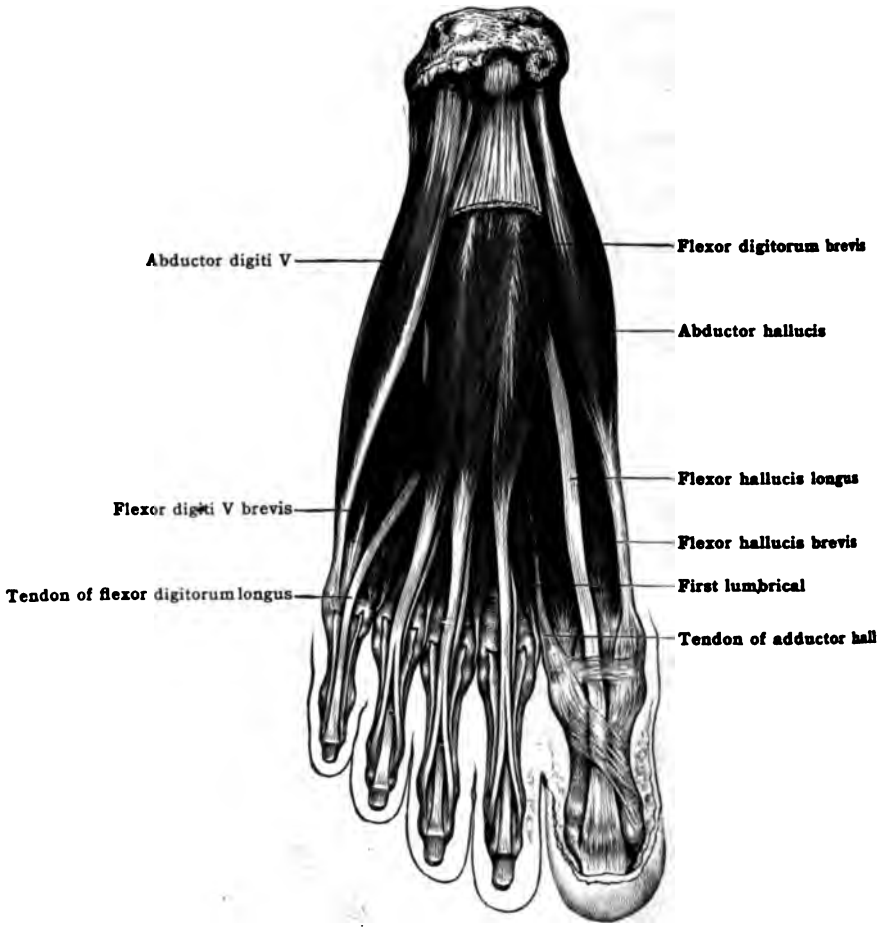
Nerve-supply.—From the medial plantar nerve by a branch which enters the middl of the deep surface near the medial margin of the muscle.

Action.—It is a strong flexor of the second row of phalanges.

Relations.—The short flexor is separated from the abductors of the big toe and lit by strong intermuscular septa (p. 524), and from the long flexor tendons and the qua plantæ (flexor accessorius) by a transverse septum in which the lateral plantar vess nerve cross the foot. In its distal two-thirds it is separated from the plantar fascia b tissue.

Variations.—The muscle shows a tendency toward reduction, one or more of its fa being frequently absent, and occasionally the whole muscle. The fasciculus for the fif

FIG. 450.—FIRST LAYER OF THE MUSCLES OF THE SOLE.



is absent in about 20 per cent. of bodies (Le Double). When a fasciculus is absent, its te usually replaced by an accessory tendon from the long flexor. The muscle or its tend be more or less fused to the tendons of the flexor digitorum longus.

b. MUSCLES ATTACHED TO THE TENDONS OF THE FLEXOR DIGITORU LONGUS (fig. 451)

The muscles belonging in this group are the **quadratus plantæ (fle** cessorius), a flat, quadrangular, bicipital muscle which runs from the med plantar surface of the body of the calcaneus to the dorsolateral margin an surface of the long flexor tendon; and the **lumbricales, four slender bi** muscles which run from the medial sides of the digital slips of the tendon medial sides of the four more lateral toes. The quadratus aids the long muscle; the lumbricales extend the last two phalanges and flex the first p of each of the digits to which they pass. The lumbrical muscles corresp

he hand. The quadratus is not there represented. The nerve-supply ıe lateral (external) plantar nerve except that for the first lumbrical ıich gets its supply from the medial (internal) plantar.

ıdratus plantæ (flexor accessorius) (fig. 451).—This muscle *arises* by two heads. *head* springs by an elongated tendon from the calcaneus in front of the lateral he tuber, and from the lateral margin of the long plantar ligament. The *medial head* tly from the medial surface of the body of the calcaneus as far back as the medial he tuber calcanei, and from neighboring ligaments.

e and insertion.—The two heads are separated at their origin by a short triangular ay soon fuse to form a single belly, but the fiber-bundles of each head in the main ely inserted. Those from the lateral head diverge to be attached to the lateral he flexor tendon. Those from the medial head are inserted on a tendon that begins lial margin and deep surface of this head, becomes broader, and is inserted as a rosis on the deep surface of the flexor tendon. There are great individual varia- structure of this muscle. The fibers of either part may be inserted with those of art.

pply.—From a branch of the lateral plantar nerve which passes obliquely across ial surface of the muscle parallel with the tendon of the flexor digitorum longus.

s.—The muscle lies in a fascial compartment with the long flexor tendons. This it is bounded on each side by intermuscular septa, deeply by the tarsus, and plantar- eptum which intervenes between it and the flexor digitorum brevis, and in which the tar nerve and vessels cross to the lateral side of the foot.

–It assists the long flexor tendon in flexing the toes. It makes the direction of the toes parallel with the long axis of the foot.

ns.—It is frequently reduced in size. The lateral head is not infrequently missing, ıead or the whole muscle much more rarely. The mode of attachment to the tendon may be inserted in part or wholly into the long flexor of the great toe. It may bout one body in twenty (Wood), an accessory slip of origin from the fibula, one of of the leg, the fascia of the leg or foot, or the medial surface of the calcaneus, etc.

ıbricales.—The three lateral muscles *arise* from the contiguous sides of the digital ı of the flexor digitorum longus in the angles of division. The first lumbrical arises ial margin of the tendon to the second toe. The fiber-bundles of each muscle con- th sides of a tendon which becomes free near the metatarsophalangeal joint and is he medial side of the first phalanx of the toe to which the muscle belongs. A tendi- ion is sent into the aponeurosis of the extensor muscle.

pply.—The three lateral lumbrical muscles are most frequently supplied by branches ramus of the lateral plantar nerve, the medial by the first common plantar digital ıe medial plantar nerve. The latter nerve may supply the two more medial muscles medial muscles may receive a double supply. The branches of the lateral plantar the deep surfaces of the muscles in the middle third. The branches of the medial ır the medial borders of the muscles near the junction of the proximal and middle

ı.—The lumbrical muscles lie in a plane with the long flexor tendons deeper than revis tendons and superficial to the adductor hallucis. The deep branches of the tar nerve and vessels pass across their deep surface; superficial branches of both ·es across the superficial surface.

–To extend the last two phalanges of the toes and to flex the first.

ns.—One or more of the muscles may be absent. Sometimes a muscle is doubled. frequently the case with the third and fourth muscles. The first may arise wholly ıdon of the posterior tibial muscle or from this and the long flexor of the big toe. ımbrical may arise from the flexor digitorum brevis. The second and fourth lum- be inserted into the tendons of the flexor digitorum brevis.

c. Intrinsic Muscles of the Great Toe (figs. 450–452)

muscles are the abductor, flexor brevis, and adductor. Of the three he first two lie in the medial fascial compartment, while the last lies in compartment covered by the flexor digitorum longus and its associated

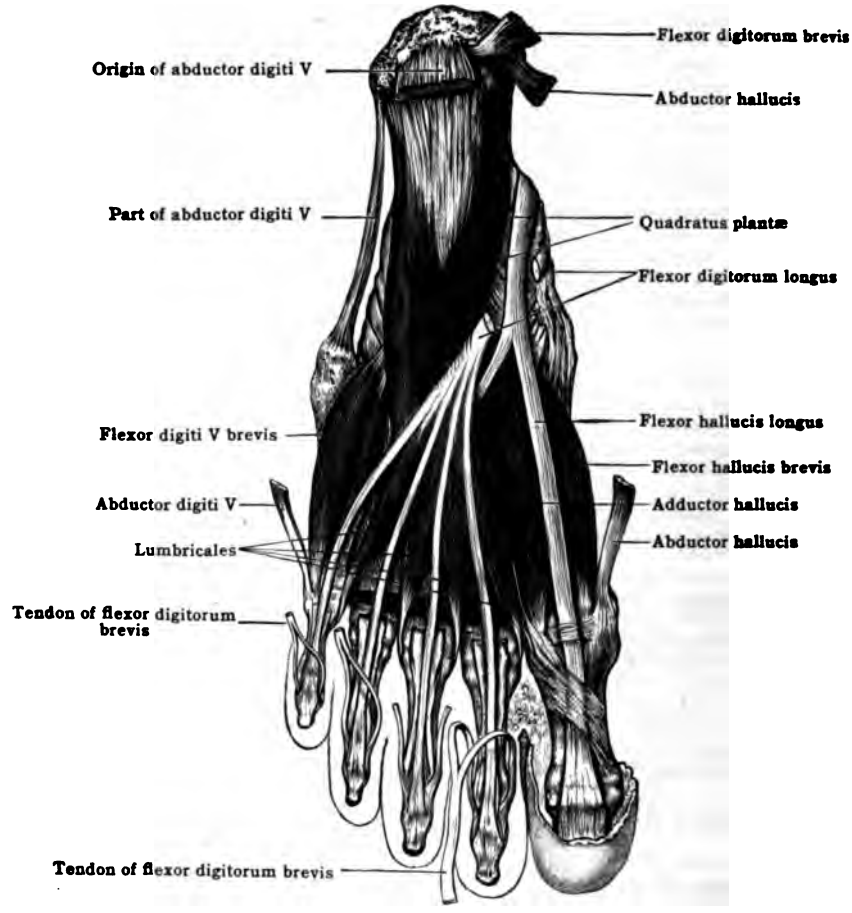
ıductor hallucis (fig. 450), the largest and most superficial of these es on the border of the sole medial to the short flexor muscle. It passes alcaneus across the tendons of the long flexor muscles, and is inserted edial side of the base of the first phalanx of the great toe and into the ɔ of the long extensor tendon. The **flexor hallucis brevis** (fig. 452) is a ıuscle which arises in the region of the cuneiform bones and is inserted le of the base of the first phalanx. Its tendons are fused with those of tor and the oblique head of the adductor. The **adductor hallucis** s composed of two distinct heads, an oblique and a transverse. The ad extends from the long plantar ligament to the lateral side of the base phalanx of the great toe. Its tendon of insertion is joined by the trans- l, which arises from the capsules of the third to the fifth metatarso- joints.

These muscles perform not only the functions indicated by their names, but also extend the second phalanx. They correspond fairly well with those of the thumb. The opponens is not normally present in the foot. The nerve supply for the adductor is from the lateral (external) plantar nerve; that for the other muscles is from the medial (internal) plantar.

The abductor hallucis (fig. 450).—*Origin.*—From (1) the medial process of the tuber calcanei; (2) the deep surface of the neighboring plantar fascia; (3) the laciniate (internal annular) ligament; (4) the septum between the muscle and the flexor digitorum brevis; and (5) a fibrous arch which extends on the deep surface of the muscle over the plantar vessels and nerves and the long flexor tendons from the calcaneus to the navicular bone.

Structure.—From the medial process of the tuber calcanei a tendinous band passes to the deep, lateral side of the muscle. Numerous tendinous bands arise from the other areas of

FIG. 451.—SECOND LAYER OF THE MUSCLES OF THE SOLE.



origin. The fiber-bundles arise from these tendons and directly from the fibrous arch. They are attached in a penniform manner to numerous tendinous slips which extend far up in the muscle. These slips become gradually fused into a tendon which appears on the superficial plantar aspect of the muscle. Opposite the distal half of the first metatarsal bone the tendon leaves the belly of the muscle and becomes closely bound to the medial belly of the flexor hallucis brevis.

Insertion.—In conjunction with the tendon of the medial belly of the flexor brevis into the base of the first phalanx. It usually sends an expansion to the extensor tendon.

Nerve-supply.—A branch from the medial plantar nerve usually enters near the middle of the lateral border of the muscle.

Relations.—It is covered by the plantar fascia and is separated from the muscles of the medial compartment by the medial intermuscular septum. It crosses the tendons of the tibialis anterior, tibialis posterior, flexor digitorum longus, and flexor hallucis longus muscles and the plantar vessels and nerves.

The flexor hallucis brevis (fig. 452).—*Origin.*—From a tendon attached to the first (internal), second and third cuneiform bones. The more lateral of its fibers are continued into the plantar calcaneocuboid ligament and the more medial into the expansion of the tendon of the posterior tibial muscle.

ructure and insertion.—The fiber-bundles give rise to two bellies, a medial and a lateral. s of the medial belly pass obliquely medially to be inserted into the tendon of the abductor is, and by a short tendon fused with this into the medial side of the plantar surface of the of the first phalanx. This tendon contains a sesamoid bone. Those of the lateral converge the tendon of the oblique head of the adductor, and the two muscles are inserted by a mon tendon, which contains a sesamoid bone, into the lateral side of the plantar surface e base of the first phalanx.

erve-supply.—A branch from the medial plantar (or first plantar digital) nerve divides over lantar surface of the muscle and gives a twig to each belly near the middle third. Rarely teral belly may receive a branch from the lateral plantar nerve.

elations.—The abductor hallucis covers it medially; the tendon of the flexor hallucis is passes between its two heads. Branches of the medial plantar vessels and nerve lie superficial surface.

endon of flexor digitorum longus

ıe adductor hallucis (fig. 452).—The **oblique head.**—*Origin.*—From (1) the tuberosity ı cuboid and the sheath over the tendon of the peroneus longus muscle; (2) the plantar ıeocuboid ligament; (3) the third cuneiform; (4) the bases of the second and third meta- s and (5) a fibrous arch which extends from the plantar calcaneocuboid ligament to the aseous fascia.

ructure and insertion.—From short tendon-slips the fiber-bundles pass forward to form a fusiform belly which is attached in a bipenniform manner to a flat tendon. The tendon s about the middle of the plantar surface of the muscle and is inserted in common with that ı flexor brevis into the lateral side of the plantar surface of the base of the first phalanx, y a slip into the aponeurosis of the long extensor muscle on the back of the big toe.

rve-supply.—A branch from the deep ramus of the lateral plantar nerve enters the middle of the lateral border of the muscle on its deep surface.

ıe transverse head *arises* from the joint-capsules of the third, fourth, and fifth metatarso- ngeal joints and from the transverse capitular ligaments.

ructure and insertion.—Of the three fasciculi, that to the little toe lies nearest the heel, o the middle toe the most distally. The fiber-bundles take a nearly parallel course to be ıed to tendon-slips which are fused into a common tendon that splits and passes on each

side of the tendon of the oblique head and is inserted into the sheath of the tendon of th flexor of the great toe (Leboucq).

Nerve-supply.—A branch from the deep ramus of the lateral plantar nerve enters the third of the deep surface of the muscle.

Relations.—The adductor hallucis is crossed superficially by the tendons of the digitorum longus and by the lumbrical muscles. On its deep surface lie the interosseous cles, and the deep plantar vessels and nerves.

Action.—The actions of the muscles of this group are indicated by the names of the i ual muscles. The abductor and the oblique head of the adductor are also flexors of th phalanx. All the muscles of the group aid in extending the second phalanx. The tra head of the adductor serves to draw together the heads of the metatarsals after they hav separated by the weight of the body during the tread.

Variations.—The extent of fusion of the abductor and adductor with the two heads short flexor varies considerably. The abductor may receive an accessory fasciculus fr medial border of the foot. Either the adductor or the flexor brevis may send a tendon base of the first phalanx or to the short flexor tendon of the second toe. The adductor frequent variations in relation to its metatarsal attachments, owing to the fact that ori a fasciculus from the body of the second (and third) metatarsal was probably normally and the transverse head was more developed (Leboucq). The **opponens hallucis** is a fas occasionally found which extends from the short flexor or the medial intermuscular sep the body of the first metatarsal. This muscle is normal in some monkeys. An **adductor secundi** has been seen to arise from various sources and become attached to the lateral the plantar surface of the base of the first phalanx of the second toe. This muscle may b with the oblique adductor. A corresponding muscle is found normally in some apes, some of the lower animals there is a special adductor for each toe.

d. Intrinsic Muscles of the Little Toe (figs. 450–452)

In this group belong three muscles, an abductor, a flexor and an opp The largest of these, the **abductor digiti quinti,** extends superficially ov lateral margin of the foot from the lateral side of the tuber calcanei base of the little toe. The **flexor digiti quinti brevis** is a small, flat m which lies on the plantar surface of the fifth metatarsal. The **opponen** small muscle lying lateral to this. The two, which are often fused, aris the cuboid. The flexor brevis is inserted into the plantar side of the base first phalanx of the little toe. The opponens is inserted into the lateral s of the metatarsal. The abductor corresponds to the abductor of the finger. The opponens and flexor brevis probably correspond to the deep p the opponens of the little finger. The nerve supply is from the lateral p nerve.

The abductor digiti quinti (fig. 450)).—*Origin.*—From (1) the lateral process of th calcanei and the lateral and plantar surface of the body of the bone in front of this; (2) th intermuscular septum; (3) the deep surface of the lateral plantar fascia, including the band extending from the calcaneus to the lateral side of the base of the fifth metatars

Structure.—The fiber-bundles run obliquely to a flat tendon of insertion. This begin the muscle near the calcaneocuboid joint, soon emerges on the medial side of the deep and becomes free near the metatarsophalangeal joint. Considerable individual vari structure is found.

Insertion.—On the lateral surface of the first phalanx of the little toe and the me phalangeal capsule. Often a slip is sent to the extensor tendon. While usually the glides over the tuberosity of the fifth metatarsal, it frequently sends a second fasciculu attached to this bone (**abductor ossis metatarsi quinti**). A special fasciculus from the tul often constitutes the lateral margin of the muscle.

Nerve-supply.—The nerve arises from the lateral plantar. It may be distributed near the deep or the superficial surface of the muscle. The former appears to be the ca the muscle is slightly developed. The chief intramuscular branches then extend ac middle third of the constituent fiber-bundles near the deep surface. In case the calcan tarsal bundles are well developed, the nerve enters the proximal margin of the muscle chief branches extend across the middle third of the more superficial muscle-bundles, terminating in the distal margin of the muscle.

Relations.—It is ensheathed by the plantar fascia and the lateral intermuscular s It lies superficial to the quadratus plantæ (flexor accessorius), the opponens and flexo of the little toe, the long plantar ligament, and the tendon of the peroneus longus muscl

The flexor digiti quinti brevis (fig. 452)).—*Origin.*—From the sheath of the peroneus the tuberosity of the cuboid, and (3) the base of the fifth metatarsal.

Structure and insertion.—The fiber-bundles take a nearly parallel course, although th is slightly fusiform. They are attached by short tendinous bands to the base of t phalanx of the little toe, the capsule of the corresponding joint, and the aponeurosis dorsal surface of the toe.

Nerve-supply.—A branch of the superficial ramus of the lateral plantar nerve send to the middle third of the plantar surface of this and the following muscle.

Relations.—It is covered medially by the plantar fascia, laterally by the abductor fifth toe. Medially it lies superficial to the third plantar interosseous muscle.

The opponens digiti quinti.—This muscle *arises* from the sheath of the peroneus longus the tuberosity of the cuboid by a slender tendon which passes over the tuberosity of the metatarsal and gives rise to fiber-bundles which are *inserted* on the lateral surface of the metatarsal.

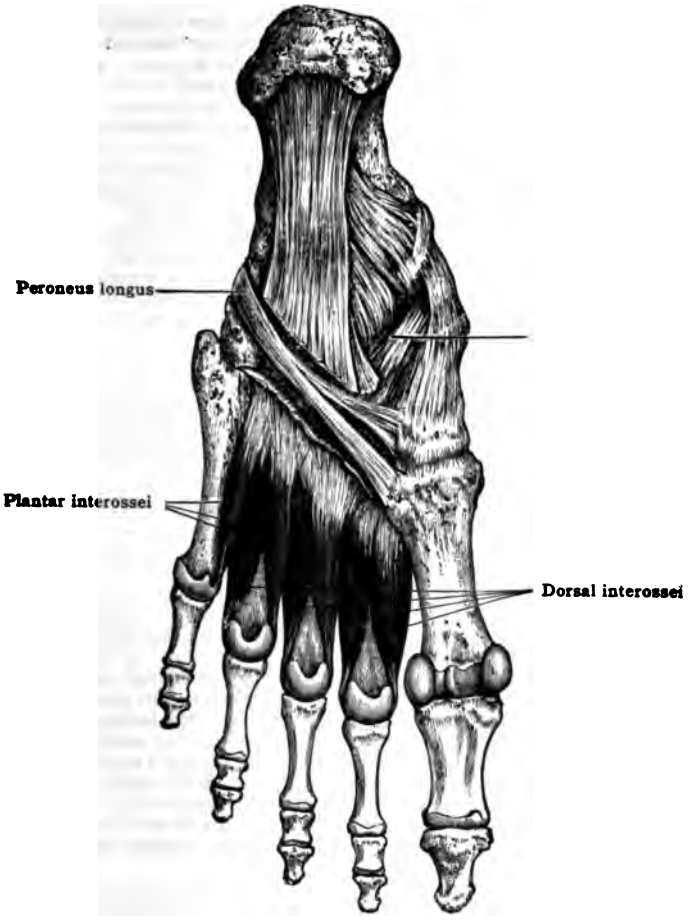
Nerve-supply.—From branches of the nerve to the flexor brevis.

Relations.—It is covered by the abductor of the fifth toe.

Actions.—The abductor and flexor brevis abduct the little toe and flex the first phalanx. act as extensors of the second phalanx. The opponens serves to draw the little toe medi- in a plantar direction.

Variations.—The muscles of this group may be more or less completely fused. The abduc-, in addition to the variations mentioned above, may send tendons to the third and fourth tatarsals. The opponens is frequently missing. The **abductor accessorius digiti quinti** is are muscle which arises from the lateral process of the tuber of the calcaneus and is inserted o the lateral surface of the base of the first phalanx of the little toe.

FIG. 453.—FOURTH LAYER OF THE MUSCLES OF THE SOLE.



e. THE INTEROSSEOUS MUSCLES (fig. 453)

Two groups of interosseous muscles are recognised, a dorsal and a plantar. The dorsal are the larger and fill the interspaces. The first two are inserted into each side of the base of the first phalanx of the second toe; the third and fourth into the lateral sides of the bases of the first phalanges of the third and fourth toes. The plantar interossei lie on the medial side of the ventral surfaces of the third, fourth, and fifth metatarsals, and are inserted each on the medial side of the base of the first phalanx of the corresponding toe. In the hand the axis about which the interosseous muscles are arranged passes through the middle finger, in the foot through the second toe. The dorsal interossei abduct from, the plantar adduct toward, this axis. The nerve-supply is from the lateral plantar nerve.

The interossei dorsales.—Each of the three lateral dorsal interosseous muscles *arises* from —(1) the sides of the shaft and the plantar surface of the bases of the metatarsal bones bounding

the space in which it lies; (2) from the fascia covering it dorsally; and (3) from fibrous proli... tions from the long plantar ligament. The first has a similar origin except that it is attac... medially to the base of the first metatarsal and to a fibrous arch extending from the base to ... head.

Structure.—The component fiber-bundles of each muscle are inserted bipinnately on a t... don which begins high in the muscle and becomes free near the metatarsophalangeal joint.

Insertion.—The first and second on each side of the base of the first phalanx of the ... toe. The third and fourth on the lateral side of the bases of the proximal phalanges of the ... and fourth toes. Each tendon is adherent to the capsule of the neighboring joint. T... send no well marked processes to the extensor tendons, as do those of the hand.

The interossei plantares.—Each plantar interosseus *arises.*—(1) from the proximal ... of the medial plantar surface of the shaft and from the base of the metatarsal on which it lies ... and (2) from expansions of the long plantar ligament.

Structure and insertion.—The obliquely placed fiber-bundles are longer than those of t... dorsal interossei, and are inserted in a tendon which lies near the medial border of the muscle ... becomes free near the metatarsophalangeal joint, and is inserted into a tubercle on the media... side of the base of the first phalanx of the digit to which it goes.

Nerve-supply.—From the deep branch of the lateral plantar nerve several rami are given off for the interossei. The nerve of each muscle enters the plantar surface in the proximal third. The interosseous muscles of the fourth interspace, however, are usually supplied by a branch from the superficial ramus of the lateral plantar nerve.

Relations.—The interosseous muscles are covered on the plantar surface by a thin fascia on which the deep branches of the lateral plantar nerve and vessels run. The first dorsal interosseous adjoins medially the flexor hallucis brevis and laterally on the plantar surface of the second metatarsal, adjoins the second dorsal interosseous. Dorsal and plantar interossei then alternate across the plantar surface of the foot until the fifth metatarsal is reached. Here the third plantar interosseous adjoins the flexor brevis of the little toe.

Action.—The chief axis of the foot may be taken to extend through the second toe. The dorsal interosseous muscles abduct—pull the digits to which they are attached away from this axis; the plantar interosseous muscles adduct—pull the digits toward the axis. The interossei all flex the first row of phalanges.

Variations.—The second dorsal interosseous may have no attachment to the third metatarsal.

Bursæ

B. intermetatarsophalangeæ.—Four bursæ between the neighboring sides of the heads of the metatarsal bones and dorsal to the transverse capitular ligaments. **B. mm. lumbricalium.**—Between the ends of the tendons of the lumbrical muscles and the transverse capitular ligaments. The three medial are more constant than the lateral.

For other bursæ in the foot, see pp. 514, 518 and 523.

MUSCLES GROUPED ACCORDING TO FUNCTION

The exact functions of many of the muscles have not yet been decisively determined Anatomical studies, the construction of mechanical models, the electrical stimulation of the musculature, and observation of the muscular activities of normal individuals and of individuals in whom given muscles or sets of muscles are absent or paralysed, have all proved valuable methods of investigation, but each method has its drawbacks, and knowledge of the part actually played by individual muscles in the normal activities of the body is as yet merely approximate. Owing to the influence of gravity, the relations of other muscles to the skeleton, and similar factors, a given muscle may perform functions which would not be deduced from a simple study of the relations of the muscle to the skeleton. Thus through the action ot gravity the iliacus flexes not only the hip, but also the knee, and the hamstring muscles flex he hip while flexing the knee. The functions ascribed to various muscles in the following table, although an attempt has been made to base them upon the more recent work on the action of the muscles, must be taken to be merely approximately correct.

The *axes* about which a bone moves at a given joint are frequently complex. For practical purposes, however, it is usually possible to determine an approximate axis about which any given movement takes place. From this standpoint diarthrodial joints may be divided into three groups, uniaxial joints, biaxial joints and multiaxial joints.

In the *uniaxial joints* movements of note may be made merely about one approximated axis. If a muscle acts on such a joint it exerts an effective pull either in one direction about this axis or in the opposite direction. Most joints of this sort are of the hinge-type, like those between the phalanges, and the movements are flexion and extension. In some joints as at the joint between the dens and atlas the joint is of the pivot-type and the movement is one of rotation in one direction or the other.

In *biaxial joints* there are two approximated primary axes of movement. Muscles acting on such joints may cause movement about either axis or about intermediate axes, the resultant of simultaneous movement about both primary axes. Joints of this sort are usually either of the saddle-type, like the carpometacarpal joint of the thumb, or of the condyloid type, like the wrist-joint. About one axis we usually get flexion and extension, about the other axis, abduction and adduction. A given muscle may cause movement about one axis or about both axes.

In *multiaxial joints* movements may be made about axes in three planes, each plane vertical to each of the other planes, and about various intermediate axes. Joints of this type are called ball-and-socket joints, although they are not always, like the shoulder- or hip-joints, similar in form to an ordinary mechanical ball-and-socket joint.

Muscles producing a movement in a common direction are called *synergists*, those which produce movements in opposite directions are called *antagonists*. If all joints were of the ginglymus type it would be relatively easy to arrange the muscles acting on the joints into synergists and antagonists although even in such joints a muscle might be so attached that it would act as a flexor after flexon has started, an extensor after extension has started. In case of arthrodial, and still more so in case of multiaxial joints, the direction of pull exerted by a given muscle with respect to a given axis varies so much with the positions of the articulating bones that muscles which in one position are antagonists in another position become synergists during the same general movement. Thus when the arm is at the side the clavicular and spinous portions of the deltoid are adductors, and the acromial portion is an abductor of the arm; but when the arm has been raised a certain distance all parts become abductors.

In the following table an attempt has been made to include the names of the main muscles acting upon the chief axes of each joint or joint groups of the head, trunk and limbs. In this table have been included not only the voluntary muscles described in the preceding section, but also several described in other parts of the book.

Facial muscles. (Cf. p. 364.)

These serve essentially to contract the various visceral orifices of the head or to retract the tissue surrounding them.

Ear.

Retractors: auricularis anterior, superior, and posterior.

Orbit.

(*a*) Retractor: epicranius (occipitofrontalis). The levator palpebræ superioris raises the upper eyelid.

(*b*) Contractors: orbicularis oculi, corrugator, and procerus.

Nasal orifice.

(*a*) Dilators: angular head of the quadratus labii superioris, transverse portion of the nasalis, and the dilatores naris.

(*b*) Contractors: pars alaris of the nasalis and the depressor septi nasi.

Oral orifice.

(*a*) Retractors:

Upward: zygomaticus, quadratus labii superioris, caninus.

Lateralward: zygomaticus, risorius, platysma, triangularis, buccinator.

Downward: triangularis, quadratus labii inferioris, platysma.

(*b*) Contractors: orbicularis oris, compressor labii, incisivus labii inferioris and superioris.

(*c*) Protractors of the lips: incisivus labii inferioris and superioris, mentalis.

2. Muscles acting on the eyeball (see Section on Eye).

To abduct the pupil: rectus medialis.

To abduct the pupil: rectus lateralis.

To direct the pupil upward: rectus superior, in association with the obliquus inferior.

To direct the pupil downward: rectus inferior, in association with the obliquus superior.

3. Muscles acting on the mandible (cf. p. 373).

(*a*) Transverse axis above the articular tubercles of the temporal bones (fig. 454 A (T)). As the articular disk glides forward over the articular tubercle it in part moves about an axis above this tubercle, in part takes a more horizontal course than if confined to movement about this axis. The condyles to some extent move forward on the lower surface of the disk. As the mandible moves forward it is depressed slightly so as to permit the incisor teeth of the lower jaw to pass those of the upper jaw.

Retraction of mandible	*Protraction of mandible*
Right and left temporal muscles, posterior two-thirds.	Right and left external pterygoids.

Protraction of the jaw is aided by the internal pterygoid and masseter muscles and the anterior part of the temporal. The digastric is an accessory retractor.

(*b*) Transverse axis through condyles of mandible (fig. 454 A (K)).

Elevation of teeth	*Depression of teeth*
Temporal muscles	Digastric muscles
Internal pterygoids	Geniohyoids
Masseters	Mylohyoids

In the elevation and depression of the anterior part of the mandible the articular disks and the condyles are pulled forward as the mandible swings about the transverse axis through the condyles. The region of the ramus near where the stylomandibular and pterygomandibular ligaments are attached moves comparatively little as the mouth opens. While some investigators have contended that these ligaments fix the jaw and make a transverse axis of movement, this is denied by others. (See Fick, bibliography.)

(*c*) Rotation about vertical axis through one condyle. (Fig. 454 B (KL)). Slight abduction about anteroposterior axis through same condyle (fig. 454 C).

Rotation about vertical axis left condyle. Upper and lower sets of molars of right side opposed to one another.

Forward movement of lower right molars
Right external pterygoid muscle

Backward movement of lower right molars
Right digastric muscle.

The right internal pterygoid, masseter and anterior third of the temporal muscles aid in the forward movement, the posterior two-thirds of the temporal in the backward movement.

4. Muscles acting on the hyoid bone. (Cf. pp. 373, 384.)
   (*a*) To elevate it: digastric, stylohyoid, styloglossus, mylohyoid, geniohyoid, genioglossus, hyoglossus, and the middle constrictor of the pharynx.
   (*b*) To depress it: thyrohyoid, sternohyoid, omohyoid, sternothyroid.
   (*c*) To protract it: genioglossus (inferior portion), geniohyoid, anterior belly of digastric, and the mylohyoid.
   (*d*) To retract it: posterior belly of digastric, stylohyoid, and the middle constrictor of the pharynx.
5. Muscles acting on the larynx (see Section XI).
   (*a*) To elevate it: thyrohyoid, stylopharyngeus, pharyngopalatinus, the inferior constrictor of the pharynx, and the elevators of the hyoid.

FIG. 454.—CHIEF AXES IN MOVEMENTS OF THE MANDIBLE. (After Fick.)

A. Movement about transverse axis *T* through the articular tubercles of the temporal bone and *K* through the condyles of the mandible. *K*, K^{I}, K^{II}, K^{III}, successive positions of *K* as the mouth is opened. *J*, *JvII*, movement of the top edge of the incisors in protrusion of the mandible. *JvIII*, position of top edge of the incisors in extreme protrusion of the mandible. Dotted line *JI–Pf*, movement of top edge of central incisors when there is no protrusion of the mandible. Dotted line *JvII–Jv*, movement of the top edge of central incisors when the mandible is protruded.

B. Movement of mandible as seen from above about vertical axis through left condyle *Kl*. The line *Kl*, *Kr* indicates the position of the tranverse axis about which elevation and depression of the lower teeth takes place.

C. Mandible viewed from behind. Abduction about sagittal axis through right condyle.

   (*b*) To depress it: sternothyroid, sternohyoid, and omohyoid.
   (*c*) To approximate the vocal folds: cricoarytenoideus lateralis; vocalis; thyarytenoideus, arytenoideus transversus.
   (*d*) To make the vocal folds (cords) tense: cricothyroideus.
   (*e*) To widen the rima glottidis: cricoarytenoideus posterior.
   (*f*) To shorten and thicken the vocal folds: thyroarytenoideus (externus), vocalis.
   (*g*) To constrict the aditus and vestibule of the larynx: aryepiglottic, thyroarytenoideus.
   (*h*) To widen the aditus and vestibule of the larynx: thyroepiglottidei.
6. Muscles acting on the tongue (see Section X).
   (*a*) To elevate it: styloglossus (especially along the sides), glossopalatinus, glossopharyngeus, and the elevators of the hyoid bone.
   (*b*) To depress it: genioglossus (in the center), hyoglossus (at the sides), chondroglossus, and the depressors of the hyoid bone.

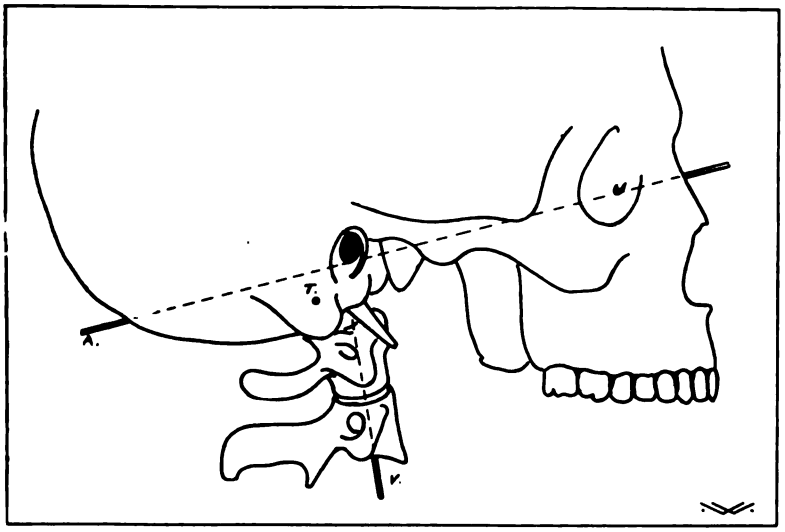
(*c*) To protrude it: genioglossus (middle and inferior portions).
(*d*) To retract it: genioglossus (anterior portion), styloglossus, chondroglossus.
(*e*) To shorten it and make it bulge upwards: longitudinalis superior and inferior.
(*f*) To narrow it and make it bulge upwards: transversus linguæ.
(*g*) To flatten it: verticalis linguæ.

When the muscles work symmetrically, these movements are symmetrical; when they do not work symmetrically, the tongue is moved from side to side, rotated, etc.

scles acting on the palate and pharynx (see Section X).

(*a*) To narrow the pharyngeal opening of the tuba auditiva (Eustachian tube): levator veli palatini.
(*b*) To widen the isthmus of the tuba: levator veli palatini.
(*c*) To open the tube: tensor veli palatini, pharyngopalatinus.
(*d*) To raise and shorten the uvula: m. uvulæ.
(*e*) To depress the soft palate: glossopalatinus, pharyngopalatinus.
(*f*) To make tense the soft palate: tensor veli palatini.
(*g*) To lift the soft palate: levator veli palatini.
(*h*) To approximate the glossopalatine arches; glossopalatinus.
(*i*) To approximate the pharyngopalatine arches: pharyngopalatinus, superior constrictor of the pharynx.
(*j*) To constrict the pharynx: superior, middle, and inferior constrictors.
(*k*) To widen the pharynx: stylopharyngeus and the muscles which protract the hyoid bone.
(*l*) To elevate the pharynx: stylopharyngeus, pharyngopalatinus.

FIG. 455.—CHIEF AXES OF MOVEMENT OF SKULL ON VERTEBRAL COLUMN
Sagittal axis; *T*, transverse axis; *V*, perpendicular axis.



uscles acting on the head (cf. pp. 382, 389, 444).

lanto-occipital and atlantoepistropheal joints. *Note.*—Flexion and extension (maximum exion, 30° extension, usually less) and abduction (15° to 20° from the midposition, fre-ly less) occur chiefly in the atlanto-occipital joints, rotation (about 30° from the mid-on) chiefly in the atlantoepistropheal joints. Abduction in the atlanto-occipital joint ompanied by rotation and extension toward the same side (Fick).

(*a*) Transverse axis above occipital condyles, (fig. 455,T).

Longitudinal axes through necks of ribs, anteroposterior and vertical axes th cartilages near chondrosternal joints. The costochondral and interchondral joints involved.

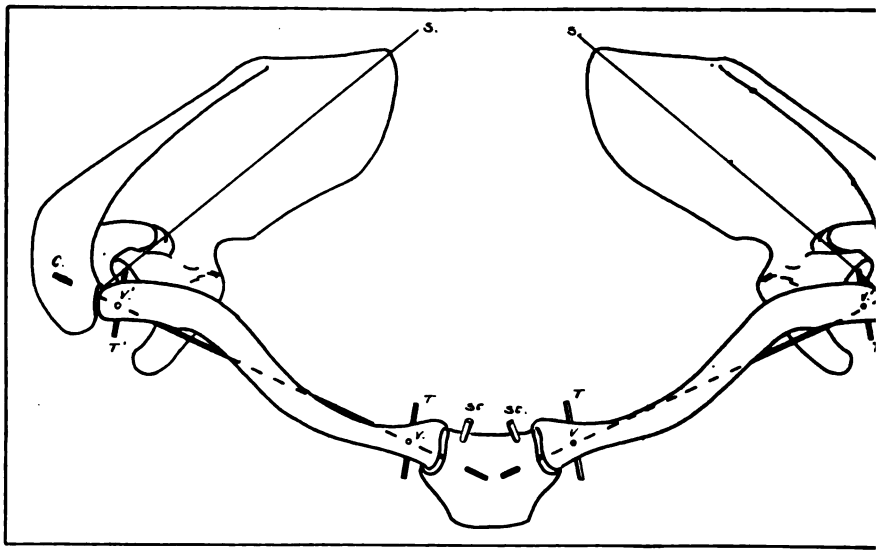
Inspiration.—Shafts of ribs swing outwards and upwards, costochondral angles flattened, sternum elevated and protracted.	*Expiration.*—Shafts of ribs s wards and downwards, costochondr increased, sternum depressed and re
External intercostals	Internal intercostals (costal part)
Interchondral muscles	Subcostals
	Transversus thoracis

The extensors of the thoracic region of the spine aid in inspiration. In forced inspi scalene, the sternocleidomastoid, the rhomboids and serratus anterior, the serratus superior, the trapezius and pectoralis minor, latissimus dorsi, pectoralis major and s may be brought into play. The abdominal muscles and the muscles of the pelvic essentially antagonists of the diaphragm. The abdominal muscles, the quadratus l the iliocostalis, the longissimus dorsi and the serratus posterior inferior lower the forced expiration.

The diaphragm plays an essential part in inspiration although according to Fick played by the diaphragm is frequently overestimated.

FIG. 458.—CHIEF AXES OF MOVEMENT OF THE SHOULDER GIRDLE.

Viewed from above. *S*, scapular axis; *C*, clavicular axis; *V*, vertical axis throu end of clavicle; *V'*, vertical axis through acromial end of clavicle; *St*, sternal axis ventral movements at sternoclavicular joint; *T*, ventrodorsal axis for elevation and d about the sternoclavicular joint; *T'*, dorsoventral axis for acromioclavicular joint.



11. Muscles acting on the abdomen. (Cf. p. 455.)
    (*a*) Constriction of the abdominal cavity: obliquus abdominis exte internus, the transversus and rectus abdominis, and phragm, levator ani, and coccygeus.
    (*b*) Reduction of pressure in the abdominal cavity: the muscles of in with the exception of the diaphragm, serve to lessen pression of the abdominal viscera.
12. Action of the muscles of the perineal region. (Cf. p. 472.)
    (*a*) To close anal canal: sphincter ani externus.
    (*b*) To constrict the anal portion of the rectum: levator ani (pubococcygea
    (*c*) To constrict the bulbus urethræ and the corpus cavernosum urethr spongiosum): bulbocavernosus.
    (*d*) To elevate the prostate gland: leavtor ani.
    (*e*) To constrict the vagina: bulbocavernosus, levator ani (pubococc tion), constrictor vaginæ.

(*f*) To cause erection of penis and clitoris: ischiocavernosus, bulbocavernosus, and sphincter urethræ membranaceæ.

(*g*) To compress the urethra and the bulbourethral (Cowper's) or the great vestibular (Bartholin's) gland: sphincter urethræ membranaceæ and the transversus perinei profundus.

(*h*) To support and lift the pelvic floor: levator ani, coccygeus, transversus perinei profundus and superficialis.

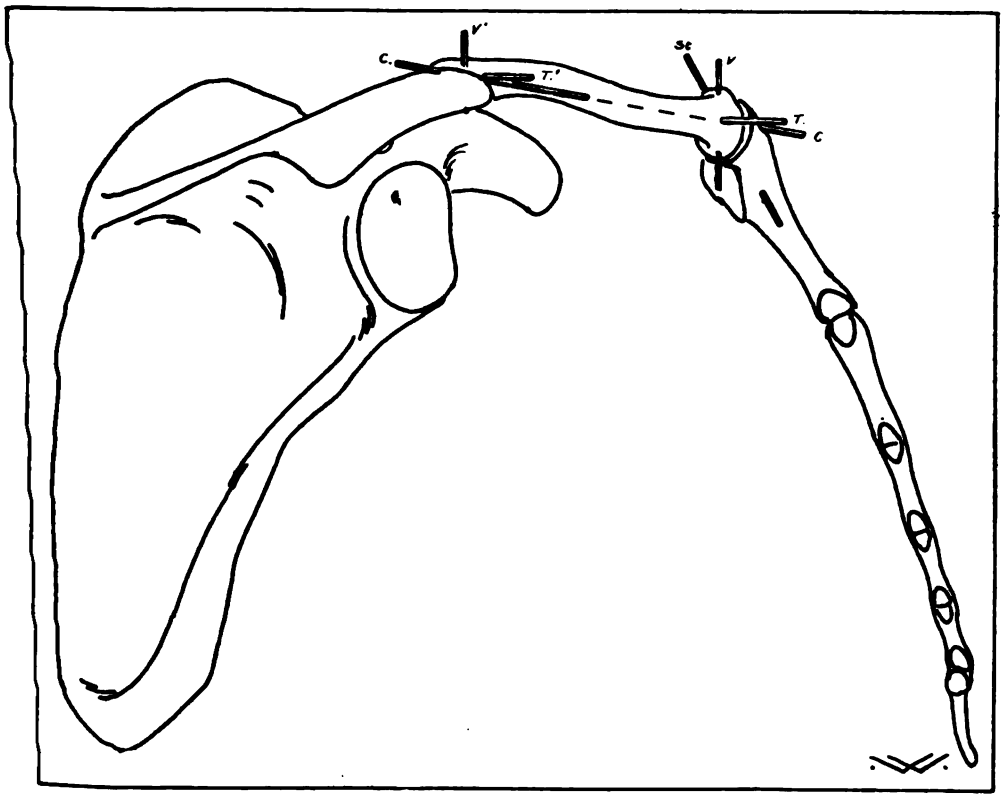
Muscles acting on the shoulder-girdle at the sternoclavicular joint (fig. 458) (cf. p. 382, 391, 403).

It is assumed that movement at the acromioclavicular joint, while enabling the scapula to accommodate itself to the chest wall, at the same time increases the extent of the rotation of the scapula about the clavicular (acromiosternal) axis.

(*a*) Dorsoventral axis (figs. 458, T, 459, T)

Abduction (scapula raised)	*Adduction (scapula depressed)*
Levator scapulæ	Pectoralis minor
Trapezius (upper part)	Subclavius
	Trapezius (lower part)

FIG. 459.—CHIEF AXES OF MOVEMENT OF THE SHOULDER GIRDLE. Viewed from the side. For explanations, see fig. 458.



The lower part of the serratus anterior is an accessory abductor. The pectoralis major (lower part) and latissimus dorsi, adductors of the arm, also indirectly adduct the scapula. The clavicular part of the sternocleidomastoid and the middle part of the serratus anterior are accessory abductors.

(*b*) Vertical axis (figs. 458, 459, V, St.)

The clavicle moves on the interarticular disk about a vertical axis through the head of the clavicle; the clavicle and disk move about an oblique axis through the sternum.

Retraction (scapula carried backward)	*Protraction (scapula carried forward)*
Rhomids	Serratus anterior
Trapezius (middle part)	Pectoralis minor
(The latissimus dorsi aids this movement)	(The pectoralis major, upper sternal part, aids this movement)

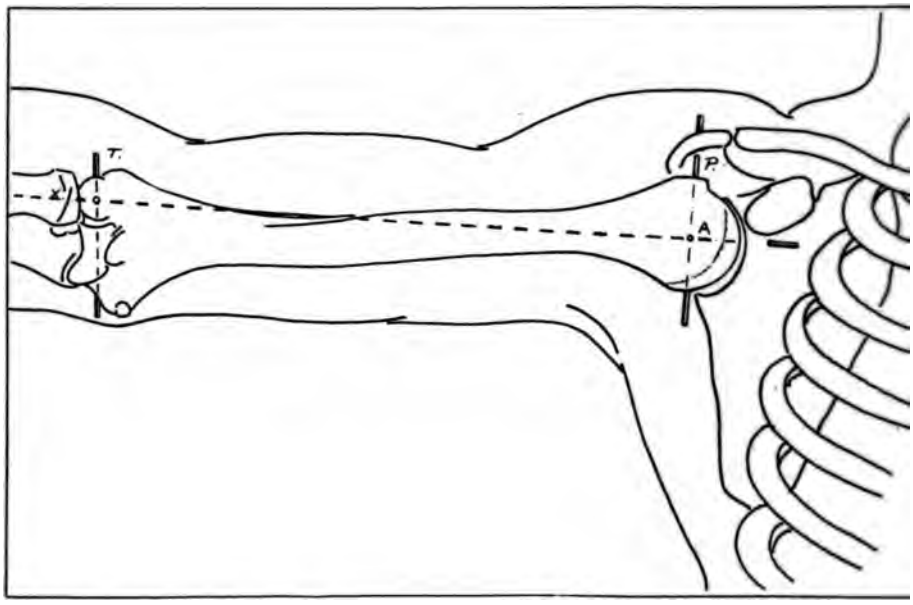
(*c*) Clavicular axis (figs. 458, 459, C)

Rotation in the direction of supination (glenoid cavity turned upward)	*Rotation in direction of pronation (gl cavity turned downward)*
Trapezius	Pectoralis minor
Serratus anterior (lower part)	Rhomboidius major

In the upward rotation the acromion and outer end of the clavicle are elevated and backwards, as well as rotated. The reverse is true of the downward rotation. The pect major (pectoral portion), and latissimus dorsi are accessory rotators in the directi pronation.

FIG. 460.—CHIEF AXES OF MOVEMENT AT SHOULDER AND ELBOW JOINTS.

A, dorsoventral axis of shoulder-joint for abduction and adduction; *P*, perpendicular shoulder-joint, arm adducted for flexion and extension. When the arm is at the side thi passes transversely through the body; *A–X*, longitudinal axis through humerus, for rot *T*, transverse axis through humerus for flexion and extension at elbow joint.



14. Muscles acting on the shoulder-joint (fig. 460) (cf. p. 397).

(*a*) Dorsoventral axis (fig. 460, A)

Abduction	*Adduction*
Deltoid	Pectoralis major (lower part)
Supraspinatus	Latissimus dorsi
	Teres major

With the arm at the side the clavicular and spinal parts of the deltoid are adductors the arm is abducted these parts become abductors. The subscapularis meanwhile chang an abductor to an adductor. The long head of the biceps and the upper part of th spinatus are strong accessory abductors. The long head of the triceps, the coracobra the short head of the biceps and the teres minor are strong accessory adductors when t is at the side.

(*b*) Transverse axis, arm at side; perpendicular axis, arm at 90° (fig. 460, P)

Extension	*Flexion*
Deltoid (spinal part)	Deltoid (clavicular part)
	Pectoralis major (clavicular part)
	Coracobrachialis

The latissimus dorsi, teres major, and subscapularis (lower part), when the arm is at t are strong accessory extensors; the short head of the biceps is a strong accessory flexor subscapularis is a powerful accessory flexor when the arm is abducted. The infraspin a flexor.

(*c*) Humeral axis (fig. 460, A–X)

Lateral rotation (supination)	*Medial rotation (pronation)*
Infraspinatus	Subscapularis
Teres minor	

The **spinal part** of the deltoid is also a lateral rotator. The adductor muscles, the clavicular part of the **deltoid**, and the long head of the biceps are strong accessory medial rotators. An important **function** of the coracobrachialis muscle and of the scapular attachments of the **biceps and triceps** muscles appears to be to hold the head of the humerus in the glenoid cavity.

Muscles acting on the forearm at the elbow-joint (figs. 460, 461) (cf. p. 411, 413, 416).

Transverse axis (figs. 460, 461, T)

Extension	*Flexion*
Triceps	Brachialis
Anconeus	Brachioradialis

The **biceps** muscle, a powerful flexor when the forearm is supinated, is a much weaker one when the **forearm** is pronated. The pronator teres and extensor carpi rad. long. are strong accessory **flexors** of the elbow-joint, the flexor carpi radialis, extensor carpi radialis brevis and palmaris **longus** are weaker accessory flexors.

Muscles acting on the radioulnar joints (figs. 461, 462) (cf. p. 416).

In the **ordinary** use of the upper extremity, supination of the foreman is usually accompanied by **extension** at the elbow-joint and lateral rotation at the shoulder-joint; pronation with flexion at the elbow-joint and medial rotation at the shoulder-joint.

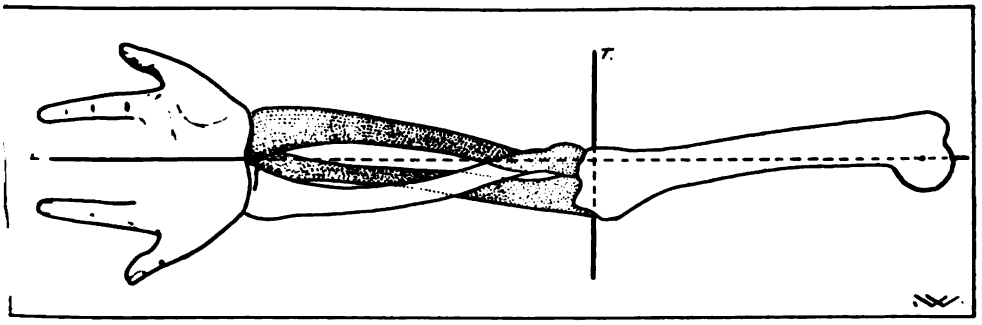
Longitudinal axis

Supination	*Pronation*
	Pronator teres
Supinator	Pronator quadratus

The **brachioradialis** and extensor carpi rad. long. bring the forearm into an intermediate position. When the arm is extended they supinate, but as the arm is flexed they tend more and more to **bring** the arm into a pronate position. The flexor carpi radialis is a powerful accessory pronator.

FIG. 461.—FOREARM IN PRONATION AND SUPINATION. (After Fick.)

T, **transverse axis** at elbow-joint for flexion and extension; *L*, longitudinal axis of forearm for pronation **and** supination.



17. **Muscle acting** on the hand at the wrist-joint. (fig. 462). (cf. p. 416.)

(*a*) Transverse axis (fig. 462, T)

Extension (dorsal flexion)	*Flexion (volar flexion)*
Extensor carpi radialis brevis	Flexor carpi ulnaris
Extensor carpi radialis longus	Flexor carpi radialis
Extensor carpi ulnaris	Palmaris longus.

The long flexors and extensors of the thumb and fingers are accesory flexors and extensors of the wrist-joint. The long abductor of the thumb is also an accessory flexor of the wrist.

(*b*) Perpendicular axis (fig. 462, V)

Radial abduction	*Ulnar abduction*
Extensor carpi radialis longus	Flexor carpi ulnaris
Extensor carpi radialis brevis	Extensor carpi ulnaris

The abductor pollicis longus and extensor pollicis longus muscles are powerful accessory radial abductors.

18. **Muscles acting** on the carpometacarpal joints (fig. 462) (cf. p. 437). Combined transverse and perpendicular axes (A and T)

Thumb

According to Fick and others there is some voluntary rotation possible at the first carpometacarpal joint.

Abduct and repose	*Adduct and oppose*
Abductor pollicis longus	Opponens
Abductor pollicis brevis	Adductor

The extensors of the thumb are accessory reposers. The long and short flexors a opposing.

Little finger

Abduct and repose	*Adduct and oppose*
Extensor carpi ulnaris	Opponens

The abductor digiti quinti and extensor digiti quinti proprius aid in reposing; the volar interosseous, the fourth lumbrical and the flexors of the little finger in opposing.

19. Muscles acting on the metacarpophalangeal joints (fig. 462).

(*a*) Transverse axes

Extension	*Flexion*
Thumb	
Extensor pollicis brevis	Flexor pollicis brevis

The extensor pollicis longus is an accessory extensor. The adductor and abductor and the flexor pollicis longus are accessory flexors.

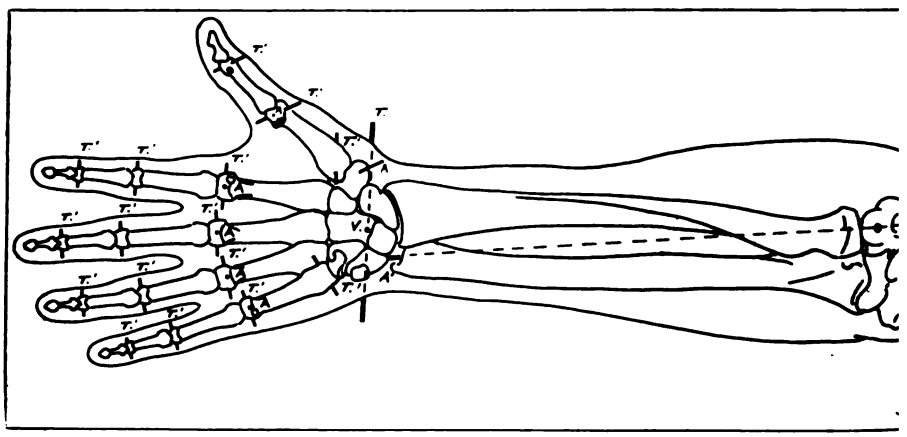
Little finger

Extensor digiti quinti proprius	Flexor digiti quinti brevis Fourth lumbrical Third volar interosseous

The abductor and long flexors of the little finger are accesory flexors of this joint.

FIG. 462.—CHIEF AXES OF MOVEMENT OF FOREARM, WRIST AND HAND.

L, longitudinal axis of forearm for pronation and supination; *T*, compromise transve for flexion and extension at wrist; *V*, volardorsal axis through carpus for ulnar and radial tion of the hand; *T'*, transverse axes for flexion and extension of the thumb and fing volardorsal axes for radial and ulnar abduction of the thumb and fingers.



Other fingers

Extension	*Flexion*
Extensor digiti communis	Lumbricals
Extensor indicis proprius	Interossei

The flexor sublimus and flexor profundus are accessory flexors of these joints.

(*b*) Perpendicular axes

Abduct from the long axis of the middle finger	*Adduct toward the long axis of the finger*
1st and 2nd lumbricals	Volar interossei
Dorsal interossei	3d and 4th lumbricals
Abductor digiti quinti	

20. Muscles acting on the interphalangeal joints (fig. 462).

Transverse axes

Extension	*Flexion*
Thumb	
Extensor pollicis longus	Flexor pollicis longus

The flexor pollicis brevis and abductor pollicis brevis are accessory extensors of this jo

Fingers; proximal joints

Interossei	Flexor digitorum sublimis
Lumbricals	
Abductor digiti quinti	

Fingers; distal joints

Extension	*Flexion*
Interossei	Flexor digitorum profundus
Lumbricals	
Abductor digiti quinti	

The extensor digitorum communis, extensor indicis proprius and extensor digiti quinti proprius are accessory extensors of the joints.

21 Muscles acting on the pelvis.

Thoracic and thoracolumbar joints (fig. 463).

Vertical spinal axes

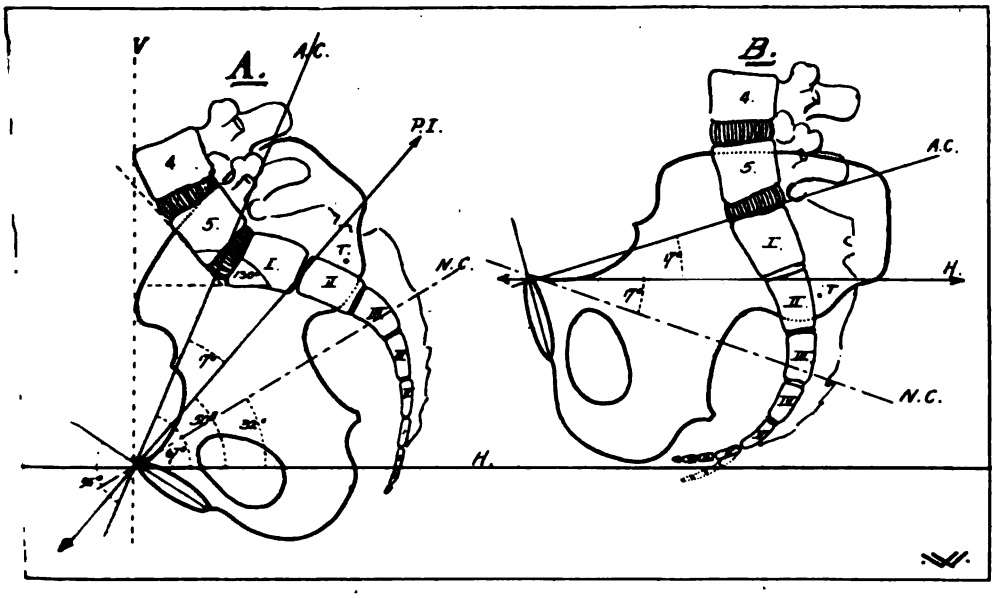
Rotation of pelvis to right	*Rotation of pelvis to left*
Left internal oblique	Right internal oblique
Right external oblique	Left external oblique

The intrinsic dorsal muscles also play a part. See action of muscles on the vertebral column.

Lumbar and lumbosacral joints (figs. 456, 463)

FIG. 463.—EXTENSION AND FLEXION OF THE PELVIS. (After Fick.)

A, pelvis, standing position; *B*, pelvis, sitting position; *A.C.*, anatomical conjugate; *N.C.*, normal conjugate; *H*, horizontal plane; *V*, vertical plane; *P.I.*, pelvic inclination; *T*, approximate position for transverse axis in movements at the sacroiliac joint.



(*a*) Ventrodorsal axes

Abduction of pelvis to right	*Abduction of pelvis to left*
Right quadratus lumborum	Left quadratus lumborum
Right sacrospinalis	Left sacrospinalis

The abdominal, the latissimus dorsi and the psoas muscles are accessory abductors.

(*b*) Transverse axes

Extension of pelvis	*Flexion of pelvis*
Quadratus lumborum	Rectus abdominis
Sacrospinalis	Oblique abdominal muscles
	Psoas minor

The psoas major muscle is a powerful accessory flexor of the pelvis, the latissimus dorsi is an accessory extensor.

22. Muscles acting on the thigh at the hip-joint. (fig. 464, B) (cf. pp. 487, 497)

(*a*) Transverse axes

Extension	*Flexion*
Gluteus maximus	Iliopsoas

The adductor magnus (posterior lower part) and also the hamstring muscles are accessory extensors; the gluteus medius, piriformis and obturator internus are weaker accessory extensors. The rectus femoris and the adductor longus and brevis, the obturator externus,

tensor fasciæ latæ, pectineus and sartorius, are powerful accessory flexors of the hip-joint th· gluteus minimus, adductor minimus, gracilis and quadratus femoris are weaker accessory fle·.·.

(*b*) Ventrodorsal axis

Abduction	*Adduction*
Gluteus medius	The adductors
Gluteus minimus	Pectineus
Piriformis	Obturator externus

The rectus femoris, tensor fasciæ latæ and sartorius are accessory abductors. The glu··· maximus and quadratus femoris are powerful accessory adductors in the standing pos··· The gracilis, adductor minimus, biceps, semitendinosus, semimembranosus and obturator ex··· nus are weaker accessory flexors.

(*c*) Vertical axis (thigh flexed 90°)

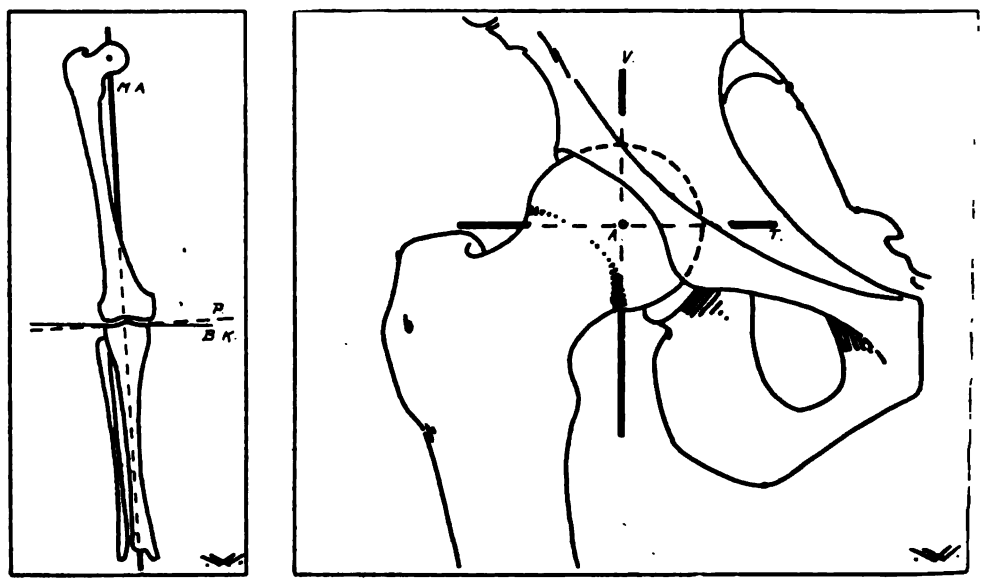
Abduction	*Adduction*
Gluteus maximus	Iliopsoas

(In addition to the abductors and adductors given above).

FIG. 464.—AXES OF LOWER LIMB.

A. Mechanical axes of thigh and leg (after Fick). *M.A.*, mechanical axis; *P*, perpendi··· to mechanical axis; *B.K.*, base of knee.

B. Axes for movements at the hip-joint. *A*, dorsoventral axis for abduction and adduc··· *T*, transverse axis for flexion and extension; *V*, vertical axis for rotation.



(*d*) Femoral axis

Lateral rotation	*Medial rotation*
Quadratus femoris	Gluteus minimus (ventral part)
Obturator internus and gemelli	Gluteus medius (ventral part)
Obturator externus	
Piriformis	

The gluteus maximus is a powerful lateral rotator as well as an extensor; the rectus femoris the lower part of the adductor magnus, the biceps, sartorius, gracilis and the dorsal part of the gluteus medius are accessory lateral rotators. The iliopsoas and the adductors longus brevis and minimus are strong medial rotators; the pectineus, semitendinosus, semimembranosus and tensor fasciæ latæ are weaker accessory medial rotators.

23. Muscles acting on the leg at the knee-joint (fig. 465) (cf. pp. 497, 516).

(*a*) Transverse axis

Extensors	*Flexors*
Quadriceps femoris	Semimembranosus
	Semitendinosus
	Biceps
	Gracilis
	Sartorius
	Popliteus

gastrocnemius is a powerful accessory flexor of the knee-joint. The gluteus maximus or fasciæ latæ through the iliotibial band help to hold the extended knee firm.

(*b*) Tibial axis (knee flexed)

Lateral rotation	*Medial rotation*
Biceps	Semimembranosus
Tensor fasciæ latæ	Semitendinosus
	Sartorius
	Popliteus
	Gracilis

scles acting on the foot at the ankle-joint (fig. 466). (cf. p. 508).

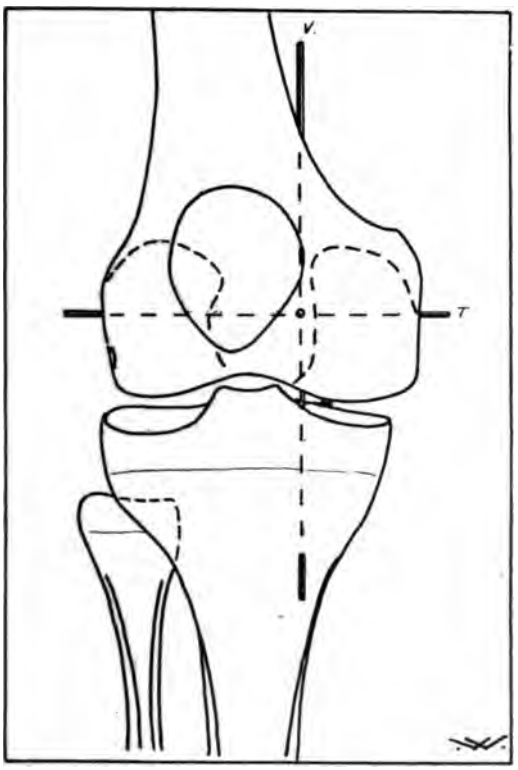
Transverse axis

Extension (plantar flexion)	*Flexion* (hyperextension)
Gastrocnemius	Tibialis anterior
Soleus	Peroneus tertius
Peroneus longus	
Tibialis posterior	
Peroneus brevis	

long extensors of the toes and the peroneus tertius flex; the long flexors of the toes he foot at this joint.

FIG. 465.—AXES OF MOVEMENT AT KNEE-JOINT.

ansverse axis, for flexion and extension. *V*, vertical (tibial) axis, for lateral and medial



cles acting on the foot at the inferior articulation of the talus (artic. talocalcanea and aneonavicularis). (fig. 466).

Talocalcaneal axis

Inversion (adduction)	*Eversion* (abduction)
Tibialis posterior	Peroneus longus
	Peroneus brevis
	Peroneus tertius

gastrocnemius, soleus, tibialis posterior, flexor hallucis longus, flexor digitorum longus alis anterior are accessory inverters at this joint; the extensor digitorum longus and hallucis longus are accessory everters.

26. Muscles acting on the foot at Chopart's joint (talonavicular-calcaneocuboid joints).

Calcaneo-midmetatarsal axis

Inversion (medial rotation)	*Eversion* (lateral rotation)
Tibialis posterior	Peroneus longus
	Peroneus brevis
	Peroneus tertius

The tibialis anterior, flexor digitorum longus, flexor hallucis longus, and extensor hallucis longus are accessory inverters at this joint; the extensor digitorum longus is an accessory everter.

27. Muscles acting on the metatarsophalangeal joints.

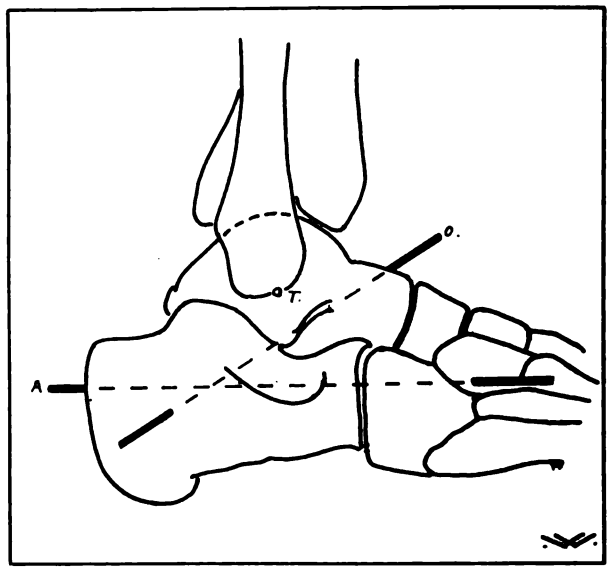
(*a*) Transverse axes

Extension	*Flexion*
Big toe	
Extensor hallucis longus	Flexor hallucis brevis.

The abductor and adductor hallucis muscles and the flexor hallucis longus are accessory flexors.

FIG. 466.—CHIEF AXES FOR ANKLE-JOINT AND FOOT.

T, transverse axis for flexion and extension at talotibial joint; *O*, compromise axis for inversion and eversion at talocalcanial and talonavicular joints; *A*, compromise axis for inversion and eversion at Chopart's joint.



Little Toe

Extensor longus digitorum	Flexor brevis digiti quinti
Extensor brevis digitorum	4th lumbrical
	3rd. plantar interosseus

The abductor digiti quinti and the long and short flexors of the toes are accessory flexors at this joint.

Other Toes

Extensor longus digitorum	1st., 2nd., and 3d. lumbricals
Extensor brevis digitorum	Dorsal interossei
	1st. and 2nd. plantar interossei

The long and short flexors of the toes are accessory flexors at these joints.

(*b*) Perpendicular axes

Abduction from long axis through second toe	*Adduction toward long axis through second toe*
Abductor hallucis	Adductor hallucis
Dorsal interossei	Plantar interossei
1st. lumbrical	2nd., 3d., and 4th. lumbricals
Abductor digiti quinti	

The transverse head of the adductor of the big toe draws the distal ends of the metatarsals closer together. The axes for this slight movement pass through the cuneiform and cuboid bones.

2. **Muscles acting on the interphalangeal joints.**

Transverse axes	
Extension	*Flexion*
Big Toe	
Extensor hallucis longus Extensor hallucis brevis	Flexor hallucis longus
Other Toes	
Extensor digitorum longus Extensor digitorum brevis	Flexor digitorum longus Quadratus plantæ Flexor digitorum brevis (2nd. phalanx only)

The adductors and abductors of the big and little toes may be accessory extensors of the interphalangeal joints.

SECTION VI

THE BLOOD-VASCULAR SYSTEM

REVISED FOR THE SIXTH EDITION

BY H. D. SENIOR, M.D., F.R.C.S.

PROFESSOR OF ANATOMY, NEW YORK UNIVERSITY

organs of circulation consist of a system of tubes or vessels which during are filled with fluid constantly moving in one direction. The major tion of the system is concerned with the continuous distribution of blood ut the body and is called the **hemal or blood-vascular** system. A ibed part of the hemal circulation is differentiated into a rhythmically ig propulsory organ called the heart. The minor portion of the system he **lymphatic system.** The lymphatic vessels convey fluid, the lymph, tissues to the hemal system.

ssential functions of the blood-vascular system are performed by the of all the blood-vessels, the **capillaries** [vasa capillaria], which form a ervading practically all the tissues of the body. Blood is carried to and capillaries by larger vessels called the **arteries** and **veins** respectively. t receives blood from the veins and propels it, in turn, into the arteries.

r to distribute oxygen to the tissues, the blood must of necessity pass through the organ before being delivered to the body at large. In gill-breathing vertebrates, the ng received oxygen in its passage through the gills, passes on to the tissues. The it is here accomplished by a single continuous chain of vessels in which capillaries , once in the gills and again in the organs and tissues in general. In man, as in other ebrates, lungs assume the function of the gills. Having received oxygen in the lungs is returned again to the heart before being redistributed throughout the body. hus in man two separate circuits or systems of blood-vessels, one traversing the lungs id ramifying throughout the body. The former is known as the **pulmonary** circula- tter as the **systemic.** Each has its own arteries, capillaries and veins; the heart is both. From the time of birth the heart is longitudinally divided into right and left that the two streams which enter it are entirely separated. The blood entering the the heart has issued from the pulmonary circulation to be driven into the systemic; ntering the right side, having traversed the systemic circuit, is returned again to the

art and blood-vessels have a continuous lining of flattened cells called endothelium; system is, therefore, a closed circuit.* The main thickness of the heart, arteries consists of additional tissue developed around the endothelial lining. It is due to hat the blood is continuously delivered to, and withdrawn from, the capillaries under nditions of pressure and velocity. The heart is mainly composed of rhythmically ; muscle and its valves are so arranged that the blood contained within it is driven tly in one direction. The walls of the largest arteries are formed to a great extent of ie, and, being constantly under tension from within, are instrumental in converting , intermittently received from the heart, into a continuous flow. The walls of the ed to smallest arteries are mainly muscular. The smallest arteries are microscopic known as **arterioles** [arteriolæ]. The muscular arteries are capable of general or tions of caliber; they are thus largely concerned in the maintenance of the arterial id in the regulation of the volume of blood which enters given localities under varying

The veins have much thinner walls than the arteries, and the venous pressure y low.

n artery divides, the combined caliber of its branches is greater than that of the f. Since the arteries divide repeatedly the bed of the blood-stream increases in as the vessels diminish in size. The rate of increase, slow at first, becomes enormous rioles. Conversely, the bed of flow diminishes as the heart is approached from the . The velocity of flow in the capillaries must necessarily be much lower than in the ies and veins. From the relative slowness of the blood flow in the systemic capil- s been estimated that their total bed is eight hundred times greater than that of the ial stem.

spleen and bone marrow the blood-channels intermediate between the arteries and ssible exceptions to this statement, but the essential conditions here are still imper- rstood.

Variations.—The distribution of the chief arteries and veins of different individuals varies so slightly in the aggregate that the descriptions given by anatomists nearly two hundred years ago differ but slightly from those in current use. Deviations from the usual type of vascular distribution are occasionally encountered in the adult, however, and their presence seems always to depend upon some disturbance of the usual course of development. When once the primitive vessels have made their appearance, the progress of vascular development is characterized by the successive appearance of alternative arterial or venous channels for the transit of blood to, or from, the capillaries of the various regions of the body. Some of the earlier channels persist throughout development; while others, remaining for a shorter or longer period, eventually disappear. Others, again, by forming connections with their fellows, or with channels of later development, may take a larger or smaller share in the composition of one or more of the adult arteries or veins. The normal vascular pattern of the human body, having been repeatedly modified during the progress of development, may be said, at length, to attain its permanent form. The production of an adult vascular system of so-called normal type in any particular individual, depends, therefore, upon the exact repetition of a complicated series of developmental changes. Should one of the numerous embryonic vessels concerned in the process fail to perform its customary role, some noticeable departure from the normal type will be encountered in the adult vascular system. Variations thus produced are more prone to occur in some regions than in others. Apart from such extensive anomalies as those in which imperfections of the aorta or pulmonary artery occur in association with arrested development of the cardiac septa, variations of blood vessels are not, as a rule, attended with impairment of function. A list of the chief variations in the arteries and veins is given later, in connection with their morphogenesis.

In the following section the heart and pericardium will first be considered followed by the arteries and veins.

A. THE HEART AND PERICARDIUM

1. THE HEART
